Connectors: switch mechanisms similar to the previous types. These serve to make the final connection to the called party. They correspond to the operation where the manual switchboard operator plugs the calling party into the called party's jack.

Additional relays: serve to introduce busy signals, ringing current, or any other special signal which should be placed in the circuit.

Military Automatic Systems

The automatic telephone system is not used in most echelons of Air Force units in the field. Other than for base-housed units, the dial telephone will not be found in lower echelon systems.

For purposes other than to acquaint the student with the fact that such systems are employed extensively at most Air Force installations, no further mention will be made of automatic telephony.

6. SOUND-POWERED TELEPHONES

Sound-powered telephones are used for point-to-point connections where the line loss is relatively low. They can also be used on switchboard connections where the performance of dry batteries in local-battery telephones is unsatisfactory. However, substandard transmission will be obtained on switchboard connections unless the loop and trunk losses are very low.

Compared with the local battery telephone EE-8-( ), the sound-powered Telephone TS-3 which employs Handset TS-10, is about 25 db lower in transmitting efficiency.

Handset TS-10 contains a resonant magnetic receiver in which the diaphragm is undamped and unclamped at the edge and the armature drives the diaphragm through a mechanical coupling. In this type of receiver, greater efficiency is obtained over the conventional type of magnetic receiver, where there is no mechanical coupling between the diaphragm and the pole pieces, without introducing an excessive amount of frequency distortion. The receiving efficiency of Telephone TP-3 is about 10 db more than that of Telephone EE-8-( ). This 10 db improvement in receiving efficiency is ineffective where the line noise is high.

The sound-powered telephone is suitable for use on point-to-point lines which have a maximum loss of about 15 db. If the line noise is excessive, this limit may drop to 5 db. If it is used in the transmission plan referred to previously, transmission will be below standard, even where the loops are very short, since the trunk line loss may exceed 15 db.

Because of the relatively high impedance of the sound-powered handset, the maximum efficiency is obtained when no induction coil is employed and the instrument is connected directly to the telephone circuit. On some short point-to-point circuits where signaling is not required, the sound-powered Handsets TS-10 may be used without other parts of the telephone.

SECTION 3 - TELETYPEWRITER SYSTEMS

1. GENERAL

Transmission of messages by means of the teletypewriter has become an integral part of the USAF communications system. Teletypewriter equipment designed for the United States Air Force is capable of operating either over wire, radio, or integrated wire-radio systems. The common types of teletypewriter equipment in use today for military communication are designed for flexibility, mobility, and ease of operation. Teletypewriter equipment may be used over a transmission facility to give direct circuit, traffic is restricted to messages between two terminals. However, in the case of a system, its flexibility permits messages to be transmitted to any destination within the system. As a system, it is as flexible as the telephone. The system is widely used in both military and civilian communications networks. Since teletypewriter equipment is portable, a variety of installations is possible. It may be operated as a mobile station when mounted in a vehicle; it may be used in any tactical situation with combat troops. Although teletypewriter equipment requires operators with some degree of skill, the operation is comparatively easy since the keyboard is similar to that of a standard typewriter.

When compared with the telephone, teletypewriter service may be considered a more efficient and expeditious agency for handling large volumes of traffic without an increase of outside plant. It has the additional advantages of providing greater transmission range over similar facilities, printed record of the messages transmitted, and more efficient use of communications because of the volume of traffic which may be handled. The teletypewriter may be used for interchanging information in a conversational manner similar to the telephone.

The United States Air Force has many uses for the teletypewriter service. One of the most extensive is the provision of these facilities for the collection and dissemination of weather data. A variety of nets may be established to transmit weather information from a central organization to the smallest unit requiring this service. A special teletypewriter is employed in the weather service. The handling of administrative and operational traffic over teletypewriter systems greatly relieves other means of communication. During combat operations, teletypewriter facilities are excellent for transmitting lengthy field orders.

Generally, the equipment requirements for teletypewriter networks are dependent upon two factors: type of circuit facilities available, and number and size of units to be served. A system is made up of numerous components including stations with their individual extensions, main transmission circuits, terminal and repeating equipment, retransmitting equipment, switchboards, and branch circuits extending to outlying localities.

The United States Air Force has available for its use a specially adapted teletypewriter used in cryptographic systems. These machines are employed extensively to transmit classified material.

2. PRINCIPLES OF OPERATION

Teletypewriter Code

No attempt will be made to discuss in detail the design features or operating methods of each teletypewriter, but consideration will be given to some of the general features applicable to all of them. Teletypewriter operation differs essentially from manual telegraph operation only in the substitution of sending and receiving machines for keys and sounders. The signaling code used is not the Morse code of manual operation but a special one in which each letter or signal is made up of five units or elements of equal length. These units or elements are known as **marking** or **spacing impulses.** Figure 2-28 illustrates this teletypewriter code.

Marking impulses or signals are those impulses which operate the selector magnets in the receiving printer. Spacing impulses or signals are those impulses which do not operate the selector magnets in the receiving printer. The marking and spacing impulses are of the same length.

Two more impulses are necessary, and being common to all code groups, complete the code group representing any letter, figure, character, or **stunt,** making the total number of impulses seven. One of these is a spacing impulse and is the first impulse sent. Its function is to set the receiving machine in motion and in readiness to receive the remainder of the code group. This impulse is the same length as the code impulses which follow and is called the start impulse. The other impulse is a marking impulse and is always the last impulse of each code group. This impulse is known as the "stop" impulse and is 1.42 times as long as any of the other impulses. Its function is to return the re-

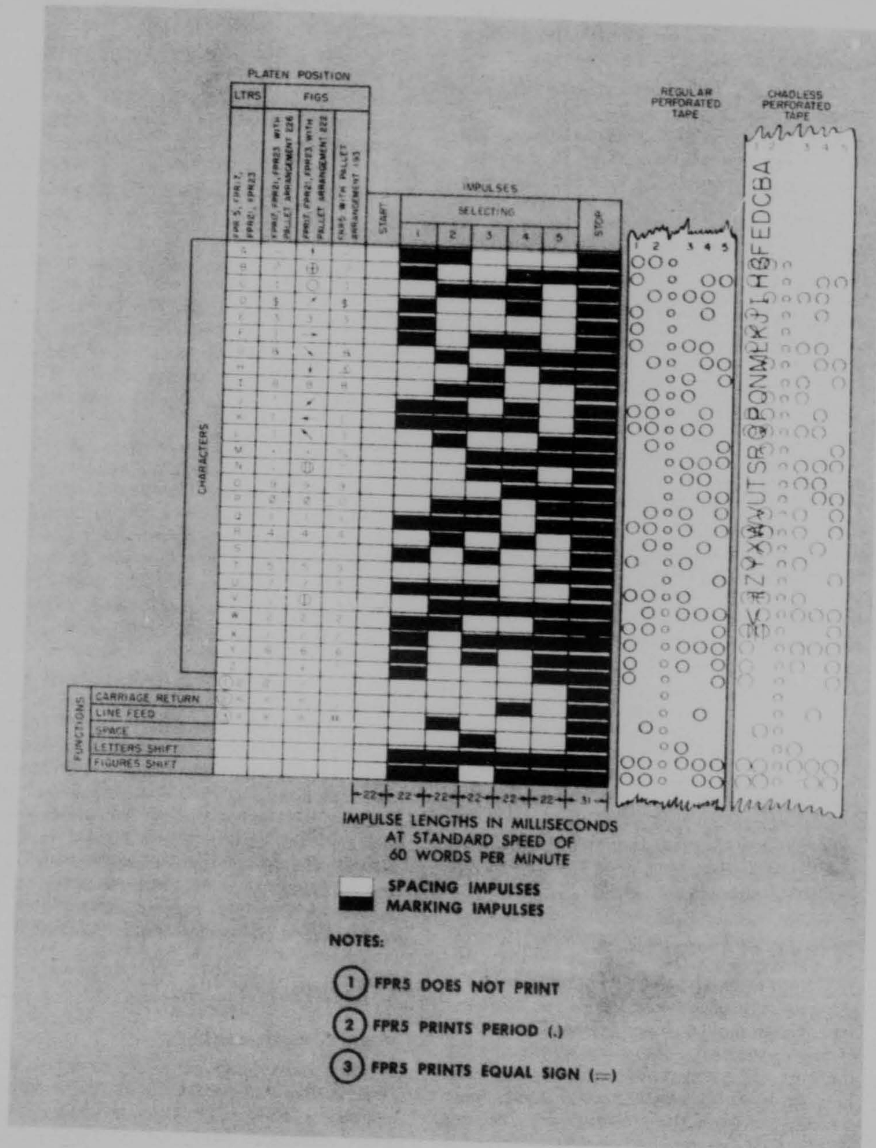

Figure 2-28 Teletypewriter Code Chart

ceiving printer to a position of readiness for the next starting impulse. This pulse maintains the synchronism between the sending machine and the receiving machine.

The teletypewriter code provides for the letters of the alphabet, the numerals, and several miscellaneous symbols in common use or specially desired, as well as for the special operations or stunts that the machines must perform, such as line feed, carriage return, miscellaneous switching and signaling features. The provisions are made by using the thirty-two combinations that the five-impulse code permits and a **letters shift-figures shift** feature. The machine must be so designed that when a certain letter key is operated at the sending machine, the marking and spacing signals corresponding to the code for that particular letter is sent out on the line, and when this signal combination arrives at the receiving machine, the corresponding type bar is selected and operated to print the letter. The code is known as the five-unit permutation code and is sometimes called the five-impulse start-stop code. A six-unit code, which contains sixty-four different signals, is used when it is necessary to transmit capitals, small letters, numerals, and punctuation, or other marks or symbols.

Speed of Operation

The standard military teletypewriter is designed to operate at a maximum speed of sixty words per minute. This high signaling speed requires not only that the transmitting and receiving machines be sturdy and dependable, but also that the transmission lines and teletype repeating apparatus be of the highest grade.

Systems of Transmission

There are two important systems of transmission in teletypewriter systems: the **neutral system** and the **polar system**. DC neutral circuits operate on the basis of current for marking and no current for spacing. A metallic pair or a wire with ground return may be used between the sending and receiving points. Simple open-and-closed operation is sometimes used between the teletypewriters connected directly to the line without relays. In such cases, operation between teletypewriters is limited to distances of approximately a mile when field wire (W-110) is used. This limitation is imposed primarily by signal distortion resulting from varying weather conditions. This distortion cannot be compensated for readily by adjustment of the teletypewriter mechanism. However, this form of signal distortion can be overcome to a certain extent by interposing an adjustable receiving relay between the line and the teletypewriter.

In DC polar circuits, approximately equal values of positive and negative voltages are applied alternately to the line at the transmitting end. At the receiving end, the polar relay responds to the direction of the current rather than to its magnitude. A one-way polar circuit generally uses one metallic conductor with a ground return, but two metallic conductors may be used. A 2-path polar circuit consists of two one-way polar circuits and is suitable for duplex operation provided the local circuits are so arranged. Over wire circuits, teletypewriter operation which is limited to one direction at a time is known as a single or half-duplex operation. A break feature is provided to enable the receiving station to break or stop the transmitting station.

In any teletype circuit (wire or radio) in which independent transmission paths are provided for the two directions of transmission, it is possible to transmit messages in both directions simultaneously. This is known as duplex operation, and is sometimes called full-duplex operation. This method involves certain inconveniences from an operating standpoint, but allows moving approximately twice as much traffic as the half-duplex method. Carrier teletypewriter service is partially suited to the duplex method.

3. EQUIPMENT

Major Components

Teletypewriter equipment is classified in a general way as "tactical" and "fixed plant" equipment. Electrically these two classes are interchangeable. However, tactical equipment is characterized by its portability and ease of installation. Fixed plant equipment

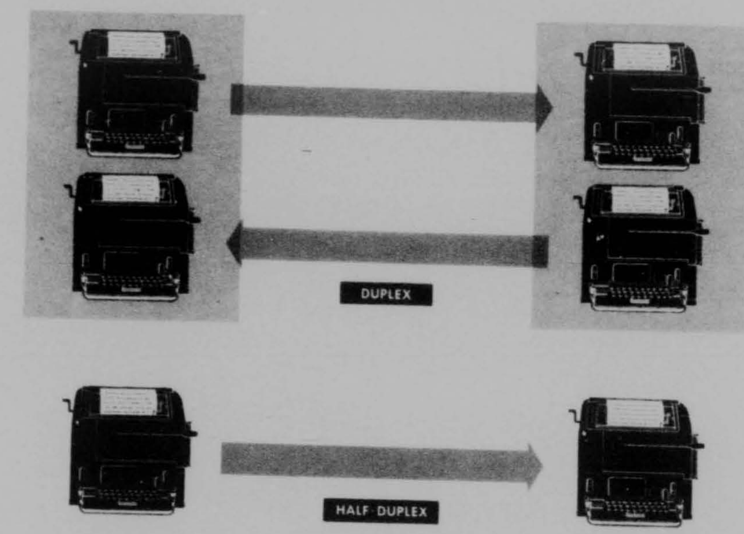

Figure 2-29 Duplex & Half Duplex Teletypewriter Operation

is not readily moved from one location to another, considerably more time is required for installation, and greater protection from the weather must be provided.

Teletypewriters which are commonly used in the Air Force have two types of keyboard. These are the communication keyboard and the weather keyboard. Columns 1 and 4 in Figure 2-28 illustrate the characters found on the communication teletypewriter keyboard, while columns 1 and 3 are those of the weather keyboard. It is noted that they are the same in the lower case but differ in some of the upper case characters. The communication arrangement has punctuation marks where the weather arrangement has symbols such as arrows to indicate wind direction, for the transmission of weather data.

Two basic forms of teletypewriter recording are used. One of these forms of recording is the printed page. The other is the perforated tape with or without printing. Equipment which records the messages as typed characters and in perforations in the tape is called a "typing reperforator". The basic forms of transmission are: manual sending from a keyboard or automatic sending by means of a perforated tape from a transmitter-distributor.

Teletypewriter equipment for tactical use is manufactured so that connections may be made rapidly with cords and plugs and without the use of tools. The equipment is portable and is packed in wooden chests. Tactical teletypewriters require more protection than that afforded by the carrying cases. The teletypewriter TG-7 ( ) is a portable page-printing machine designed for two-way communication. It is the major component of Teletypewriter Set EE-97 ( ). When assembled for use, the chest provides a convenient operating table and seat for the operator. This machine operates on 115-volt direct, or alternating, current. It is arranged so that 25, 40, or 50, 60 cycle alternating current may be employed. For printing messages, the single page or multiple copy may be used. The teletypewriter may be used over wire circuits, radio circuits, or through a teletypewriter switchboard in a manner similar to the telephone.

THIS PAGE IS DECLASSIFIED IAW EO 13526

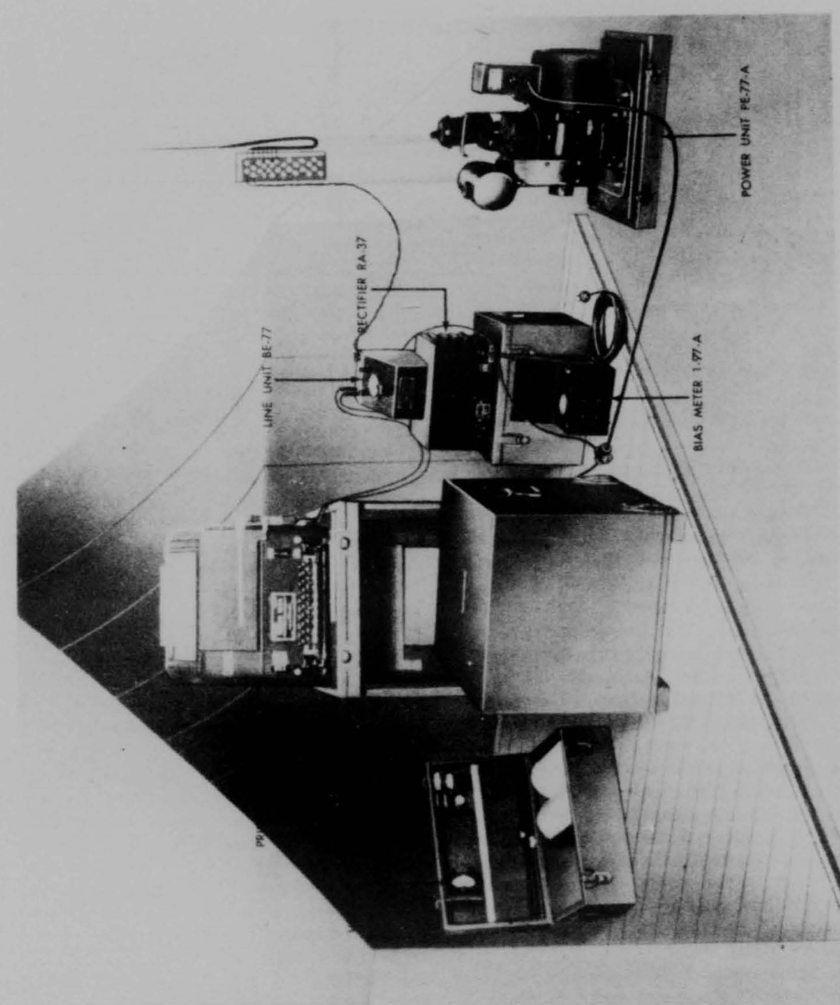

Figure 2-30 Teletypewriter Set EE-97

Automatic tape transmissions are accomplished by the use of reperforator transmitter and distributor sets. There are several types used by United States Air Force units for the transmission of both weather and communication messages.

The TG-26 and the TG-27 Reperforator Transmitting Sets each consist of a sending-receiving transmitter-distributor, connection box and chest. The TG-26 is equipped with the communication characters while the TG-27 is designed for the transmission of weather data.

The typing reperforator may be used to transmit directly to the line and to monitor the message by printing on, and perforating, a tape. When tape transmission only is desired, the typing reperforator may be operated locally and the tape thus perforated may be used for operating the transmitter-distributor. The typing reperforator may also be connected to the circuit to receive signals from a distant point to prepare a tape for subsequent transmission. The following are some of the most common operating combinations of TG-26 and associated TG-26 sets or TG-27 and TG-37 sets which may be connected in the circuit:

To send manually from the typing reperforator into a local loop to print and reperforate a tape. Perform the same operation and simultaneously print a page copy.

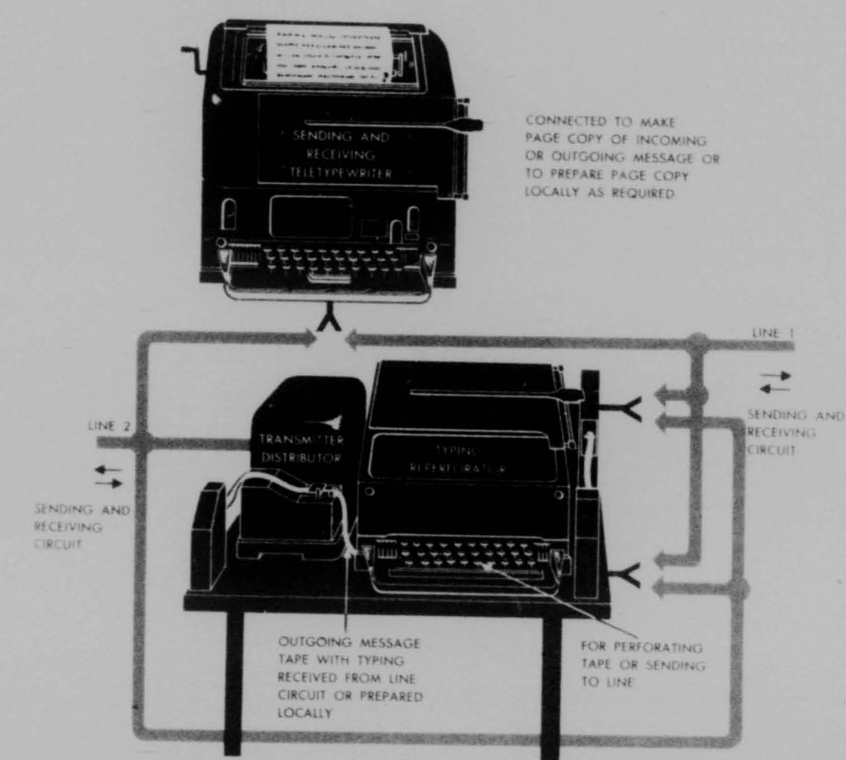

Figure 2-31 Reperforator Transmitter TG-26

THIS PAGE IS DECLASSIFIED IAW EO 13526

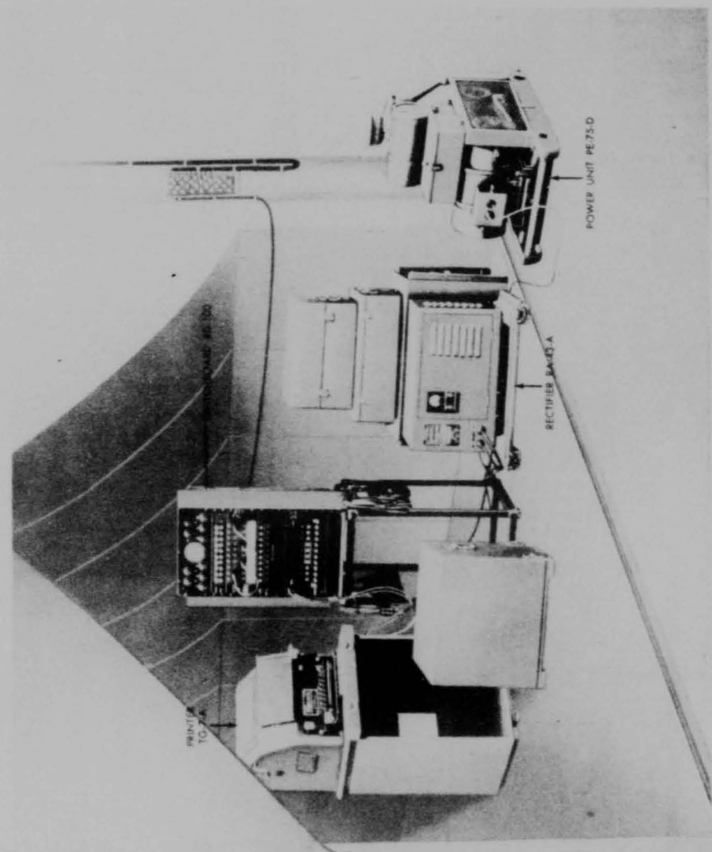

Figure 2-32 Telegraph Central Office Set TC-3

To send into a local loop from the transmitter distributor, with tape previously perforated, to print page copy.

To send from the typing reperforator into a signal line and at the same time print and perforate a tape. Perform the same operation and print a page copy simultaneously.

To receive line signals and print and perforate a tape and simultaneously print a page copy. Operate the typing reperforator in a local loop or connect it to a line to receive printer signals. In either case, print and perforate a tape.

The typing reperforator and the transmitter-distributor are equipped with individual motor power switches.

The type of tape used with TG-26 is called "chadless." In this tape the perforations are partial in order to retain paper for the typed symbols. The perforations for a character are offset six spaces to the left of the printed character. Using the arrangement of perforator and transmitter-distributor permits the handling of a larger volume of traffic, since the tapes may be prepared locally and characters sent into the line automatically at the maximum line circuit signaling speed which may be 60 words a minute (3600 groups per hour) or higher.

The TG-25 is a motor-driven tape reperforating machine which receives electrically transmitted signals through the medium of a selecting and perforating mechanism into code combinations of holes in a paper tape. This tape may then be used for retransmitting these code combinations on other similar printing telegraph circuits, thus eliminating manual preparation of tape with a perforator at the relaying station. This type of machine provides an expeditious means for relaying messages and is commonly employed in Air Force installations.

The TC-3 is a complete, transportable teletypewriter exchange or central which can be easily and quickly installed at any headquarters requiring the use of a switching central with a capacity of ten teletypewriter lines or trunks. The line capacity can be increased by adding one Switchboard BD-100 for each additional ten lines. However, not more than three switchboards (capacity, 30 lines) can be used together as a single office because of power equipment limitations, length of patching cords and other factors. Each switchboard supplies the current and provides switching and repeating facilities for neutral operation of its ten teletypewriter lines or trunks. Provision is made for connecting any teletypewriter line to any other line or trunk or groups of instruments connected to the switchboard by means of patch cords. The operator's teletypewriter serves him in the same manner as the operator's telephone does with a telephone switchboard. He employs it to answer calls and to supervise connections.

Auxiliary Components

Certain additional equipment is required for completing the installation of the equipments previously discussed. These additional components include line units, rectifiers, repeaters, and power supplies.

The **Line Unit** BB-77 is a component of Teletypewriter Sets EE-97 and TC-16. The line unit is used to make connections between neutral-type telegraph circuits and teletypewriter station equipment, and to repeat signals which are transmitted from the line into the teletypewriter receiving mechanism. The line unit may be used for measuring voltage of the DC power source, and for measuring and adjusting the quality of the received signals. The unit in itself is small and compact.

On long tactical telegraph circuits it is often necessary to amplify or repeat telegraph signals so that the current received at the receiving machine will be strong enough to operate the receiving mechanism. This is accomplished by inserting **telegraph repeaters** in the circuit at periodic intervals. In tactical wire systems, telegraph repeaters TG-30 and TG-31 are used.

Telegraph Repeater TG-30 is a DC telegraph terminal-type repeater used for making connections from two-path polar or polarential line circuits to neutral type local circuits such as used in teletypewriters, Switchboard BD-100, Line Unit BE-77, and carrier telegraph terminals when long polarential circuits are employed. The TG-30 contains a built-in rectifier for operation on

THIS PAGE IS DECLASSIFIED IAW EO 13526

115 or 230 volts DC and also contains a built-in telegraph set. A 115-volt power receptacle provides an outlet for supplying power to operate a teletypewriter set.

The Telegraph Repeater TG-31 is a DC telegraph intermediate-type repeater for retransmitting signals from one polarential line section to another polarential line section (differential sending only). This type of repeater does not reform or retime signals. It will operate unattended on dry cell or storage batteries when a teletypewriter is not required at that point. It contains many of the same features that are contained in the TG-30.

Commercial-type repeaters are frequently used in rear areas where long distance circuits are employed. These repeaters are referred to as "package-type" and generally are installed in fixed plant installations.

When a source of AC power is available, a **rectifier** is normally required to convert the AC power to 115-volt direct current for the operation of the teletypewriter signal circuits and the line unit. Rectifiers RA-34 and RA-87 are the more common types furnished with the equipment. These units are small and readily installed.

A total maximum power input of about 200 watts is required for each teletypewriter set. All sets normally operate on stable sources of direct current or 50- to 60-cycle alternating current at 115 volts, although they will operate satisfactorily on stable voltages between 105 volts and 125 volts. Where rectifier RA-87 is available the sets may be operated on 50- to 60-cycle alternating current at stable voltages between 85 and 135 volts, and 179 and 270 volts.

The **power units** employed with this type of equipment for field operation are gasoline engine-driven generators which are capable of furnishing up to 250 watts at 115 volts DC. The unit is small and weighs about seventy-five pounds. It is provided with its own special packing case. Another unit is slightly larger and is capable of furnishing about 2.5 kilowatts of 120-volt AC power. This unit weighs approximately 320 pounds.

Whenever possible, commercial power or other local power facilities are used. This reduces the number of personnel required to operate the station, and also reduces the problem of maintenance since the gasoline engine requires a considerable amount of maintenance to keep it in the best operating condition. Furthermore, it conserves fuel, particularly when the station is operated on a twenty-four hour basis.

4. REQUIREMENTS AND PLANNING

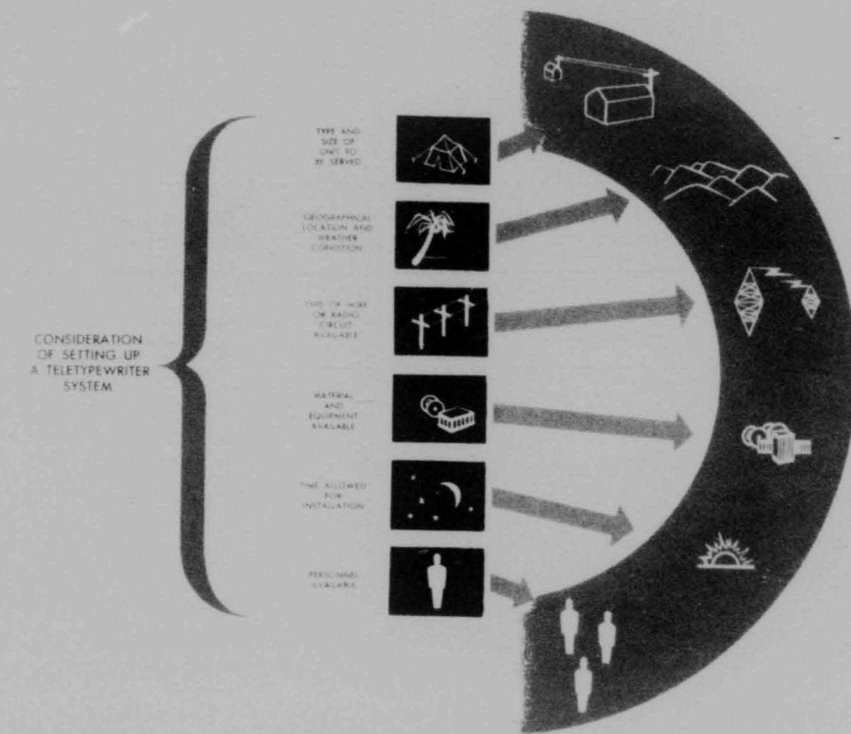
For planning teletypewriter systems and teletypewriter equipment installations, many factors must be considered in order to insure efficient and expeditious service. Advantage of telephone circuits should be taken as often as possible by superimposing telegraph circuits on them. This practice tends to effect economies, both in the amount of material used, and in the number of operating personnel required.

Whether teletypewriter equipments are used on direct (point-to-point) circuits or in a teletypewriter system, the following factors are important.

a) Type and size of unit to be served.
b) Geographical location and weather conditions.
c) Type of wire or radio circuits available.
d) Material and equipment available.
e) Time allowed for installation.
f) Personnel available.
g) Tactical situation.

Teletypewriter systems should be planned to give the greatest flexibility possible, in order that all units of an Air Force organization may communicate with each other directly by switching, or through a relay station. Planning of a teletypewriter system also includes the proper coordination with other staff sections of an organization. By doing so, implementation of plans is facilitated and quicker service insured. It readily may be seen that teletypewriter service greatly expedites the activities of an air force organization. Because of the flexibility of a teletypewriter system, the ease of operation and installation of the equipment, great volumes of traffic can be handled quickly and efficiently.

Teletypewriter equipment designed for field use is made to employ the same facilities provided for telephone systems or may be installed as a separate system. The use of



teletypewriter facilities greatly relieves the burden on telephone circuits and at the same time increases the traffic handling capacity of the communications system.

Present research and development in teletypewriter equipment and facilities will broaden the field for the use of this equipment both on the ground and for air-to-ground communication.

SECTION 4 - TRANSMISSION LINES

1. GENERAL

This section includes descriptions of the various common types of transmission lines, a discussion of the nature of these lines and of simple circuits.

The section will serve a dual purpose: to introduce a subject not discussed elsewhere, and to serve as an introduction to the following section on carrier telephony. The student must be acquainted with the capabilities and limitations of transmission lines in order to understand the principles of carrier operation.

Figure 2-33b Common Types of Transmission Lines

THIS PAGE IS DECLASSIFIED IAW EO 13526

2. TYPES OF TRANSMISSION LINES

There are many types of transmission lines employed for military purposes. Many of these are listed in Figure 2-33. The most commonly used types include field wire, rubber-covered cable, open-wire lines, and lead covered cable.

Field Wire

For temporary construction over short distances assault or field wire (Figure 2-33) may be employed. The range with which satisfactory conversation may be had over these types of wire may be extended by the use of loading coils and repeaters which will be described in succeeding paragraphs. Assault and field wire are intended for use under combat conditions and therefore must be able to absorb a great deal of punishment. The wire is constructed of both copper and steel strands. The copper strands are intended for the transmission of the currents while the main function of the steel strands is to give mechanical strength. However, both components lend to the mechanical strength and to the conductivity of the wire.

Field Cables

Field cables are rubber-covered, varying in size from two to ten pairs. The two pair cable is a spiral-four quad primarily used for 4-channel carrier operation over intermediate distances (up to 150 miles when aerial construction is used). However, experience has proved that greater distances may be obtained when this cable is properly constructed, whether aerially or underground. Figure 2-33 illustrates the construction of spiral-four cable. The cable is constructed with connectors having built-in loading coils, so that induction is automatically added as length of cable are joined.

The 5 and 10-pair cables are used mainly for short loops where a number of circuits are required. These cables are also provided with connectors which can be plugged together for rapid construction of the line. Figure 2-34 illustrates the construction of a five-pair rubber-covered cable.

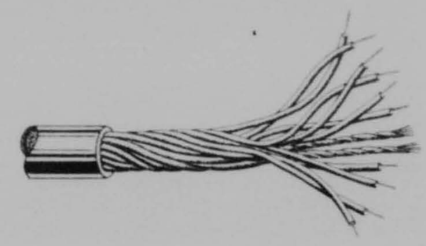

Figure 2-34 Five-Pair Cable Construction

Open-Wire Lines

Open-wire lines have relatively low losses at voice and carrier frequencies and can be used to provide circuits with satisfactory transmission characteristics for long lines within a theater of operations, although the use of repeaters at regular intervals is standard practice.

A type of open-wire construction has been developed for military use which combines the features or economy of shipping, space, weight of material, and good transmission characteristics which permit the operation of carrier systems up to 32,000 cycles per second. Such lines have transpositions designed for a maximum of two crossarms with four pairs per crossarm. Open-wire lines will usually employ 080 or 104 copper-steel for new construction and repair.

Commercial type of open-wire construction (ten-pin crossarms) is commonly used in a theater of operations, especially where permanent, long distance service is required.

Lead-Covered Cables

When the situation is stable enough to permit their use, lead-covered cables are employed to obtain comparatively large numbers of voice frequency circuits. Usually these circuits are built to include loading and repeaters. By burying the cable, a stable transmission medium is afforded.

Lead-covered cables have paper-insulated conductors twisted as pairs or quads. The cables are manufactured in many sizes from 7 quads (14 pairs) to 150 quads or more. The quads may be of two types: multiple-twin and spiral-four or star quad. The multiple-twin quad consists of two twisted pairs twisted together to form a quad, the diagonally opposite wires being used as a pair. Wires in long distance cables of American manufacture are usually 19 or 16 gauge solid copper.

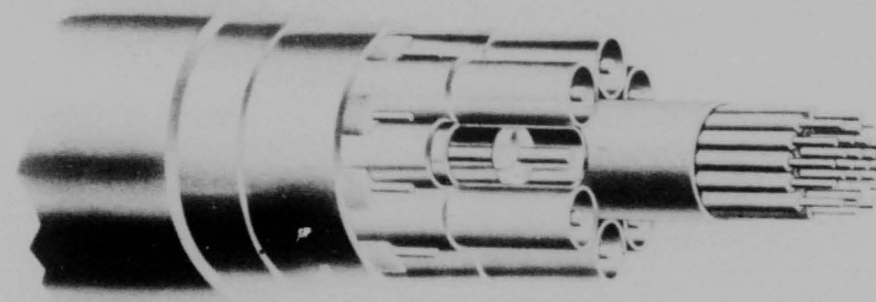

Figure 2-35 Coaxial Cable

Submarine Cables

Double-paper insulated submarine cables are suitable for depths of water up to 250 feet without danger of sheath collapse or excessive water penetration along the cable in case of sheath failure. Such cables may function satisfactorily for months or years in greater depths, but there is danger of a gradual sheath collapse or flattening due to excessive pressure, which may force the wires through the insulation. Special submarine cables are designed for much greater depths. Rubber-covered cables and wires may be employed as submarine cables, in emergencies. Care must be taken in this case to insure that the cable will not be subject to excessive abrasion or other mechanical damage and that all splices and connections are made water-tight.

Coaxial Cable

Coaxial cable in its basic form consists of a center conductor mounted inside of and coaxial with an outer metallic tubing or metallic braid conductor and separated from it by spaced insulators or solid insulation. Coaxial cable is an excellent means for transmitting high frequencies since its characteristic impedance is extremely low (usually around 75 ohms). It is used commercially for long lines: telephony, telegraphy, and more recently, for television. Figure 2-35 shows several coaxial cables within a common sheath and separated from each other by insulating materials. Many individually insulater copper wire conductors are often included to provide for more transmission paths and to help fill up space which otherwise might be wasted with unnecessary amounts of insulation material.

3. NATURE OF TRANSMISSION LINES

Electrical Characteristics

Metallic lines are affected by electrical and mechanical factors which tend to disturb the transmission of messages over the line. There are four fundamental characteristics which exist in a line when currents are passed through them. These are: resistance, capacitance, inductance, and leakage.

Resistance. Every conductor offers resistance to the flow of electricity. The resistance

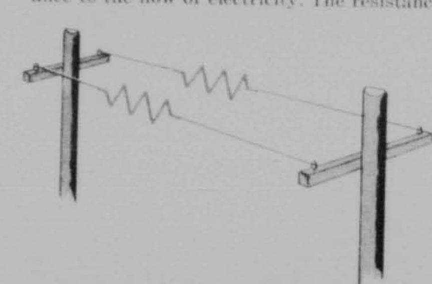

Figure 2-36 Every Conductor Offers Resistance

of a few feet may be of no particular consequence, but the resistance of several miles of wire is great enough to be considered. In telephone practice, the resistance of a line is stated in terms of ohms per loop mile. A loop mile includes the resistance of both conductors of a pair or twice the resistance of one conductor of the pair. One of the most widely used sizes of wire has a resistance of 10 ohms per loop mile. Therefore, if a line is many miles long the resistance of the line is large and must be taken into consideration.

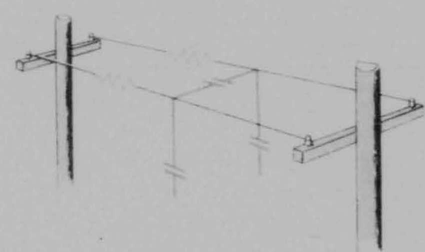

Figure 2-37 Any Two Conductors Separated by a Dielectric Form a Capacitor

Capacitance. Any two conductors separated by a dielectric form a capacitor. Two conductors when separated by air or any other dielectric material, such as paper or mica, serve as the plates of a capacitor to produce capacitance between the wires.

In like manner, the two wires serve as one place of a capacitor and the ground will serve as the other, thus, providing capacitance to ground. As the area of the plates of a capacitor increase and as the distance between the plates decrease, the capacitance increases as the length of the line increases.

Inductance. Every conductor offers some inductance to a varying current. Because of the varying currents associated with the transmission of intelligence over a telephone, there are lines of magnetic force both in the conductor and in the immediate adjacent space. Since the current which produces these lines is varying, the associated magnetic field also varies. This magnetic field will cause other currents to be set up in the wire itself. These are known as self-induced currents.

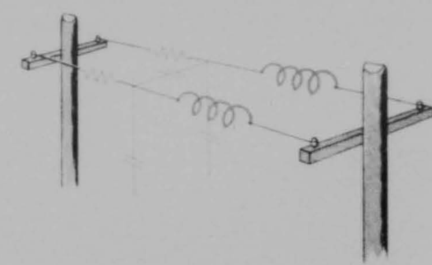

Figure 2-38 Every Conductor Offers Inductance When AC Passes Through It.

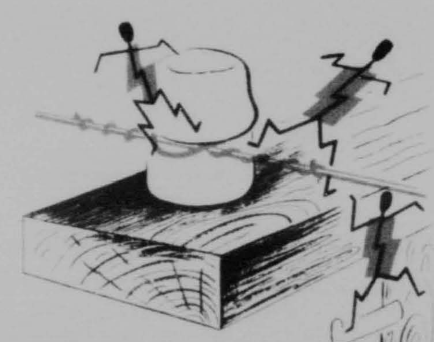
Also, if there are other wires which parallel the line carrying the current there will be currents induced in them, caused by the magnetic field encircling them. This is known as "mutual inductance." Wire lines other than telephone lines, carrying current, (such as power lines) adjacent to telephone lines, tend to set up magnetic fields and produce induced currents in the telephone lines. Normally, self-inductance of a line is small and the effect harmless whereas mutual inductance in a telephone line is the more harmful characteristic and must be given due consideration when designing a line.

Leakage. Since no insulator is perfect and although the insulation resistance between a pair of wires is very high, there is a certain amount of current dissipation between wires and ground. This loss of current is referred to as leakage. The amount of leakage depends



upon the insulation resistance, and varies with the weather conditions. Leakage increases in damp and wet weather.

Physical and Mechanical Characteristics

The fundamental characteristics of wire lines just discussed are further affected by the physical and mechanical characteristics of metallic lines. The physical properties, composition, and mechanical design of the conductor offer a variable resistance to the passage of electrical currents which depends upon the properties of the material selected for the conductor. Since the electrical properties of a line vary, it is logical to assume that the quality of transmission of messages will vary accordingly. While it is convenient to indicate that these electrical properties exist at definite points along the line, for the matter of computing the behavior of the line it must be remembered that they are distributed evenly throughout the line. In other words, each infinitesimal part of the line will have each of these characteristics.

Characteristic Impedance. If alternating current is passed through a telephone line which is infinitely long, the cumulative effect of the electrical characteristics discussed earlier would be so great that practically zero current would flow at the distant end of the line. Therefore, if the distant end of the line were open-circuited or short-circuited, the impedance of the line measured at the input end would be the same since there would be little or no current flow in the circuit. The line would have a definite impedance that would not change regardless of how the distant end was terminated. This impedance is called the "characteristic impedance" of the line. It can be expressed simply as the impedance of an infinitely long line, or the equivalent of an infinitely long line. The characteristic impedance depends upon the size of the conductors, the spacing between the conductors, the type of line construction, and the frequency of the transmitted current. Hence, the characteristic impedance of two different lines is not necessarily the same. Two identical lines, however, constructed in the same way will have the same value of characteristic impedance for a given frequency. Since the characteristic impedance varies with the different types of wire lines, the design of equipment is based on the characteristic impedance of the ideal transmission line. In the majority of cases, an open-wire line has a characteristic impedance of from 500-700 ohms. In cases where the line lacks the ideal impedance, equipment is added to the line so that it will approach the ideal condition.

Reflection Loss. Another phenomenon that occurs in all types of wave propagation is that of reflection. For example, when light strikes the surface of a clear body of water, some of it travels at slightly decreased velocity through the water to illuminate the bottom, while the remainder of the light is reflected from the mirrorlike surface of the water. An electrical wave behaves in a similar manner when the characteristics of the medium through which it is traveling changes. (See Figure 2-39.) Part of the energy travels on down the line while the remainder of it is reflected back toward the source. In wire communications, a reflection is more apt to occur at the junction of two different types of wire lines or at any point at which the characteristic impedance of the line makes a sudden change. The reflection of energy is

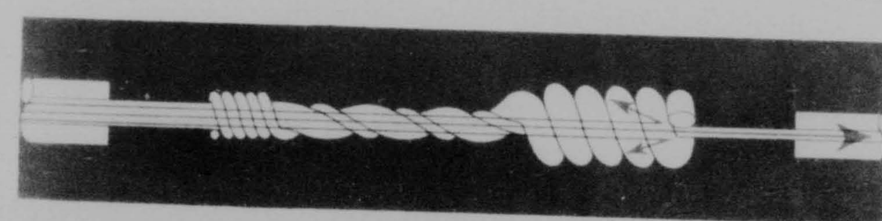


Figure 2-39 Reflection Loss

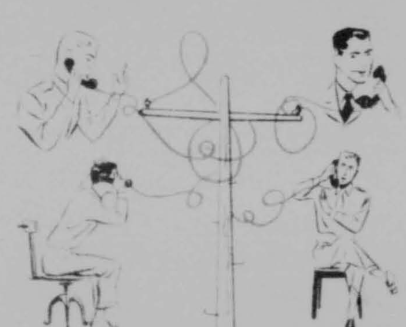
THIS PAGE IS DECLASSIFIED IAW EO 13526

called the reflection loss. In order to reduce reflection losses, most telephone equipment is designed to have the approximate characteristic impedance of the ideal transmission line.

Attenuation and Frequency Distortion. Since all the power entering the transmission line at the input is not received at the output end, there is a definite loss that must be associated with the characteristics of the wire. In telephone and telegraph practice, this loss is called "attenuation." The attenuation of a line is not constant for all frequencies that the line is called upon to transmit. The higher the frequency the higher the attenuation. In other words for a given line, the attenuation is proportional to the frequency. Since the low frequencies are attenuated to a lesser degree than the high frequencies, distortion occurs. Low frequencies are transmitted better than the high frequencies and therefore are better understood. This distortion is known as "frequency distortion." It may be corrected by inserting loading coils or equalizers, or a combination of both, in the line. The function of these is to increase the transmission of the high frequencies.

Crosstalk. A common interference and characteristic of improperly designed and constructed telephone and telegraph systems is crosstalk. Crosstalk may be defined as intelligible sounds heard on one circuit as a result of speech transmission over another circuit. The three principal causes of crosstalk are: the **magnetic effect** between two circuits, the **capacitance effect,** and **resistance unbalance** in its own circuit. Crosstalk may



result from the leakage current between two circuits. Normally, with properly maintained circuits, the insulation is sufficient to make the crosstalk caused by leakage only a minor consideration. Crosstalk may be produced by magnetic effect; that is, by the magnetic field of one circuit cutting the wires of another circuit, and inducing a current in that circuit. Because of the greater separation of the wires in an open-wire line there is a greater difference in the voltages in each wire of the adjacent pair than will occur in adjacent pairs of a cable. The magnetic effect in an open-wire pair, therefore, is greater than in a cable pair.

Capacitance effect is caused by the difference in the capacity between the wires of two circuits. Since the capacitance increases as the separation of the two wires decreases, it is reasonable to expect that the capacitance effect will produce crosstalk in the circuits in cables. The difference of potential in one circuit causes a difference of potential in an adjoining circuit, producing crosstalk.

Resistance unbalance is caused by one wire of a pair having a greater resistance than the other wire. This difference of resistance may be the result of employing different gauges of wire, improper splices, poor connections, or faulty equipment. A line may be balanced by correcting the improper conditions that exist in the construction or by adding the proper amount of resistance to the other wire of the circuit in order to make the resistance of the wires equal. The adding of the resistance is to be avoided if possible since it increases the attenuation of the circuit.

Noise. Interference which produces an unintelligible sound heard over telephone circuits may be defined as "noise." Though crosstalk currents may appear as noise, the principal cause of noise is the induced currents from power lines. A special type of noise produced from a conglomeration of unintelligible speech sounds is known as "babble."

Babble occurs mostly in cable lines, where any crosstalk heard may be induced simultaneously from a number of other circuits as a result of the close grouping of the wires within the cable.

The disturbing effect of noise depends upon the intensity and frequency of the current producing the noise. Experiments have shown that the disturbing effects of noise are most pronounced at a frequency of 1100 cycles per second. Noise is not only irritating to the listener, but if the intensity is great enough, it may reduce the intelligibility of the conversation. It is important, therefore, that the noise level of the circuits be kept below a point that will not seriously interfere with telephone conversations.

Noise introduced by power lines may be largely eliminated by adequate separation of the lines. Normally a separation of the width of a road will prove a sufficient distance for the normal voltages employed in electrical distribution systems. However, for the high voltage transmission systems a greater separation will be required.

Transmission Losses and Gains

Since any line facility of the type described decreases the intensity of the voice currents as they pass through the transmission line, and the additional line and terminal equipment introduce additional losses, some method must be employed to make up these losses. The term "transmission losses" is employed to describe these losses. On short lines there may be no need to apply means for making up these losses since the conversation still may be readily understood. However, on longer lines the transmission losses may reach such proportions that it becomes necessary to make them up in order that intelligible speech may be reproduced. Telephone repeaters are employed in order to overcome these losses. The repeater is a vacuum tube device and may be adjusted to give the desired value of amplification or gain. Several repeaters may be employed if the circuit is long.

The transmission losses and gains are expressed in terms of a unit called the **decibel** (abbreviated as **db**). For wire communication, a signal level of one milliwatt (0.001 watt) has been adopted as the standard reference level. Zero db corresponds to one milliwatt of power. A positive (+) number of db indicates a power level greater than one milliwatt; while a negative (—) number of db indicates a power level less than one milliwatt.

A form of graph known as an **energy level diagram** is used in both the design and maintenance of long lines employing repeaters. These diagrams give a pictorial or graphic illustration of energy levels throughout a circuit. The signal levels expressed in db's are shown for both the transmission line and the associated terminal and intermediate equipment. Figure 2-40 illustrates such a diagram. The simplest method of measuring transmission losses is to transmit a signal of zero db on the line and then measure the output at the desired points with a decibel meter. A decibel meter is an ammeter calibrated so that the scale reads directly in decibels. If the db meter indicates a reading of —10 db, then the line has a loss of 10 db at that point. This method, however, has two disadvantages: First, it is difficult to design a db meter sensitive enough to operate on the small amount of power present in a long transmission line; secondly, it is difficult to construct a meter that is accurate over a wide range of frequencies such as is employed in wire communications.

A method which overcomes these two difficulties is to amplify the signal to be measured by a known amount, and then to rectify the output to produce a direct current. The DC output may then be measured by a DC decibel meter. This method insures that sufficient power will be available to operate the meter and at the same time removes any of the inaccuracies that may be present because of the frequency. Instruments of this type, incorporating an amplifier, a rectifier, and a DC decibel meter in a single unit, are known as "direct reading transmission measuring sets." The amplifier of this set is provided with a control which enables the operator to vary the gain. The gain control is calibrated so that by combining the dial reading of the gain control with the reading of the db meter, the power level at the input of the instrument may be determined.

Correction of Transmission Losses

The following is a more detailed discussion of the methods by which the transmis-

THIS PAGE IS DECLASSIFIED IAW EO 13526

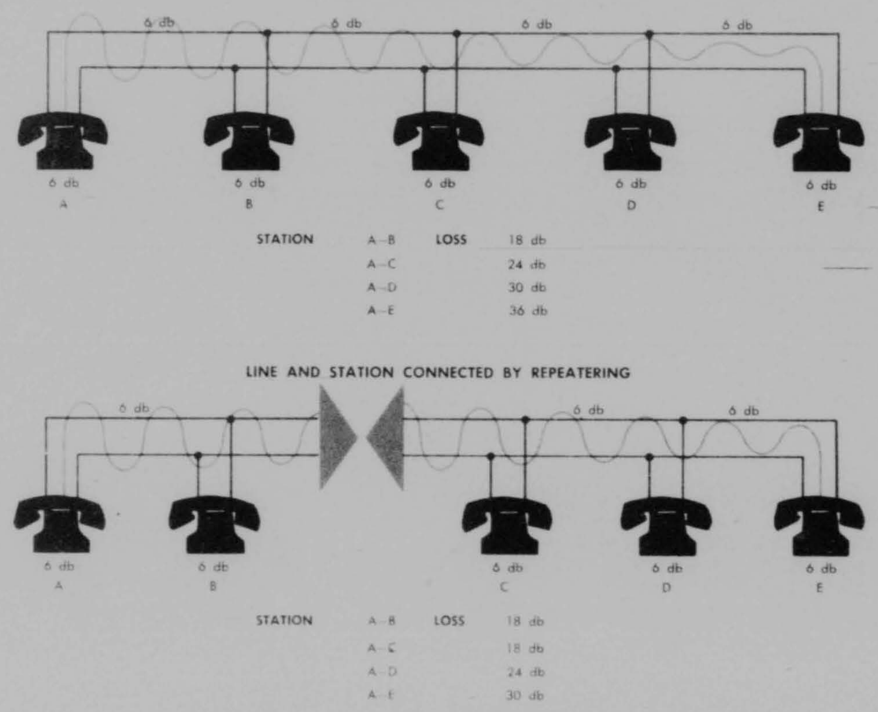


Figure 2-40 Transmission Loss

sion losses may be corrected. In the preceding paragraphs some of these have been briefly mentioned but it is necessary for the communications officer to have a more complete understanding of these methods.

The **attentuation** of a transmission line may be decreased by reducing resistance, capacitance, leakage, or any combination of these. The resistance of the circuits may be reduced by employing a larger gauge wire; the capacitance of the circuits may be reduced by increasing the spacing of the wires on the crossarm, and the leakage may be decreased by the use of a higher grade insulating material on the wires and the insulators. All of these methods greatly increase the cost of construction and therefore may be impractical. A method which is both simple and economical is that of loading.

Loading consists of increasing the inductance of the transmission line by adding inductance in series. This practice reduces the attenuation and thereby increases the range of communication. The practice of adding inductance to the line tends to equalize the attenuation at the different frequencies that are present in wire communication circuits, and as a result lessens the amount of frequency distortion in the circuit. In addition to these improvements, the loading of the line tends to make the characteristic impedance of the line remain more nearly constant with the changing frequency.

The most practical way of increasing the inductance of a line is to connect loading coils in series with each wire of the line at certain specified intervals. The line then is known as a "loaded line."

Although loading coils decrease the attenuation of the line over voice frequencies, they increase the attenuation at frequencies above the normal voice band, unless the coils are spaced at such close intervals as to be uneconomical and impractical. For this reason, lines which are designed to transmit a wide range of frequencies, such as are employed in a carrier system, are seldom loaded. Instead, repeaters are used to compensate for the attenuation.

The amount of crosstalk in a line depends to a great extent upon the design and construction of the particular circuits. Crosstalk tends to increase proportionately with length of parallel circuits, with an increase in strength and frequency of the transmitted signal. Circuits using repeaters increase the strength of the transmitted signals. Since carrier systems utilize repeaters on long lines and operate at high frequencies, the tendency for crosstalk is further increased.

Crosstalk may be reduced by the correct spacing of repeaters. If two circuits are close together at a point near a repeater station, and one circuit is carrying the weak current entering the input of the repeater, the circuit carrying the strong current tends to interfere with the circuit carrying the weak current. A practical remedy for this condition is to keep circuits carrying strong currents as far removed from circuits carrying weak currents as possible. Where this separation is not feasible, more repeaters may be added so that no repeater will be required to provide a very large amount of gain. This increases the number of repeaters required in the circuit. However, with each repeater producing less gain there will be a more nearly equal value of the currents flowing in the circuit at all times, and will tend to decrease the amount of crosstalk in the circuit.

On open-wire lines, crosstalk reductions depend mainly on three factors: resistance balance, configuration of the wires on the poles, and transpositions. Resistance balance is primarily a question of maintenance and usually presents no special problems. However, configurations and transpositions do require special consideration.

There are several types of configurations employed to reduce crosstalk. Insulators on crossarms are arranged so that individual

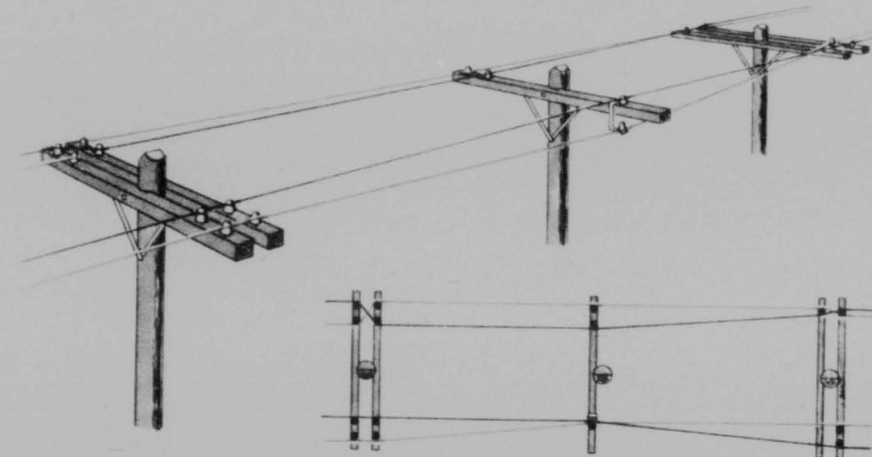

Figure 2-41 Types of Transposition

THIS PAGE IS DECLASSIFIED IAW EO 13526

pairs have a greater spacing. This configuration results in a decrease in the difference of the voltages induced, the voltages, which are now more nearly equal, tend to cancel each other, with a consequent reduction in crosstalk. A limitation of this method is the danger of closely spaced wires swinging together in the wind.

In spite of the many types of transpositions, the principle is the same. Wires are crossed over or transposed in a manner that the induced voltages tend to cancel, thus reducing crosstalk. The methods used in cable lines differ somewhat from those used on open wire lines. This is mainly because the wires in the cable are crowded closer together. In the cable, the wire pairs are twisted together and in turn, pairs are twisted to form a quad. Quads are in turn spiraled about the cable core. The principle cause of crosstalk in cables is the capacitance difference between the wires of the cable. Capacitance unbalance is reduced at the time of installation by testing cable quads at predetermined splices, then splicing quads with a high value of capacitance in one direction with a quad with a low value of capacitance in the other direction. The matching of quads in this manner reduces capacitance unbalance to a minimum and therefore greatly reduces crosstalk.

Field wire lines present no special problem in connection with crosstalk since the wires are wound spirally, effecting a continuous transposition.

Since noise, like crosstalk, is an induced effect, similar measures are used to reduce noise. However, since the principal source of noise is the paralleling of an electric power line, the methods of transposition are not adequate although they will provide some help in reducing noise. This may be more clearly understood by considering the special case created by power lines. The power line operates at much higher voltage and carries a much greater current than does the telephone line. Therefore, a greater magnetic field is created by the power line and it is consequently able to induce much greater currents in the telephone line. Whenever practical, the ideal way to eliminate interference from power lines is to avoid any parallel between power lines and telephone lines. In many cases, parallels with little separation cannot be avoided. For the normal distribution system of the electric utility, road distance separation should prove sufficient. For transmission systems, however, this will not prove adequate; greater separation will have to be effected in order to reduce the noise to a sufficiently low value to make the line usable. If adequate separation may not be attained, it may be necessary to make use of certain measures in addition to balancing and transposing the telephone conductors. These measures usually require the cooperation of the electrical utility. The particular techniques vary somewhat with each situation, but include such measures as rearrangement of the transformer connections, or insertion of filters in the power line to reduce the harmonics present in that source. Special configurations of the power line conductors provide a better electrical balance.

Although the attenuation in a line usually is undesirable, there are occasions when it is desirable. If the output of a repeater is greater than desired, attenuation is introduced intentionally. A resistance network, known as a "pad", is used to produce intentional loss in a circuit. Pads consist of resistance in series (series arms) and are designed to provide any required amount of loss. A pad has two properties: the amount of loss that it will produce in a circuit which is expressed in db; and the impedance it presents to the circuit, expressed in ohms. Since most of the telephone equipment is designed for 600 ohm impedance, pads are usually designed to have an input and output impedance of 600 ohms.

Filters are in many respects similar to pads. The principle difference between pads and filters is that pads are designed to produce approximately the same loss at all frequencies, while filters are designed to produce high losses at some frequencies and low losses at others. Filters are made up of inductors and capacitors, arranged to offer high losses to given frequencies. The three fundamental types of filters are the high-pass filter, the band-pass filter, and the low-

pass filter. The high-pass filter will pass all frequencies above a certain specified frequency. The low-pass filter will pass those frequencies which lie below a specified frequency. The band-pass filter will pass those frequencies which are within a specified frequency band.

Because frequency distortion occurs when the attenuation of a line is not the same at all frequencies, it sometimes becomes necessary to use a network to correct the unequal attenuation. Such a network is called an "attenuator equalizer" or simply "equalizer." Equalizers consist of inductors, capacitors, and resistors arranged in a network. The losses produced by the equalizer vary inversely with the loss of the line. Thus, if the loss in the line is high with the high frequencies, the losses in the equalizer will be low at these frequencies and high where the loss of the line is low. Equalizers are generally used with repeaters in such a manner that the weak signal passes through the equalizer prior to entering the repeater. This permits a more nearly even amplification over all frequencies employed on the line.

4. TYPES OF CIRCUITS

General

Wire circuits are classified in two ways: according to use, as either a trunk line or a local loop, and according to the type of transmission path employed.

A **trunk line** connects switchboards at two different points and is normally a high quality line since the distance between switchboards may be great. Considerable care must be taken with this type of construction in order to obtain the desired quality of transportation.

The **local loop** is a circuit employed to connect the subscriber's telephone to the switchboard. It is usually a short line and may not be as well constructed or have the same high qualities of transmission required of a trunk circuit.

The classification of circuits according to the transmission path employed is of great importance to the communications officer since a knowledge of this will permit him to make the best use of the wire facilities available to him.

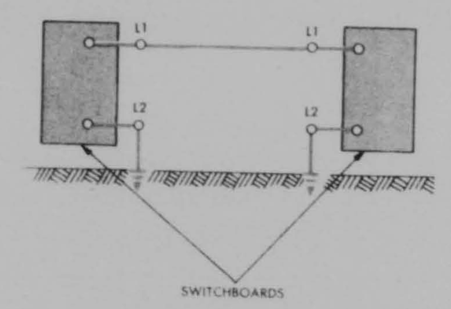

Figure 2-42 Ground Return Circuit

Unbalanced Circuits

Unbalanced circuits are those in which one side of the line has a greater resistance than the other. This type of circuit is employed primarily for economy of construction. The cause of unbalance is, normally, the use of ground return. There are two applications of this: the ground-return circuit and the simplex circuit.

Ground-Return Circuit. The ground-return circuit employs one wire as one side of the circuit and the earth as the other side of the circuit. Figure 2-42 illustrates this type of circuit. The ground-return circuit is inherently unbalanced, noisier, more subject to crosstalk, and messages over them are more easily intercepted than is the case with balanced circuit. A ground-return circuit requires that one wire only be installed and therefore may be constructed more rapidly and at the same time requires one-half as much wire to construct. At the same time, the circuit is more likely to fail completely if that one wire is damaged.

Simplex Circuit. Before discussing the simplex circuit, it is necessary to introduce the **repeating coil.**

Repeating coils are used in field wire systems to make possible the construction of simplex and phantom circuits for additional telegraph, teletypewriter, or telephone channels. The coils consist of two windings on a magnetic core, carefully balanced to pre-

THIS PAGE IS DECLASSIFIED IAW EO 13526

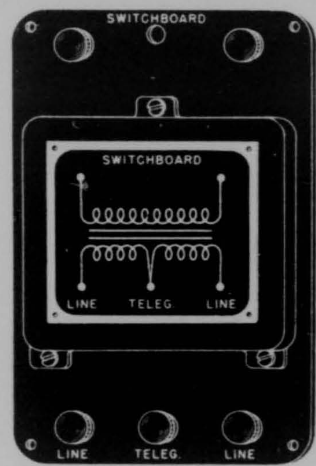

Figure 2-43 Repeating Coil C-161

vent crosstalk. The ends of one winding are brought out to two terminals, marked LINE, which are connected to the incoming wire line. The ends of the other winding are brought out to two terminals, marked SWITCHBOARD, which are connected to the switchboard line terminals. The midpoint of the line side of the coil is brought out to a fifth terminal, marked TELEG, that can be connected to provide a simplex or phantom circuit.

The coil commonly issued for use in the field is Coil C-161.

The simplex circuit is obtained by placing a repeating coil at each end of the metallic circuit. Usually the coil at each end is located in the line as close to the switchboard terminal strip as practicable. The binding posts marked **LINE** are connected directly to the line, and those marked **SWITCHBOARD** are connected to the desired line terminals on the switchboard. The telephone circuit is completed inductively through the coil. The binding post marked TELEG is connected to one line terminal of the telegraph set. Usually this line to the telegraph set is referred to as the telegraph leg. Ordinarily the other line terminal of the telegraph set is connected to a suitable ground near the instrument.

When a telephone is installed on a simplex line without a switchboard, the repeating coil terminals marked SWITCHBOARD are connected directly to the telephone.

Switchboards integrally equipped with repeating coils and terminal strips have the repeating coils permanently connected between the switchboard terminal strips and certain line units. The simplex circuit is then obtained by connecting the desired line to the proper line terminals on the switchboard, and running the telegraph leg from the corresponding telegraph binding post to the telegraph set.

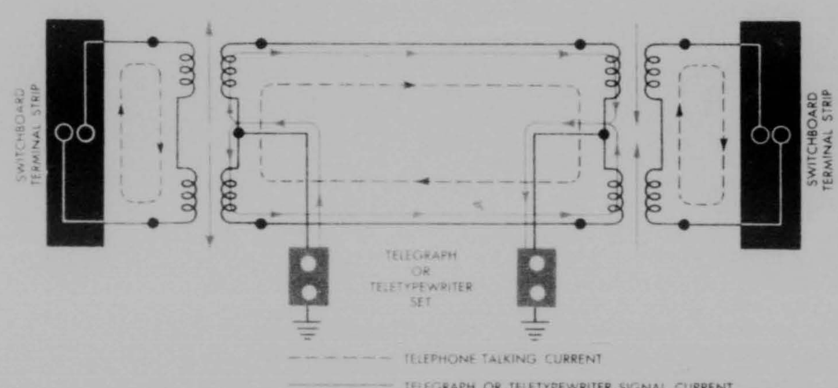

Figure 2-44 Simplex Circuit

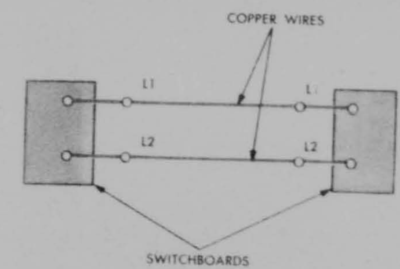

Figure 2-45 Balanced Circuit

Balanced Circuits

The balanced circuit is completely metallic. It requires two wires to make it complete. It derives its name from the fact that it has the same characteristics on each side of the line. It is the most commonly employed type of line since it has very good transmission characteristics, and, therefore, affords a high quality of service. Figure 2-45 represents the balanced circuit.

Phantom Circuit

A phantom circuit may be constructed from two metallic circuits and four repeating coils, two at each end of the lines. The two binding posts marked TELEG at each end of the lines form the phantom circuit, and may be connected to an unused pair of line terminals at the switchboard.

If desired, the phantom circuit thus formed may be simplexed itself to obtain a telegraph circuit in the same manner described in the preceding paragraph for a single metallic circuit. This requires the use of an additional repeating coil at each end of the lines.

5. TESTING AND MAINTENANCE

When outside wires develop faults such as contacts with ground, short circuits, crosses with other circuits, or open circuits, these faults may be located by using test equipment. The test equipment consists of voltmeters and Wheatstone bridges, in combination with tones, ringing voltages, and DC voltages. The test equipment employed by the military is specially packed for field use and contains many different combinations of the basic test equipment available. In addition,

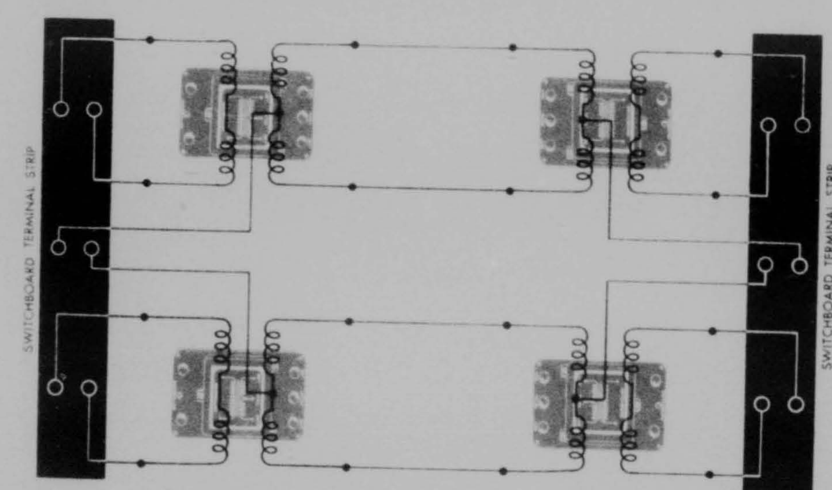

Figure 2-46 Phantom Circuit

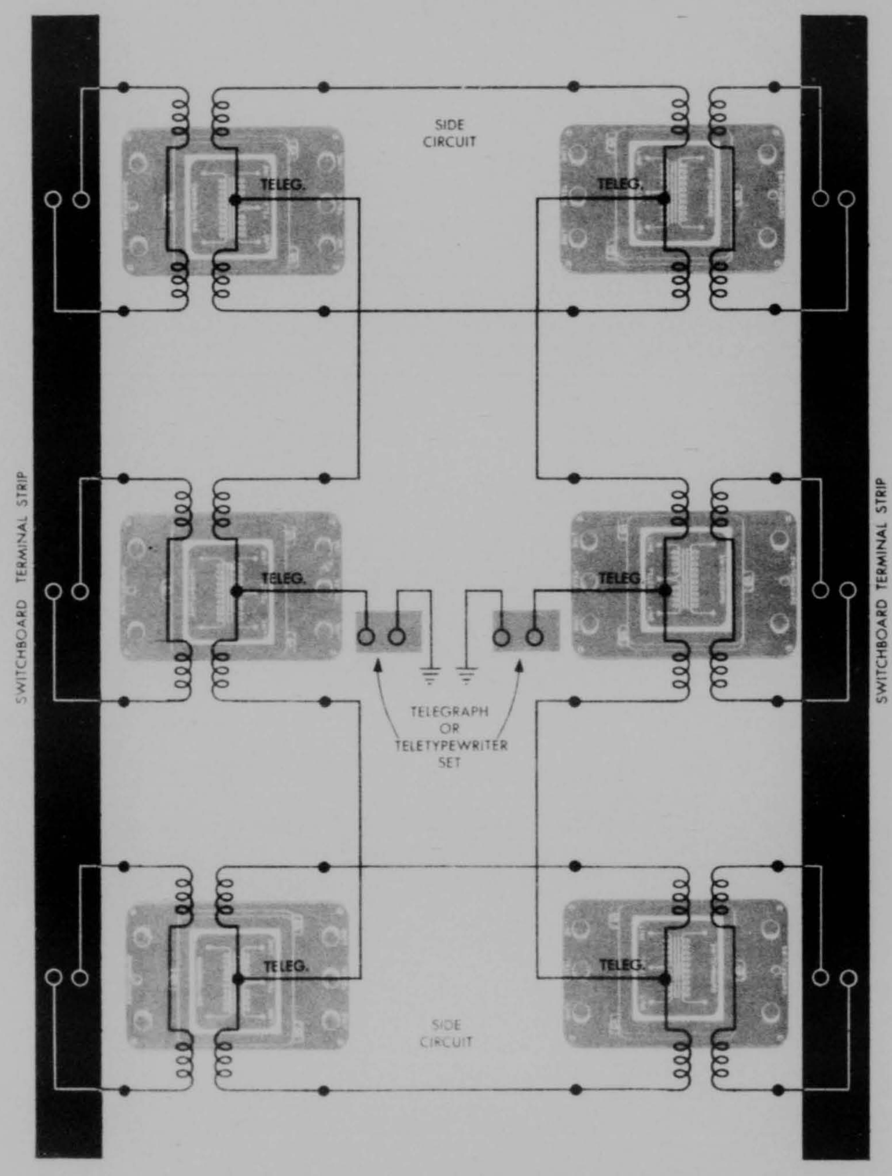

Figure 2-47 Simplexed-Phantom Circuit

much of the same equipment may be used to test for faults in central station lines and equipment. After the faults have been localized, they may be cleared by any of the techniques indicated and with the aid of the various maintenance equipment which is available for this type of work.

The tests which can be performed with test equipment installed in telephone centrals may be briefly summarized as follows:

a) Test calls can be originated and answered on magneto and common-battery loops.

b) Tests can be made with a voltmeter to check the continuity of a circuit and to detect accidental grounds, short circuits, crosses, and opens.

c) Ringing voltage can be applied to a circuit as a step in detecting grounds, short circuits, or opens.

d) The capacitance from line to ground or to another line can be indicated by the swing of the voltmeter needle in combination with the initial application of a potential through the voltmeter to the line.

e) Voltages may be measured.

f) Conductor loop resistance and insulation resistance can be measured with a voltohmmeter or Wheatstone bridge.

g) Approximate locations of open circuits on open-wire lines can be estimated from the capacitance tests with a voltmeter.

A small central with a fixed plant switchboard ordinarily will be equipped with a portable Wheatstone bridge for use in finding faults on the lines and for other test procedures. At the terminal of a main cable route there will generally be a somewhat larger test set for testing purposes, while the large centrals will be provided with a built-in test board.

When a loop or trunk circuit fails, the following procedures may be adopted to clear the trouble. The trouble is analyzed by making overall ringing tests and talking tests. Then specific tests are made to localize the trouble on the circuits which fail on the ringing and talking tests. In the smaller centrals, these tests may be made with a voltmeter at the switchboard. While in larger centrals, they may be made with a test unit or test board. The line is sectionalized and analysis tests are made on each section to determine its condition. When the section with the fault is discovered, the test board nearest that section is employed to locate the fault more exactly. After the fault has been located as closely as possible by these electrical means, it is necessary to patrol the line and physically locate and clear the fault.

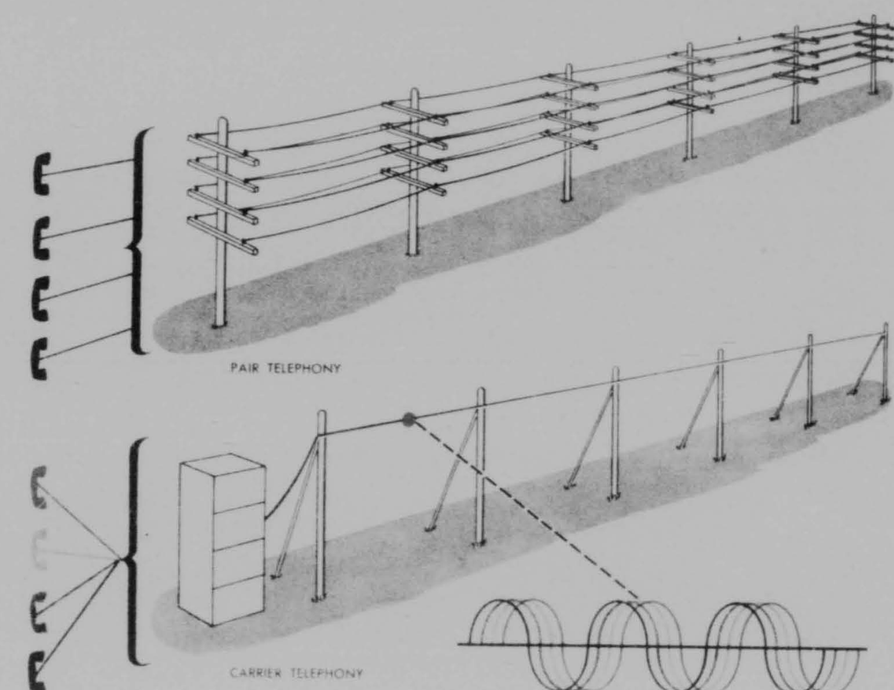
Test and control board equipment provide jacks and patching cords for removing circuits from service as may be required for trouble tests, routine tests, or other transmission measurements. Furthermore, it provides arrangements for monitoring and talking on the lines. The monitoring jacks may be arranged in some test boards to make the circuits under test busy at associated switchboards. This avoids interference between the regular traffic and test calls and gives full control of the circuit being tested to those making the tests. In centrals where these automatic make-busy features are not provided, it will be necessary for the testing personnel to ask an operator to make the circuit busy at the switchboard.

SECTION 5 - FUNDAMENTALS OF CARRIER TRANSMISSION

1. GENERAL

A most important military development in the field of wire communications is carrier transmission. This development is a major step in the satisfaction of the military management requirements of time, space, materiel, and personnel through the economies it effects. These savings will be further discussed in the section below. In addition, car-

THIS PAGE IS DECLASSIFIED IAW EO 13526



rier transmission adheres to the communications principles of reliability, economy, flexibility, security and mobility.

Purpose

Theoretically, a transmission line is capable of transmitting frequencies from zero to infinity. However, because of practical considerations, a standard transmission line is capable of efficiently transmitting frequencies ranging from zero to approximately 150,000 cycles per second. The voice frequency range is from 200 to 2,700 cycles per second, so it is apparent that only a very small portion of the potential frequency range capabilities of the line is utilized when a single voice conversation is transmitted over the standard transmission line. In effect, the entire frequency range above 2,700 cycles is wasted. However, there is a way to reallocate or space out several 2,500 cycle voice-frequency bands or voice channels in this otherwise wasted region, making it possible to transmit several conversations simultaneously without mutual interference and thus utilize more fully the capability of the transmission line. This reallocation, or spacing out, of the normal voice channel to obtain several facilities over the same line is accomplished by carrier systems.

It is readily seen that superimposing of several voice-frequency channels on a single transmission line will have some immediate advantages. The chief advantage is the more economical usage of line construction materials. The saving in wire alone will often more than justify the use of carrier systems. Additional economies in time, personnel, and space further justify the use of this system since wire construction is time consuming,

requires large numbers of men who are not always readily obtainable, and includes the necessity for storage and operating space for vehicles, as well as equipment.

2. PRINCIPLES OF OPERATION

Carrier equipment and systems were originally developed for commercial use. The advantages of carrier systems were recognized by the military, and packaged items were designed for use by tactical forces in the field. Because of the military adoption of the carrier in wire communications, it is worthwhile to discuss the basic principles involved. To understand the method by which many channels of telephone and telegraph are obtained over the same wire which formerly provided a single channel, an explanation of carrier current, modulation, and demodulation is necessary.

Carrier Current

An alternating current of a constant predetermined frequency is generated at the terminal of a carrier system by an oscillator. This current is known as "carrier" current because it serves to carry the superimposed voice currents. The process of superimposing the voice currents on the carrier current is known as "modulation", and the device which makes this possible is the modulator. All that results from impressing the voice frequency on the carrier frequency is a reallocation or shifting of the voice frequency range to some other frequency range. For example, the normal 2,500 cycle band of voice frequencies is, as stated previously, from 200 to 2,700 cycles. However, this band of frequencies can be shifted by the use of carrier frequencies so as to occupy the frequency range from 3,100 to 5,600 cycles. Therefore, in this case, it is possible to transmit two messages simultaneously on the same transmission line without mutual interference; one message will occupy a frequency range from 200 to 2,700 cycles while the other will occupy the range from 3,100 to 5,600 cycles. If additional carrier frequencies were generated with a sufficient separation between each band so that they would not interfere with each other, it would be possible to transmit more messages over the same transmission line. All these messages being transmitted over the carrier system and a common transmission line behave as if they were being transmitted over separate transmission lines. At the receiving end the intelligence is separated by a process called "demodulation". This process is the reverse of the process at the sending end.

Modulation

When two different frequencies are combined in a modulator, the original frequencies appear at the output of the modulator together with several other frequencies. Two of these other frequencies are of particular concern: the first is the sum of the original two frequencies and the second is the difference between the two original frequencies. The sum of the two original frequencies is known as the "sum frequency", and the difference between the original two frequencies is known as the "difference frequency". Hence the four frequencies of particular concern which appear at the output of the modulator are: the voice frequency, the carrier frequency, the sum frequency, and the difference frequency. For example, if a 1,000-cycle frequency is combined with a 10,000-cycle frequency, the output of the modulator contains the two original frequencies of 1,000 and 10,000 cycles, the sum frequency of 11,000 cycles, and the difference frequency of 9,000 cycles. The sum and difference frequencies are known as the upper and lower modulation components, or, more commonly, as the upper and lower sidebands. Either the upper or lower sideband can be used to carry the message currents. Figure 2-48 is a block diagram showing how the modulator combines two different frequencies and the filter which permits only the desired sideband for transmission to pass.

Demodulation

In a sense, demodulation is remodulation. In demodulation, the transmitted sideband is combined with the frequency of the original carrier to reconstruct the original transmitted signal. To continue the example given above, if the lower sideband of 9,000 cycles

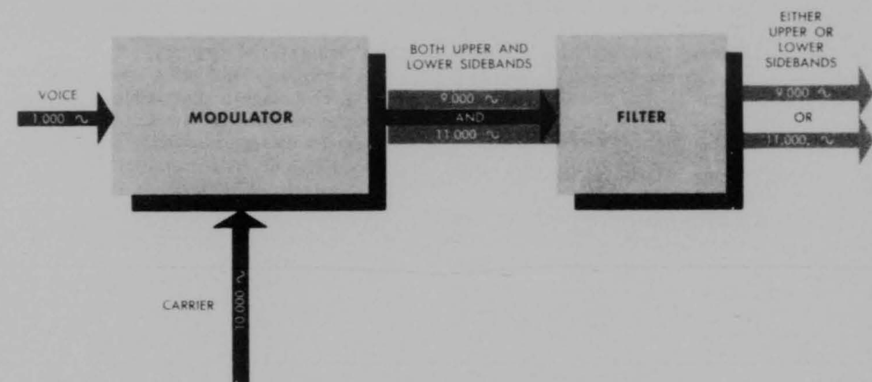


Figure 2-48 Formation of Upper or Lower Sidebands

were transmitted, it would be recombined with the 10,000-cycle carrier frequency at the receiving point where demodulation takes place. The recombination again produces the sum and difference frequencies of 19,000 and 1,000 cycles. A filter removes the undesired frequencies and permits the desired frequency of 1,000 cycles to pass. Hence, in demodulation the received sideband is combined with the carrier frequency of the original signal to reconstruct the original signal that was superimposed upon the carrier frequency. Figure 2-49 is a block diagram illustrating demodulation.

Carrier Filters

A typical carrier system is shown in Figure 2-50. A hign-pass filter and a low-pass filter are combined in a single unit known as a "line filter" which is connected to the line to separate the higher frequency carrier currents from the lower frequency voice currents. At the switchboard side of the carrier terminals, hybrid coils separate the transmitting and receiving branches of the carrier circuit. Low-pass filters are used at the inputs of the modulators to eliminate all frequencies outside of the voice range. The

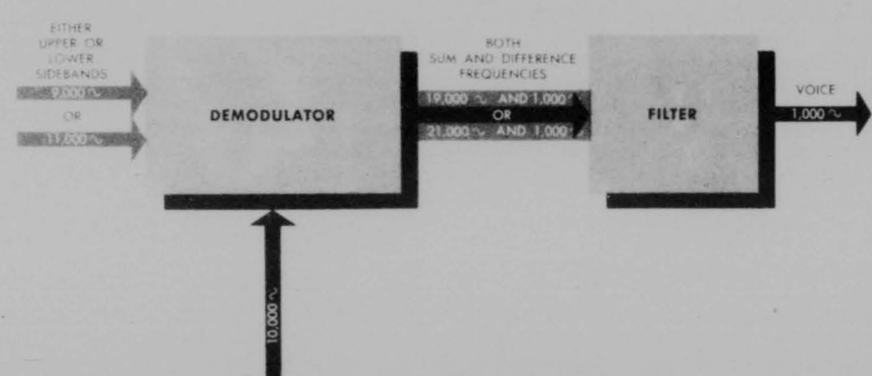

Figure 2-49 Demodulation of Sidebands

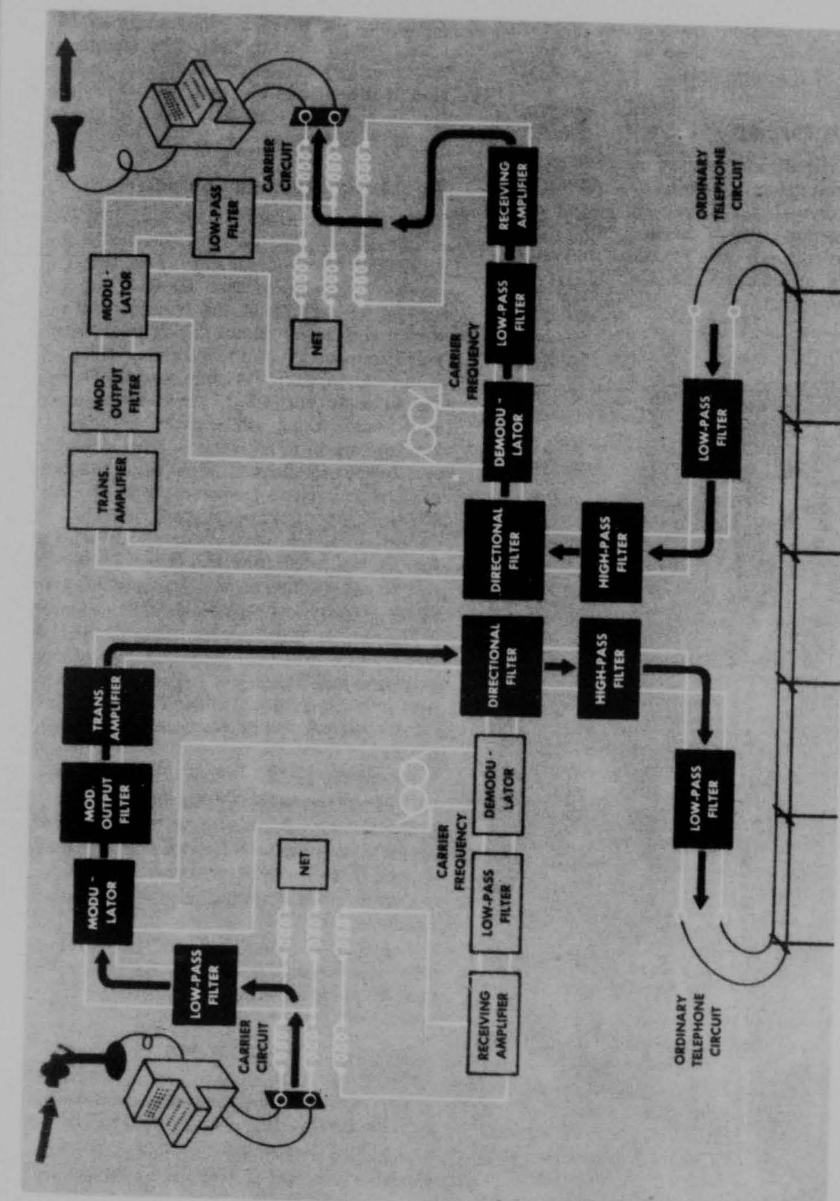

Figure 2-50 Operation of a Single Carrier Channel

modulator out-put filters eliminate all undesired modulation components. Likewise, low-pass filters are used in the receiving branch of the terminals.

3. EQUIPMENT

The circuit components of telephone terminal equipment have been described in some detail above because they are present in all major components of carrier equipment. We will now examine the functions and characteristics of separate items of military carrier equipment.

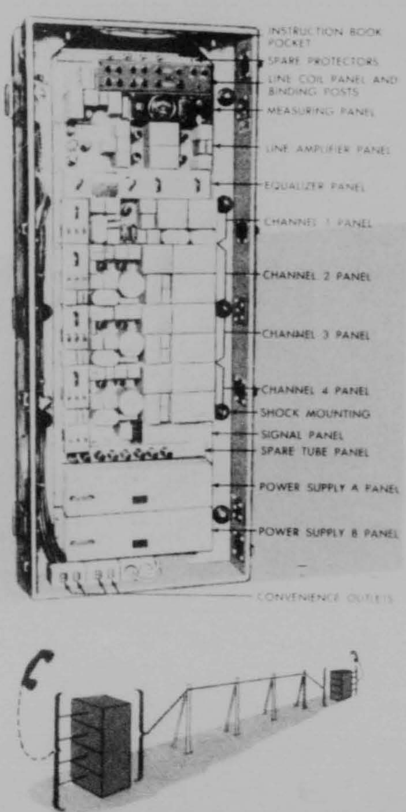

Figure 2-51 Telephone Terminal CF-1-A

For purposes of discussion, carrier equipment may be divided into three classifications: terminal equipment, line equipment, and ringing equipment. A general description of these types together with their function in a carrier system is given in the following paragraphs.

Telephone Terminal Equipment

Telephone terminal CF-1-( ) is the basic equipment of any carrier system. It provides four telephone channels; channel 1 at voice frequency, and channels 2, 3, and 4 at carrier frequencies at the transmitting terminal, shifted by demodulation back to the voice frequencies at the receiving terminal. Any or all of the CF-1 channels may be employed with the CF-2 telegraph terminal equipment (which will be described later) to transmit up to four teletypewriter messages per telephone channel. The four channels require an over-all frequency band of about 200 to 12,000 cycles per second, each channel occupying about 2,600 cycles. Each of the four is separated from the others by filters. A general outline of the features of telephone terminal CF-1-A follows:

Means for terminating the spiral-four cable,* with protection against lightning and extraneous voltages. (*CF-1's are generally used with spiral-four cable. The spiral-four carrier system will be discussed later in this chapter.)

Means for providing two DC simplex circuits over the spiral-four cable pairs.

Modulating, demodulating, filtering, and amplifying equipment for one voice-frequency and three carrier-frequency channels.

Common transmitting amplifier for four channels.

Common receiving amplifier for four channels with adjustable equalization to compensate for the attenuation characteristics of the spiral-four cable.

Means for monitoring and talking on all channels.

Test oscillator and transmission measuring circuits for making line-up adjustments.

Signaling device for communicating with repeater stations and other terminals over one simplex circuit.

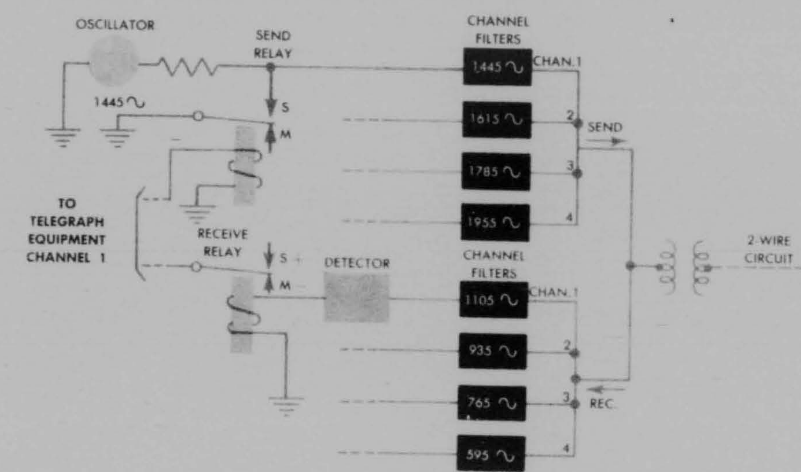

Figure 2-52 Elementary Block Diagram of Telegraph Terminal CF-2-C

One power supply for line amplifier signal circuit, and one for channel amplifiers, modulators, demodulators, and test oscillator. Operation on AC supply of 110-125 or 220-250 volts, 50-60 cycles with automatic fall-back to operation from a 12-volt storage battery during AC power failure.

Telegraph Terminal Equipment

If four (or fewer) telegraph channels are required in a carrier system, a telegraph terminal equipment CF-2-( ) is added to the CF-1 at each end of the system. A general outline of the features of this equipment follows:

It is suitable for two-wire operation over any telephone circuit having a net loss of not greater than about 25 db and uniform loss-versus-frequency characteristics over the range of 300 to 2,500 cycles.

Provides four two-way voice-frequency telegraph paths, each capable of teletypewriter operation at speeds of 60-75 words per minute.

Provides a DC circuit in each of the four channels for half duplex or full duplex operation.

Contains meters and controls for checking and adjusting telegraph channels for optimum operating conditions.

Is equipped with telegraph relay testing features, and tools necessary for relay maintenance.

Includes positive and negative 130-volt rectifiers in each bay. Each rectifier contains an automatic reset device to protect the rectifier tubes in case of AC line failure. AC power at 103-128 or 207-253 volts, 60-60 cycles, is required for the operation of these units. No provision is made for emergency operation from storage batteries.

The CF-2-B has the same features as the CF-2-A, except that it is assembled into one bay, or case, instead of two.

A second item of terminal equipment often used in carrier systems is Telegraph Terminal CF-6 which provides two additional channels for voice-frequency telegraph operation. A CF-6 may be used separately or in combination with a CF-2. In the latter case, its four frequencies (two per channel) are spaced with the eight frequencies of the CF-2, 170 cycles apart in the voice range from about

THIS PAGE IS DECLASSIFIED IAW EO 13526

THIS PAGE IS DECLASSIFIED IAW EO 13526

THIS PAGE IS UNCLASSIFIED

340 to 2,400 cycles. Therefore, when four-wire operation is used, a CF-2 and CF-6 can combine to operate twelve two-way telegraph circuits, since transmission in each direction is over a separate line pair and each of the twelve frequencies can be transmitted in both directions. All of these telegraph circuits require only one channel of the associated Telephone Terminal CF-1. This example gives a true indication of the value of carrier.

Repeater Equipment

At the points in a carrier system where repeaters are required, Repeater CF-3-A is connected in the four-wire line. The repeater has power equipment similar to that at the terminals and provides a separate equalizer and amplifier for each direction of transmission. When required for the maintenance of the system, facilities are provided for talking over channel 1. A general outline of the features of Repeater CF-3-A follows:

Means for terminating the spiral-four cable in each direction, with protection against lightning and extraneous voltages.

Means for providing two DC simplex circuits in each direction over the spiral-four cable pairs.

Two amplifiers, one for each direction of transmission, common to all four channels, with variable equalization for the attenuation characteristics of the spiral-four cable.

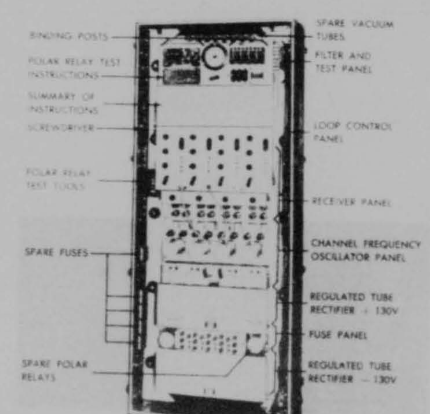
Transmission measuring circuit for making line-up adjustments.

Means for monitoring and talking on channel 1, the voice-frequency channel, without interfering with the other three channels.

Signaling device for communicating with terminals and other repeaters over one DC simplex circuit.

Power supply for operation on 110-125 or 220-250 volt, 50-60 cycle AC, with automatic fall-back to 12-volt storage battery operation during AC power failure.

Repeater CF-5 is used in conjunction with 2-wire facilities. This repeater makes possible greater transmission distances in a circuit which was converted from four-wire to two-wire operation at or near each terminal. It is composed of two independent amplifying circuits, one of which is associated with the AB (terminal A to terminal B) direction of transmission of 20,850-32,250 cycles, and the other with the BA direction of 200-11,600 cycles. Filtering and equalizing circuits are associated with those of amplification and transmission measuring controls are also included. Signaling and talking circuits are also provided with this repeater.



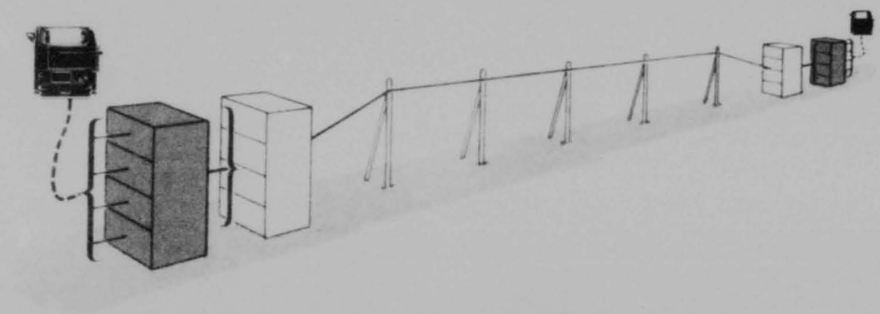


Figure 2-53 Telegraph Terminal CF-2-B

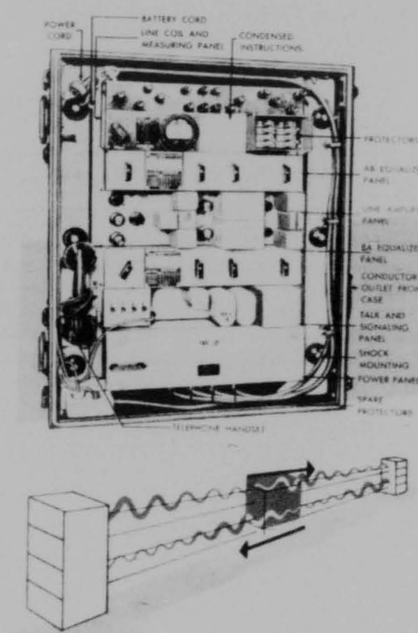

Figure 2-54 Repeater CF-3-A

Converter Equipment

At the junction of two-wire and four-wire facilities in a carrier system, a converter CF-4 is placed in the line to effect the change-over. It permits operation of the four channel system, discussed above, over a single pair of nonloaded open wires. A frequency range of 200-11,600 cycles is used in one direction of transmission, and a range of 20,850-32,250 cycles is used in the opposite direction. The CF-4 does not contain a means for talking over the system since usually it will be located adjacent to its associated terminal. If these units are some distance apart, a separate talking channel may be provided by using Telephone Units EE-105 or separate field wire facilities.

Carrier Hybrid CF-7 is a converting device for connecting a two-wire line to either a Telephone Terminal CF-1 or a Repeater CF-3, both of which are designed for four-wire operation. With this equipment, which requires no power and is installed in a small

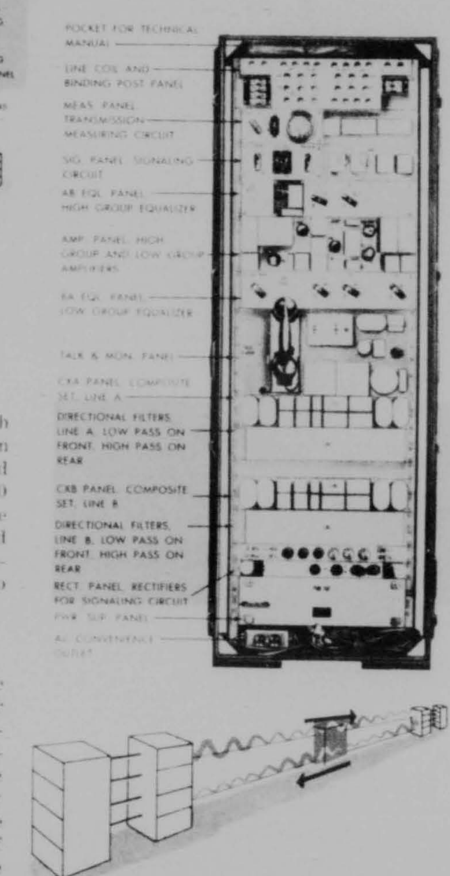

Figure 2-55 Repeater CF-5 (2-Wire)

THIS PAGE IS DECLASSIFIED IAW EO 13526

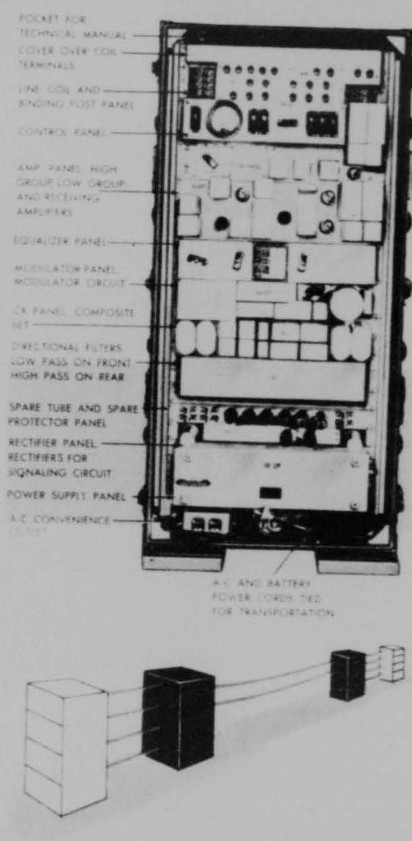

Figure 2-56 Converter CF-4 (2-Wire to 4-Wire)

carrying case, four two-way telephone circuits can be obtained over a single pair of wires. In addition, two grounded DC telegraph circuits or one of these and a DC signalling circuit may be operated over the pair. In place of one of the telephone circuits, four voice-frequency telegraph channels can be made available by applying CF-2's at the telephone terminals.

Ringing Equipment

With the development of carrier equipment, a device which could ring or signal over the voice frequencies employed became necessary. The low frequency (16 and 20 cycle) ringing current supplied from switchboard and magneto telephone sets was not suitable for ringing, so Ringer Equipment EE-101 was incorporated in carrier systems for this purpose. When installed at the terminals and connected between the switchboard or telephone set and the line, the ringer equipment responds to the low-frequency current, rectifies and filters it at 20 cycles, raises it to voice-frequency by means of a 1000/500 cycle oscillator or vibrator, and sends it out over the line. The ringer at the receiving station operates in reverse to convert the note back to the low frequency required to energize the switchboard or telephone.

4. CARRIER SYSTEMS, GENERAL

Carrier operation is desirable since it permits maximum use of existing facilities, reduces the amount of open-wire construction, and saves in shipping space and weight of materials. The carrier equipment can be transferred readily from one location to another as the requirements change. The time required to establish a given number of carrier circuits on existing transmission lines is much less than is required to string additional wire facilities.

Carrier systems are of three types which differ only in the method of handling the two-directional transmission of messages as required for telephony. These three kinds are physical four-wire, balanced two-wire, and

Figure 2-57 Carrier Hybrid CF-7

Carrier system	No. of circuits	No. of pairs	Type of line	Type of operation	Approx. frequency range (kilocycles)	
					A to B	B to A
Spiral-four	4	2	CC-358-( ) or open wire	Physical 4-wire	0.2-11.6	0.2-11.6
Carrier hybrid	4	1	Open wire	Balanced 2-wire	0.2-11.6	0.2-11.6
Open wire converter	4	1	Open wire	Equivalent 4-wire	20.8-32.2	0.2-11.6

Figure 2-58 Carrier Systems

equivalent four-wire. The particular type used has important reactions on the application and layout of carrier systems. All three methods are employed with tactical equipment. Fixed plant carrier systems using packaged equipment (more or less standard commercial equipment) work only on the equivalent four-wire principle.

The physical four-wire system uses separate pairs of wires and the same band of frequencies for both directions of transmission. The system uses two independent one-way transmission paths like the ordinary four-wire telephone circuit except that the frequency band extends beyond the voice range. Physical four-wire systems are used for carrier on cables because this results in the lowest practicable top frequency and lowest attenuation for a given number of circuits. When used on open-wire circuits, physical four-wire systems are subject to high crosstalk between high signal strength outgoing currents of one system and low signal strength incoming currents of the same frequency in another system, unless repeater spacings are suitably reduced.

The balanced two-wire system requires only one pair of wires for operation. It uses the same frequency band for operation in both directions. Hybrid coils and balancing networks are used at terminals and repeater stations to separate the two directions of transmission. The transmission path between terminals is like an ordinary two-wire telephone circuit except that higher frequencies are transmitted. Freedom from instability and ringing is obtained by the balance between the lines and networks and by use of short repeater sections (closer spacing of the repeaters) and with only moderate gains at each repeater. Balanced two-wire operation is of use principally on open-wire lines but may be applied to other types for short distances. The number of balanced two-wire carrier systems which can be worked on an open wire line, without danger of high values of crosstalk between different systems, will depend on the repeater spacing, the type of line, and other factors.

The equivalent four-wire system uses only one pair of wires but the frequency bands for the two directions of transmission are different. Separation of the two directions of transmission at repeaters is accomplished by means of filters. This avoids the disadvantage of balanced two-wire operation while requiring only one pair of wires and retaining all of the transmission advantages of a four-wire system. However, these advantages are gained at the expense of more than doubling the top frequency of the system. For this reason, equivalent four-wire operation is normally used only on open-wire lines. Since a given frequency band always transmits in the same direction for any system on the line, crosstalk is of the far-end type (originates at the far end of the line). Therefore, repeaters of high gain may be used on a line with suitably designed transpositions.

5. TACTICAL CARRIER SYSTEMS

Some types of tactical carrier telephone systems and the types of lines on which they are normally used are tabulated in Figure 2-58. A discussion of several of these types follows below:

THIS PAGE IS DECLASSIFIED IAW EO 13526

Spiral-Four

The basic equipment of the spiral-four carrier system or the 100-mile spiral-four system, includes the Telephone Terminal CF-1, Repeater CF-3 and the necessary cable.

Spiral-four carrier equipment is designed basically for use as a physical four-wire system on Cable Assembly CC-358. Figure 2-59 shows schematically the arrangements for nonrepeatered and repeatered circuits.

Each system provides one voice-frequency and three carrier telephone circuits in the frequency range 200-11,600 cycles. Transmission characteristics permit 6-db repeatered circuits about 150 miles long when the cable is installed as an aerial cable or laid on the ground, or about 400 miles long when it is buried. Transmission factors limiting the length are loss variations caused by temperature changes and noise. In practice, buried cable lengths have been considerably less than 400 miles. Normal repeater spacings are about twenty-five miles and are limited by noise and available repeater gain. When noise is low, somewhat longer spacings can be used with some complications in maintenance.

When no intermediate repeaters are used, as in Figure 2-59a, circuit lengths up to thirty-five miles or more may be used by increasing the transmitting output at the terminals. Means are provided in the terminal equipment for accomplishing this gain. Under favorable noise and crosstalk conditions, single section systems can be operated for distances of fifty-five miles at 6-db net loss or eighty miles with a 30-db net loss. The gain of the terminal is sufficient for this purpose. When these extremely poor conditions are encountered, singing may occur in the spiral-four cable.

The two DC channels are provided over the

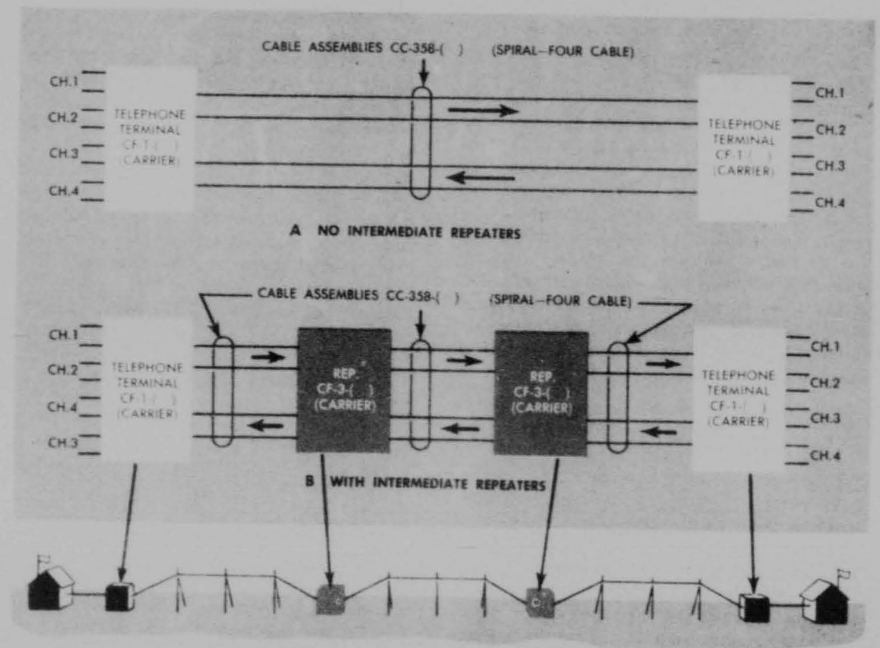

Figure 2-59 Spiral-4 Carrier Systems

two simplexes of the cable. Normally, one of these is used as a signaling channel to call the intermediate repeater attendant so that the other may be used for a telegraph circuit by one or two repeater sections.

The spiral-four system may be used on an emergency basis over two pairs of nonloaded Wire W-143 with repeater sections about fourteen miles in length. There are some restrictions on the use of W-143 for this purpose, such as its characteristic of capacitance unbalance, which may give noisy operation in certain areas having high static noise levels.

The spiral-four system can be used as a physical four-wire system on two open-wire pairs. The method of setting up such a system is the same as for the spiral-four cable system, except that the instructions with the equipment do not give typical equalizer settings for open-wire circuits. However, these settings may be determined during the line-up tests.

The transmission lines used with a carrier system may be combinations of open-wire, spiral-four cable, or Wire W-143 without serious effects on transmission except for some increases in the system losses. This makes the system useful in forward combat areas where well-constructed open-wire lines may not exist. Single systems may be operated on a nonrepeatered basis for lengths of 100 miles or more of open-wire circuits, giving four circuits on two pairs of wires. Circuit lengths may be increased by the use of repeaters. Two or more systems on the same line lead to crosstalk difficulties and require much shorter section lengths and repeater spacings for high grade transmission performance.

Carrier Hybrid Systems

Carrier Hybrid CF-7 which already has been discussed, may be combined with spiral-four equipment for balanced two-wire carrier operation using the same frequency band for each direction of transmission over open wires. This saves one pair of wires as compared with the physical four-wire system of operation, but places certain restrictions on the length of the repeater sections and the required regularity of line construction. Carrier Hybrid CF-7 includes a repeating coil hybrid, a balancing network, protectors, and a composite set for deriving two DC telegraph channels. Figure 2-60 shows by block diagram the lay-out of a carrier hybrid system.

Repeater section lengths must be kept short in this system to avoid singing difficulties. On well constructed lines with small irregularities, nonrepeatered circuits may be worked for sixty-five miles at 61-db net loss and 135 miles at 30-db net loss on 80 mil copper-steel pairs. Longer lengths may be operated with repeater spacings of about fifty miles on the 80 mil copper-steel wire. If the lines are damaged or poorly constructed, and have changes in wire spacing or gauge, or have short lengths of inserted cable, the usable gain will be reduced. Such irregularities may reduce the maximum length of

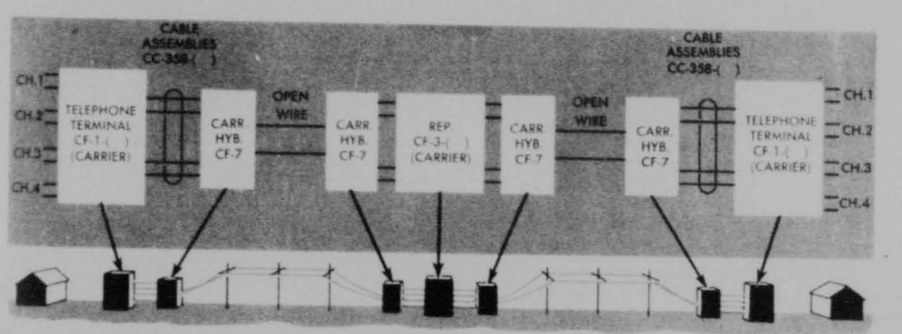

Figure 2-60 Balanced 2-Wire Carrier Hybrid System

THIS PAGE IS DECLASSIFIED IAW EO 13526

nonrepeatered circuits to not more than 45 miles at 6-db net loss and 115 miles at 30-db net loss. Irregularities in line construction are likely to be more common in forward areas and this characteristic of the carrier hybrid system should be allowed for in laying out systems in such areas.

If more than one carrier hybrid system is operated on a line, near-end crosstalk will occur between oppositely directed paths. On new carrier transposed lines of military construction, it will be possible generally to operate two carrier hybrid systems per cross-arm within the permissible crosstalk performance in forward areas. Existing lines may have poor crosstalk characteristics and operation of a number of systems will generally involve accepting higher crosstalk, increased circuit losses, or reduced repeater spacings.

The carrier hybrid system can be used on Wire W-143 or spiral-four cable for moderate distances. If both pairs of the spiral-four cable are used for these distances, crosstalk between the two systems will approach the maximum tolerable for forward areas. If one pair in the spiral-four becomes damaged, operation on a balanced two-wire basis in the faulty section can be used as an emergency measure.

The carrier hybrid system can be converted readily to a physical four-wire system or vice versa, especially in the case of nonrepeatered systems. This allows considerable flexibility in the use of the two systems. Where sufficient pairs are available, physical four-wire circuits provide a more stable and less vulnerable system with wide latitude in the makeup of the wire line. The carrier hybrid system is for use where pairs are at a premium and the distance to be spanned is within the capabilities of the system as limited by its particular line irregularities. Use of the system on very irregular lines in forward areas is possible on a single section basis provided no attempt is made to insert large amounts of gain; that is, the system may be used to yield more circuits on a pair of wires but not to increase the range by any great amount in such cases.

The carrier terminal and its associated hybrid coil may be separated and connections between the two made on a four-wire basis. This is illustrated in Figure 2-60, where spiral-four cable is shown connecting the terminals to the hybrids. This separation of the two units of equipment may be found desirable to avoid long cable lengths between the hybrid and the open-wire line. For example, it may be desired to place the terminal equipment in a less exposed place so that it may be camouflaged. However, this separation should be avoided whenever possible, since it tends to make the adjustment of the balancing network in the hybrid awkward.

Pair-Per-System Operation of Telephone Terminals

An emergency method for operating over open-wire lines on a pair-per-system basis is shown in Figure 2-61. This is an emergency arrangement for use only when the carrier hybrid and the open-wire converter systems are not available, and there are not sufficient pairs available to permit physical four-wire operations. Again, the carrier principle of using more than one frequency of one pair is employed.

It is not possible in this system to insert gain at either terminal, as this would cause circuit instability and singing. Simultaneous transmission in both directions is possible without encountering these interferences, provided the correct dial settings are made at each terminal. With these settings, the overall net loss of each channel would exceed the line attenuation by about 9 db. If properly adjusted, the circuits will not sing under any line conditions.

The circuit lengths with this system are limited to about twenty-five miles on 80 mil copper-steel wire for circuits having 18-db net loss, and about sixty miles for point-to-point circuits with 30-db net loss. Distances about three times as great may be spanned on 104 mil copper wire. Any inserted cable would reduce these lengths by the insertion loss of the cable.

Open-Wire Converter System

The open-wire converter system is an equivalent four-wire system, designed for operation over open-wire pairs without the limitations of the physical four-wire and carrier hybrid systems. This system uses the Converter CF-4 (Figure 2-56) and the Repeater CF-5 (Figure 2-55) in conjunction with the Telephone Terminal CF-1-51C.

Figure 2-62 shows a block diagram of a repeatered open-wire converter carrier system. The transmission over the open-wire line in one direction is 200-11,600 cycles, while 20,800-32,200 cycles is employed in the other direction for transmission. Converted to kilocycles these frequency spans read 0.2-11.6 and 20.8-32.2.

The telephone terminal equipment is connected over two pairs of wires to the converter and then to the open-wire line. At the converter on one end of the line, the band of frequencies used to transmit the voice currents is the normal of 0.2 to 11.6 kc. However, the frequencies employed at this end for the reception of incoming currents occupy the band from 20.8 to 32.2 kc. The function of the converter at this end of the line is to convert these frequencies to the normal band of 0.2 to 11.6 kc and feed them to the telephone terminal equipment. At the other end of the line, the function of the converter is reversed. It passes the incoming frequencies of 0.2 to 11.6 kc directly to the terminal equipment but raises the frequencies to the outgoing currents from 20.8 to 32.2 kc. The Repeater CF-5 is used to increase the allowable length of the system. Furthermore, it provides for separate amplification of the transmission in each direction by separating them by a system of high and low pass-band filters and then amplifying each band separately.

The system will provide four circuits per pair, and the circuit may be operated at 6-db net loss for distances up to approximately 1,000 miles (with some relaxation of crosstalk standards if systems are operated for such great distances on adjacent pairs). The

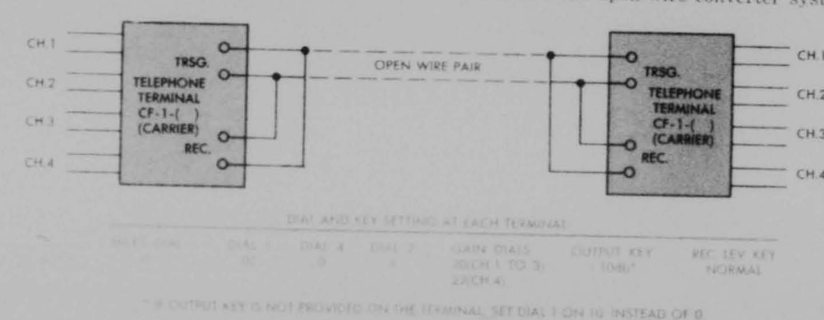

Figure 2-61 Pair-Per-System Operation of Telephone Terminals CF-1 ( )

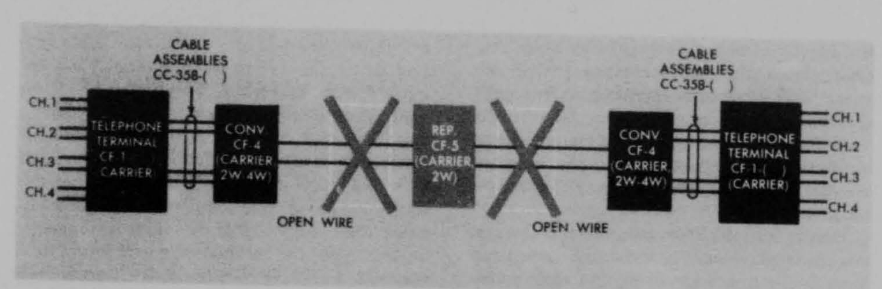

Figure 2-62 Open-Wire Converter Carrier System

normal repeater distance on 080 copper-steel is eighty to ninety miles. Noise and available gain limit repeater spacings. When used as a single section system without repeaters, distances up to 135 and 200 miles can be spanned with 080 copper-steel wire, for circuit net losses of 6 db and 30 db, respectively.

On four-pair and eight-pair open-wire lines, properly transposed, each pair may be used for an open-wire converter system. These will provide a maximum of thirty-two telephone channels on eight pairs of wires. This system may be used on the same pole line with fixed plant packaged carrier systems and on most foreign systems.

Combinations of the open-wire converter system on open wire in tandem with the spiral-four system can be operated without bringing the channels down to voice frequency at the junction point. Converter CF-4 and Repeater CF-3 are used at the junction in this case. Converter CF-4 may also be used alone at the junction of the open-wire line and the cable if the cable length does not exceed approximately one mile in length. This may be useful for camouflaging the approach to the carrier terminal, and it avoids the transmission penalties of having cable in the open-wire circuit. However, a source of power must be provided to operate the converter.

6. MULTICHANNEL VOICE-FREQUENCY CARRIER WIRE TELEGRAPHY

In general, carrier telegraphy uses an alternating current of fixed frequency for each channel, which is switched on and off at the sending end by a sending relay actuated by DC signals. Frequencies in the voice-frequency band are used for carrier telegraph systems. The carrier currents are transmitter through their respective channel filters, and at the receiving end are again separated by filters before being sent to the detector in order that the original may be reconstructed.

Circuits suitable for telephone transmission are used. However, since each telegraph channel uses only a small part of each voice-frequency channel, it is possible, therefore, to use more telegraph channels over the same voice-frequency band. Simultaneous operation of several (two to twelve) telegraph circuits may be obtained in the voice range, with each circuit being capable of duplex operation. (Simultaneous operation in each direction).

Carrier telegraph systems are operated on two-wire circuits, four-wire circuits, or the equivalent in which the transmission in the two directions is independent. In two-wire carrier telegraph operation, different frequencies are used for the two directions of transmission. In the case of four-wire, the same frequencies may be used in both directions. When using the same frequencies in this manner, the requirements as regards crosstalk between the two sides of the circuit are more severe for full-duplex telegraph operation than they are for telephone operation. Excessive crosstalk coupling between the two sides of the circuit will cause serious impairment of telegraph signals transmitted in one direction due to the telegraph currents being transmitted in the other direction.

Power levels used in carrier telegraph systems must be properly coordinated with telephone transmission levels. If the net loss from the originating long distance telephone switchboard to a point in the circuit is 0-db, this point is said to be at 0-db transmission level. The power in dbm (db referred to one milliwatt) per carrier telegraph channel, at a point of 0-db transmission level, is known as "specific level." Various particular adjustments of telephone and telegraph equipment gains or losses are made in order to realize proper telegraphic levels.

Carrier telegraph systems are available for operation on one or more of the four telephone channels of a spiral-four cable system using the Telephone Terminal CF-1 together with Telegraph Terminal CF-2. The latter may be used on any circuit employing the CF-1 equipment, both wire and radio. A schematic of a four-channel carrier telegraph terminal is shown in Figure 2-53. Telegraph on two-wire or four-wire basis is normally associated with other terminal equipment. In this case, the method of operation is designated two-wire or four-wire, depending upon whether the connection between the telephone terminal equipment and the tele-

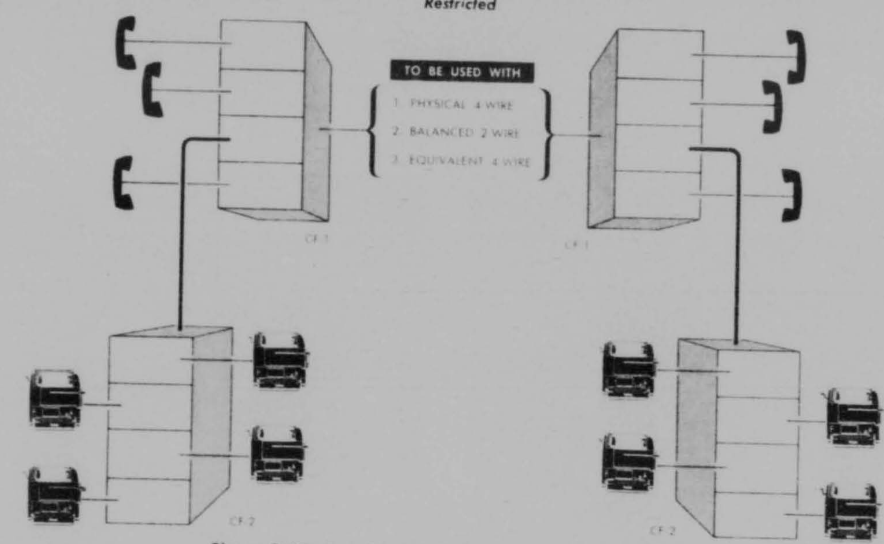

Figure 2-63 Capabilities of Carrier Terminal Equipment

graph terminal equipment is two or four wires. If a two-wire connection is used, four telegraph circuits can be obtained, using four frequencies for one direction of transmission and four different frequencies for the other direction of transmission. The addition of Telegraph Terminal CF-6 to this system will provide two additional telegraph circuits and make a total of six circuits available. If a four-wire connection is used between the telephone terminal and the telegraph terminal, the eight available telegraph frequencies, can be used to provide eight two-way telegraph circuits. In this case, the addition of the Telegraph Terminal CF-6 will increase the number of telegraph circuits to twelve.

7. SPEECH-PLUS-SIMPLEX AND SPEECH-PLUS-DUPLEX SYSTEMS

These systems are designed to derive carrier telegraph from a portion of the frequency band used by a telephone channel while retaining the use of the channel for speech. The speech-plus-simplex (S + SX) system, which is a British term, provides service in both direction on a circuit but in only one direction at a time. The speech-plus-duplex (S + DX) system is used both by the American and British forces. It provides full-duplex service (simultaneous operation in each direction) but may be operated half-duplex if required. The terms "half-duplex" and "simplex" are synonomous.

The British speech-plus-simplex equipment is built in three types: S + SX Nos. 1, 2, and 3. Nos. 1 and 2 are arranged to use carrier frequencies of 300, 900, and 2,300 cycles per second. No. 3 uses carrier frequencies of 300, 1,740, and 2,300 cycles per second. With any one of these three types of equipment, two telegraph circuits, together with one speech channel, may be obtained by using the 300 and 2,300 cycle channels for the telegraph circuits and the intervening frequencies for the telephone channel. One S + SX system normally uses either the 300 or 2,300 cycle frequency and uses the same frequency for both directions of transmission. Two such systems are therefore required to obtain two telegraph circuits from one speech channel. When adverse line conditions interfere with transfission, the telegraph is worked at one of the emergency frequencies of (900 or 1,740 cycles). In the S + SX equipment, the carrier is transmitted for spacing and interrupted for marking.

THIS PAGE IS DECLASSIFIED IAW EO 13526

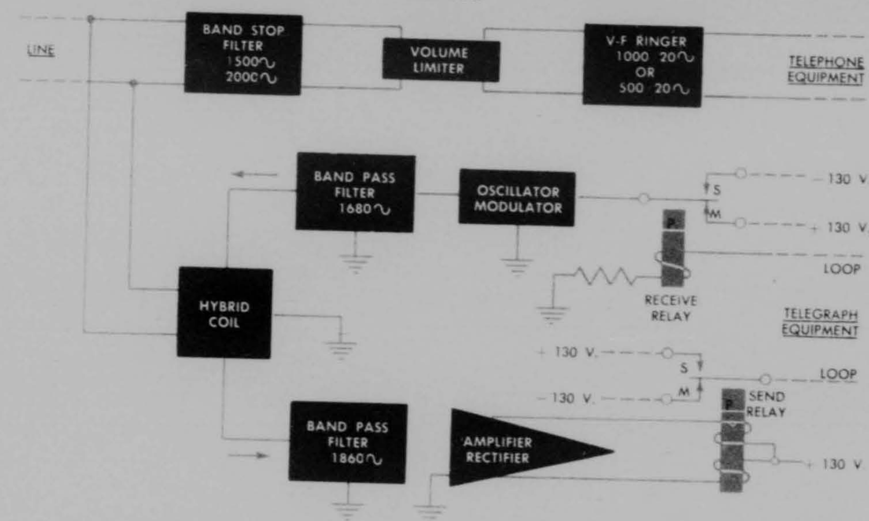

Figure 2-64 Block Diagram of Speech-plus-Duplex System

In the speech-plus-duplex (S + DX) system, a band from about 1,500 to 2,000 cycles is eliminated from the speech transmission circuit and used for telegraph purposes. The carrier midband frequencies employed are 1,680 cycles per second for one direction of transmission and 1,860 cycles per second for the other direction. Carrier is transmitted for marking and interrupted for spacing. The British equipment is known as British Apparatus, V.F., Telegraph S + DX. The American equipment, Telegraph Terminal TH-1 TTC-1, is shown in block diagram in Figure 2-64.

SECTION 6 - FACSIMILE

1. GENERAL

The reproduction of intelligence in its original form over great distances and in the most efficient manner possible is accomplished at present by using facsimile equipment operating over normal telephone or voice-frequency radio circuits. The intelligence to be transmitted or reproduced may be photographs, map photos, serial photos, weather maps, sketches, or mimeographed, printed, written, or drawn material.

The purpose of this section is to acquaint the student with the manner in which this is done, the basic principles of operation of facsimile equipment and its uses by the United States Air Force, to discuss the capabilities and limitations of military facsimile equipment, and to explain the installation and operation of facsimile equipment.

The problem of transmitting facsimile intelligence involves the photo-electric analysis of the subject matter at the transmitting station and then reproducing that matter in the proper relationship as to size, tone value, and position at the receiver end. This is accomplished by a mechanical-optical system combined with an electrical method of transmitting that which the optical system sees.

The **photo-electric tube** has often been called the electric eye, but unlike the human eye, it does not possess the ability to see several images at any one instant. The photo-electric tube, or cell, merely sees and measures the over-all light value reflected from the area it is made to look at, whether it is the outside landscape, the interior of a small room, or a minute spot on a piece of paper. In other words, the photo-electric tube cannot see a distinct picture, but sees a blur or monotone which contains the average light value of the entire picture.

Obviously it is not possible to show a picture to a photo-electric tube for an instant and expect the tube to analyse all the detail for subsequent transmission. It is first necessary to break the picture down into small areas containing monotone values of detail which the photo-electric tube is capable of analyzing correctly. It is for this purpose that minute portions of the picture are progressively scanned, the reflected light values measured, transmitted to the receiver, and assembled in their proper order.

2. PRINCIPLES OF OPERATION

General

The photo-electric analysis of the copy being transmitted is accomplished by a beam of light being projected from an exciter lamp onto a minute portion of the copy which is mounted on the drums of the sending transceiver. The transceiver is a combination transmitter and receiver. This beam of light is successively projected on to the copy as the drum moves axially, with each revolution, along the shaft in an amount equal to the area being scanned.

During operation, the drums of both transceivers rotate at constant and identical speeds. The drums are fed from right to left along the shafts upon which they rotate. These shafts are threaded with 96 threads to the inch, and the drums make 90 revolutions per minute, thus traveling 0.94 inches per minute. As the beam from the exciter lamp is focused on the copy mounted on the drum of the transmitting machine, it shines on successive elemental areas of the copy in lines around the circumference of the drum, always 1/96 of an inch to the right of the previous line. As the beam strikes various shades between black and white on the copy,

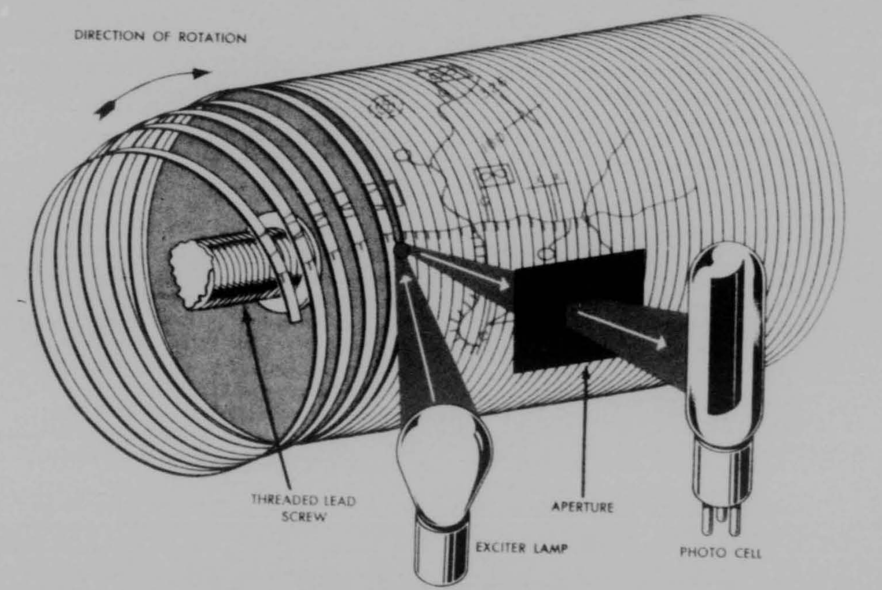

Figure 2-65 Principle of Facsimile Operation

THIS PAGE IS DECLASSIFIED IAW EO 13526

more light is reflected from the copy.

The photo-cell sees the reflected light from these successive elemental areas of the copy and translates what it sees into varying electrical impulses. The intensity of the electrical impulses depends entirely upon the intensity of the reflected light values. These impulses control the strength of a signal which travels over a regular voice channel (wire or radio) to the receiving transceiver, where the process is reversed, thus a complete reproduction is built up from the original copy.

Transmitting

In transmitting, a high-stability tuning-fork-controlled oscillator serves as the control for the entire unit. Energy from the oscillator is amplified and furnishes power for the synchronous motor which turns the shaft or lead screw upon which the drum rotates and moves from right to left. Energy from the oscillator is amplified in the power supply and furnishes a closely regulated voltage for the exciter lamp. Light from the exciter lamp is focused on a spot on the drum by a condenser lens. Light reflected from this spot focused on the copy is projected onto the photo-cell through a small aperture and lens system. The aperture limits the field of illumination scanned by the photo-cell to an area of about 1/100 of an inch square. Variations in light hitting the photo-cell control the amplitude-modulator upon which is impressed the carrier furnished by the fork oscillator unit. This carrier circuit passes through the voltage amplifier, gain control, power amplifier, and decibel meter, and is then sent out to the receiving equipment.

Receiving

In receiving, the fork oscillator unit in the transceiver performs the same functions as when transmitting. It controls the synchronous motor which turns the shaft turning the drum at the same constant speed as at the transmitting station. In other words, the drum turning the copy being transmitted and the drum turning the sensitized material at the receiving station are in exact synchronism. The process is in direct reversal for reception except that in photo printing a recording lamp is cut into the circuit to replace the electric eye. For direct contact recording, a stylus replaces the recording lamp.

Contrast

For successful operation, much attention must be paid to contrast. Contrast, the difference between black and white, is indicated by the maximum and minimum signal strength that may be obtained from the copy to be transmitted. Black or white may be made to give either the maximum or minimum signal strength desired. This depends upon the type of reproduction being made at the receiving station. Signal strength is measured in decibels and is indicated on the db meter. The correct contrast range is where the weakest signal received is just strong enough to record, and where the maximum signal will record as dark as is possible within the limitations of the recording method being used. For example, in the direct contact recording method, if the maximum signal is too great, the current flowing to the stylus will cause it to burn holes through the recording paper. Since the contract range varies with the different methods of recording, the receiving operator determines the contrast range to be established and the transmitting operator sets the range by making the proper readjustments at his station.

Phasing

Phasing is the last step before the actual transmission is begun. This is a short term for synchronization and probably is a more important step in the operation than establishing the correct contrast. The transmitting and receiving transceiver must be in perfect synchronization. They must be in step with one another. In other words, they must be phased. Failure to phase the equipment properly may result in the clamping bar on the transmitting machine appearing in the received copy as a blank space which would result in the received copy being cut in two; also one drum might commence turning before the other in which case an incomplete copy would result.

To phase properly, the transmitting operator, having obtained the contrast range

requested, disengages the drum-feed mechanism and moves the drum along the shaft, or lead screw, until the light beam strikes the white spot on the phase ring, and as the drum turns, a phase pulse is transmitted.

While the phase pulses are being transmitted, the receiving operator sets his drum in phase with that of the transmitter by setting his selector switch at the "record photo" designation. The phase button is then depressed completing a phasing circuit built in the transreceiver. This actuates the phasing magnet so that it stops the drum from turning until the phasing pulse is received from the transmitting machine. As the phase pulse is received, it actuates the magnet again, allowing the drums to turn in unison. This permits the same identical spots on both drums to pass the scanning points at the same instant. Care must be exercised not to touch either of the drums after they have been phased, or the process may have to be repeated.

As mentioned above, there are two methods of recording. The photographic method, and the direct recording method.

Photographic Recording

Photographic recording may be accomplished so that **positive** or **negative** copy is obtained.

In positive recording, black portions of the copy are translated into high-level signals which print at the receiving station as black. It naturally follows that white will print as white. When only one copy of high fidelity reproduction is desired, this method is used. This procedure requires photographic processing after the transmission is completed. It is important that the contrast range be established at 12-db's difference between black and white.

Negative recording is used when more than one copy of the transmission is required. Photographic processing is required to develop the negative, and extra copies are obtained in the same manner that prints are made from any photographic negative. Because of the reversal of black and white reproduction, black is translated as white and white as black. For this process, the contrast range is established at 8-db's difference.

Direct Recording

Direct recording gives the same black and white reproduction as the original. However, degree of detail and half-tone reproduction are sacrificed with this method of facsimile transmission as compared with positive transmissions. No further processing is required and here again, the contrast range must be established as 12-db's.

In this method, Teledeltos paper, a metallic coated paper, replaces the photo paper used in the other methods. The pressure of the stylus on the paper varies directly with the incoming signal.

3. FACSIMILE EQUIPMENT

Facsimile Equipment RC-120. This is a general purpose page machine sending a sheet of copy up to 7 x 8⅜" in about 7½ minutes. It is generally described in the preceding discussion. Facsimile Equipment RC-120-A and RC-120-B include minor improvements in design, but can be used interchangeably with Facsimile Equipment RC-120. A Converter CV-2/TX may be used with these models to permit transmission over radio-telephone channels.

Facsimile Set AN/TXC-1. In general appearance and technical features, this equipment is similar to the RC-120 models. This also is a general purpose page machine, sending a sheet of copy up to 12" x 10" in about twenty minutes. Converter CV-2/TX may also be used with the equipment. This equipment is not interchangeable with the RC-120 models.

Installation

In the installation of equipment in the field, several factors must be taken into consideration:

Operating Circuit. Great care will be exercised to insure that, should a telephone circuit be used, the circuit is free from crosstalk, is in itself electrically balanced, and free from outside operator interruption.

Power Requirements. For normal operation, any AC source furnishing 100 to 130 volts at 50 to 65 cycles will suffice. A source of supply should be readily available to furnish fully charged 6-volt storage batteries for emergency operation.

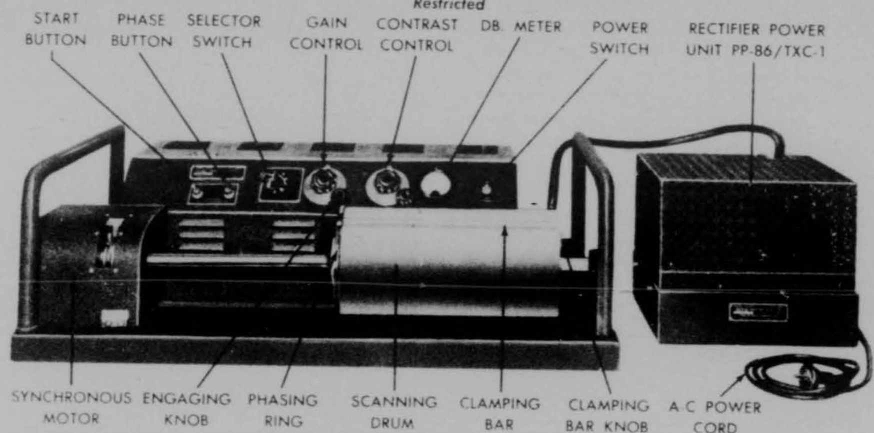

Figure 2-66 Facsimile Equipment AN/TXC-1

Space Factor. The operators must have adequate space in which to function. Normally, a fixed dark room is desirable for the necessary photographic activities. The portable dark room, a component of the equipment, can be made to suffice if required.

Noise Factor. Noise does not enter the picture as long as it is not electrical in nature so as to cause any induced unbalance of the circuit or equipment.

Light Factor. Light does not need special consideration since the operator requires only sufficient light to work comfortably. However, care must be exercised that sunlight or any other strong light is not permitted to shine directly on the copy to be transmitted.

Additional Items. If a volume of photographic transmissions is expected, a large table, sink, and running water also should be provided.

In choosing a location for setting up equipment, a flat solid surface within six to eight feet of the power source should be selected.

For AC operation, the power supply PE-140 will be used. This is a component of the equipment. This power supply stabilizes the power input to a constant level. For best results, it should be placed at the extreme right of the transceiver at the limit of the connecting cord. This is to prevent any power disturbance from entering the transceiver from the power supply.

For emergency DC operation, any fully charged 6-volt storage battery will furnish power for all transceiver models AN/TXC-1 RC-120-A, or RC-120-B. For the RC-120, a Power Equipment PE-150 is furnished and will be used.

For radio transmission, a converter CV-2/TX is used. In brief, this converter changes the signal from amplitude-modulated, such as is used for wire transmissions, to frequency-modulated for radio transmissions.

For successful operation of facsimile equipment, experienced facsimile operators (SSN 893) and facsimile technicians (SSN 894) are required to overcome the problems encountered in the routine installation, operation and maintenance of this equipment.

4. CAPABILITIES OF THE EQUIPMENT

As has been stated, facsimile offers the opportunity to transmit copy, from one area to another, in its original form. Facsimile will transmit photographs, map photos, aerial photos, weather maps, sketches, or any printed material which is written, or drawn. Perhaps the greatest use to be applied to facsimile in the Air Force is the transmission of weather maps and aerial photographs. An aerial photo could be taken, developed, and then transmitted to a headquarters hundreds of miles away in a matter of just a few hours for the whole procedure.

Should copy be too large for a single transmission, it can be broken in sections and each section transmitted separately and then reassembied in the proper order after the transmissions have been received.

It may be possible to photograph, enlarge or reduce the size of the copy to be transmitted. This would depend entirely upon the nature of the copy to be sent and on the amount of detail in the copy.

5. LIMITATIONS OF THE EQUIPMENT

Facsimile transmissions require a high-quality line, one which is balanced and free from noise and crosstalk. It is not advisable to attempt operation on a ground return circuit. Unlike teletype or similar equipment which can operate on any frequency on a very narrow band width, facsimile equipment requires the full voice frequency band for efficient operation. Facsimile, therefore, occupies the entire physical circuit for the entire frequency assigned. On the other hand, teletype will operate on a much poorer quality circuit, and, by the use of associated equipment, several channels can be established on one physical circuit.

Where facsimile is used to transmit plain text, it competes with teletype which can transmit at the rate of 60 words per minute on a tape for an indefinite period of time. Transmissions of 300 words per minute are possible on facsimile but, the time required to change sheets and to accomplish the photographic processing necessary makes it impracticable.

Transmission over radio channels is susceptible to interference from other radio channels, subject to fading and static. These interferences cause fading, distortion, and blurred impressions on the received copy.

The availability of trained technical personnel for the proper operation and maintenance of this equipment are factors limiting its use.

Facsimile is the best method for transmitting intelligence in its original form and in the fastest possible manner.

Facsimile requires a high-quality circuit and highly trained operating and maintenance personnel.

Facsimile cannot compare with other means of straight message transmission when ease of operation is considered.

Recent experiments have shown it possible to transmit by means of facsimile from ground to air. This was accomplished when a weather map was transmitted to a plane in the air.

As improvements are made in this equipment and as its capabilities are increased, it is felt that more widespread use will be possible.

CHAPTER 3 - RADIO COMMUNICATIONS

SECTION 1 - GENERAL

1. USE

Radio, as a means of communication, satisfies to a high degree the principle of mobility. It is especially applicable to quickly changing situations in which wire communications are unable to keep up with the rapid movements.

Radiotelegraphy is the normal means of radio communication when the distances involved are great and when, by reason of the subject matter and the time factor, formal messages in cipher and code are required.

Radiotelephony is used when person-to-person communication is required in the interests of speed and necessity and when, by reason of the nature of the communication or the time factor involved, security is relatively unimportant.

The knowledge in the field of radio communications expanded greatly as a result of the pressure of necessity during World War II. There was little application of radio waves at frequencies above 100 megacycles prior to 1940. During the war, however, radio communication equipment was actually built and operated at 5,000 megacycles and radar equipment was constructed to operate at 30,000 megacycles. Radio and wire communications have been made increasingly complementary with advancements in equipment design. This has resulted in greater flexibility of communication systems and in greater use of telephony over both

THIS PAGE IS DECLASSIFIED IAW EO 13526

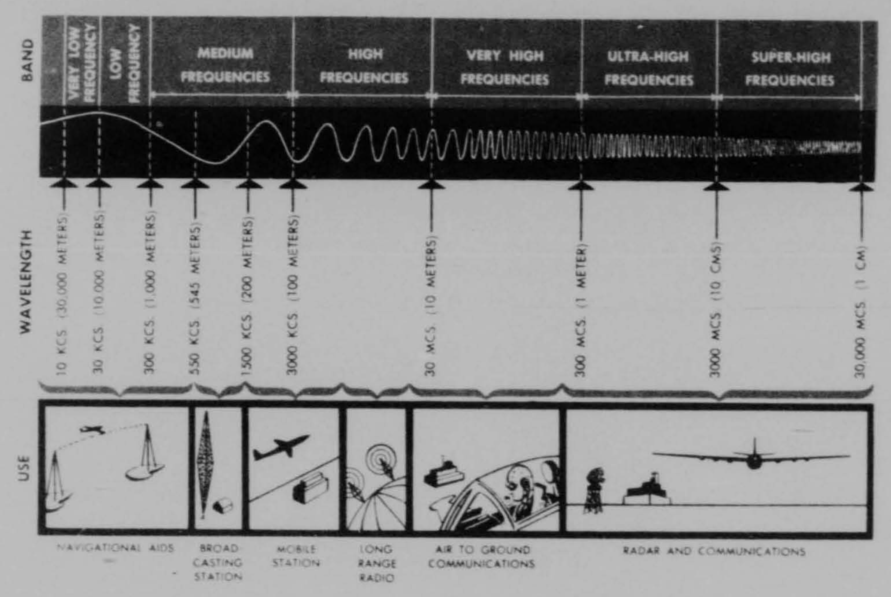

Figure 3-1 Radio Frequency Spectrum

media. This integration employing frequency modulation, pulse-time modulation, telephone and telegraph carrier, has resulted in economies in the use of the overcrowded frequency spectrum.

2. TYPES OF RADIO EQUIPMENT

Before examining the field of radio communications, it first is necessary to consider the types of radio equipment commonly used to meet USAF requirements.

The Joint Army-Navy nomenclature system classifies all radio sets according to the following types.

Airborne. A set installed and operated in an aircraft.

Air-Transportable. A set specially designed to be transportable by air, according to specification or military characteristics.

Ground, Fixed. A large set erected and operated at a permanent location, usually for long-distance communication.

Ground, General. A set which can be installed and operated for two or more types of ground use, that is, a set which can be used both as a vehicular ground set and a portable pack ground set.

Ground, Mobile. A set installed as an operating unit in a motor vehicle which vehicle has no function other than transporting the radio equipment.

Ground, Pack or Portable. A set capable of being carried by a man (or a horse) and operated, while stationary or in motion, by one person. This class includes those sets commonly known as "walkie-talkie" and "handy-talkie."

Ground, Transportable. A semiportable set, capable of being transported from place to place, but requiring a conveyance if moved for any considerable distance.

Ground, Vehicular. A set installed in a vehicle which is designed for functions other than carrying radio equipment, such as a set installed in a tank or armored car.

Shipboard. A set installed and operated from aboard a surface vessel.

General Utility. A set which can be used in two or more of the general type installations; airborne, shipboard, and ground.

3. RADIO FREQUENCY SPECTRUM

Military radio sets sometimes are further classified according to the frequency band in which they operate. Figure 3-1 shows the frequency spectrum as well as some of the uses of the various bands.

SECTION 2 - PRINCIPLES OF RADIO

1. GENERAL

In an electrical sense, the principles of radio are merely refinements of the basic principles that we learned in wire. The basic difference between these is that radio principles require the necessary devices permitting transmission between two points without physical connection.

The problem of transmitting intelligence in this manner is not a great one if we recall our electrical fundamentals. In the 1800's the German physicist, Hertz, discovered that an electrical spark would radiate energy. This was caused by the fact that the spark generated about it a magnetic field which, when induced into a second conductor, could produce a spark similar to the one generated although much weaker in amplitude.

Basically then, our problem in radio is to develop a device of somewhat the same nature as the spark and to modify it for the purpose of conveying intelligence.

Hertz's research proved that energy could be transferred through space with the earth's magnetic field the transporting medium. Thus it became the task of the radio pioneers to develop equipment which would generate alternating currents of a frequency high enough to permit efficient radiation. This frequency is known as radio frequency.

2. THE VACUUM TUBE

General

While working with the incandescent lamp in 1883, Thomas Edison noted that a black deposit appeared on the glass globes. In an attempt to eliminate this he placed a metal plate inside of the globe. While this did not remove or eliminate the black deposit, it inadvertently made a great contribution to the development of radio which was then still in its infancy. Edison noted that when he placed a meter between the filament and the plate, a small electric current was flowing in the circuit. At the time, Edison did not know why this current flowed and he merely noted this in his records.

Today, it is know why this current flows. When a filament is heated, streams of electrons are emitted. This is called the **Edison, or thermionic effect.** The fact that the electrons given off by the hot filament will collect on the plate, or anode, and will flow in the path of least resistance back to the filament, constitutes the basic principle used in the vacuum tube today.

Physical Characteristics

Vacuum tubes are categorized generally according to their physical characteristics and functions. Vacuum tubes are classified according to the number of elements contained within the glass or metal envelope.

Diode. The simplest tube is the diode. It is a two-element tube, containing an electron emitter called a cathode and an electron collector called an anode, or more commonly, the plate. This tube serves as a "valve" in a circuit, permitting current to flow only when the anode has a positive potential. Because it was first developed by a British scientist, Ambrose Fleming, the earliest diodes were known as "Fleming valves."

Triode. The diode did not fill all of the functions desired of a tube. True electron control did not exist until an American, Lee deForest, perfected the triode tube which added another element to the tube, called the "grid." By placing a high positive potential on the plate, the electron flow from the cathode could be controlled very easily by a small amount of negative voltage on

THIS PAGE IS DECLASSIFIED IAW EO 13526

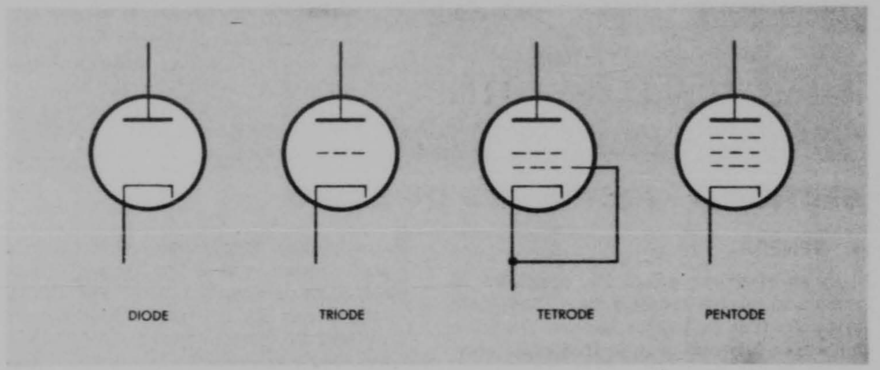

Figure 3-2 Physical Characteristics of Vacuum Tubes

the grid. The voltage impressed on this grid is more commonly known as "grid bias." Thus the triode can be used to vary and control a higher voltage and current in the anode circuit merely by a variation of a small amount of change in grid voltage.

Tetrode. The tetrode, or four element tube, had to be developed in order that the tube could be used to amplify signals at a high frequency. Because of the inter-electrode capacitance that exists in the triode between the plate and the grid, electron flow is impeded. The capacitive effect causes the tube to regenerate, that is, to feed back voltage into the grid circuit, causing oscillation. (Oscillation is considered later in this section.) The addition of another element, known as the **screen grid**, located between the control grid and the plate, reduces this feedback of voltage. A positive potential lower than that of the plate when impressed on the screen grid accomplishes this reduction.

Pentode. Some of the electrons on striking the anode bounce off and are attracted to the screen grid, causing current to flow in the screen grid circuit. Known as "secondary emissions," this reduces plate current flow. Consequently, another element known as the "suppressor grid" is placed between the screen grid and the plate. Since it is at the same potential as the cathode, it repels any electrons which bounce off the plate, but because of its construction, it permits the fast moving electrons emitted from the cathode to go directly to the plate with a minimum of retardation. The addition of this third grid produces a five-element tube called a pentode.

Beam Power Tube. The beam power tube, a form of tetrode, is also used in circuits where the secondary emission is reduced by designing the elements so that the electrons travel in sheets, rather than drifts. This high concentration of negative charge reduces the potential between plate and screen grid sufficiently to prevent the secondary emission.

Other Types. Other types of tubes are the photo-electric and cathode-ray tubes which are covered in detail elsewhere in this text.

Functions

Although the capabilities of vacuum tubes are being expanded more and more each day, below may be considered reasonably complete the possible uses of the tubes as described plete. These functions are:

Rectification: The ability of the vacuum tube to convert alternating currents to direct currents. This is a property possessed by all vacuum tubes since electron flow can only be in one direction, that is, from the negative source to the positive potential.

Amplification: The ability of the vacuum tube to control a large power or voltage with a small power or voltage. This is one of the most important uses of the vacuum tube.

Oscillation: The ability of the vacuum tube to generate high-frequency alternating currents. This is accomplished by permitting part of the tube output to "excite" itself and cause an alternating current to flow within the circuit.

Frequency conversion: The ability of the vacuum tube to receive different frequency inputs and to produce a totally different frequency output. By introducting various voltages of different frequencies to the elements, the resulting current flow can be a combination of or difference between the input frequencies.

Modulation: The ability of the tube to vary the frequency or amplitude of its output at an audio rate.

Detection: The ability of the tube to produce a current flow from a modulated wave which will conform to the original signal used to modulate the wave.

Other uses include the conversion of light energy to electrical energy, and vice versa. The former is accomplished by the photo-electric cell and the latter by the cathode-ray tube.

This consideration of the vacuum tube, brief as it is, should be sufficient to produce understanding of the general considerations of radio transmission and reception.

3. RADIO FREQUENCY GENERATION

Before transmission of intelligence by radio methods can be made, it is necessary to develop a carrier wave of radio frequency. The device that generates this carrier wave is known as an oscillator.

The Simple Oscillator

A simple oscillator circuit is shown in Figure 3-3. Assuming that switch S can be thrown to either position, when it is thrown left it connects capacitor C across the battery. Electrons will flow from the top plate to the bottom plate of the capacitor making the bottom plate negative. If the switch is then thrown to the right, the extra electrons which have gathered on the bottom plate will return to the top plate through inductor L thus creating a flow of current and a magnetic field around L. This action equalizes the electron charge which stops electron flow in the circuit. The magnetic field in collapsing induces a voltage across L due to self-induction. This new voltage aids the electron flow to the top plate and thereby causes more electrons to pile up on the upper plate. Current will then flow in the opposite direction, that is, from the top plate to the

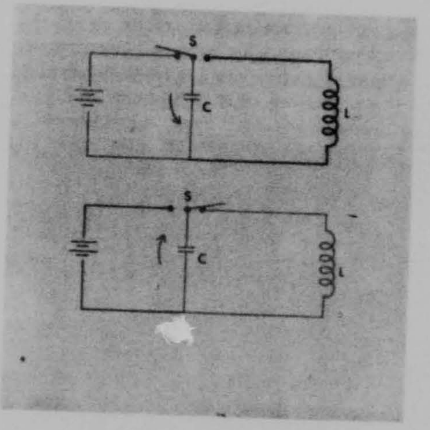

Figure 3-3 Simple Oscillator

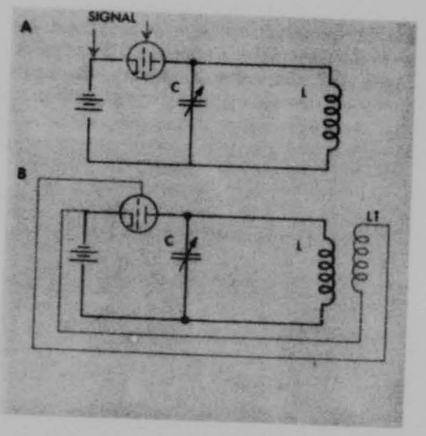

Figure 3-4 Simple Vacuum Tube Oscillator

bottom plate. Soon the bottom plate has an excess of electrons and current flow starts in the opposite direction. The rate at which this current will oscillate back and forth, or its frequency, will be determined by the values of L and C. The larger the values of L and C, the longer the time needed to charge C. This results in a low frequency.

Were it not for the resistance of the circuit these oscillations would continue indefinitely. However, the circuit resistance causes each succeeding oscillation to be of lesser amplitude with the result that eventually there is no current flow. In order to have further oscillation, it is necessary to turn the switch to the left to charge the capacitor and then to the right to start the chain of events again.

The frequency relationship is:

$$f = \frac{1}{2\pi\sqrt{LC}}$$

In our simple oscillator, we are faced with two problems: first, to overcome the circuit resistance and prevent damped oscillations or oscillations of decreasing value; the second, to supply new voltage to the circuit whenever the need arises.

The circuit resistance can be overcome by increasing the voltage through the circuit. (See Figure 3-4). In this circuit, a triode tube has been placed. The oscillation radio frequency in the coil-capacitor circuit causes a radio frequency voltage to be placed on the grid of the tube. Condensor C1 provides a path for the radio frequency. Resistor R serves to provide a bias for the grid and at the same time to provide a path for excess electrons which might pile up on the grid. The output of this tube is amplified. In order to sustain oscillations, it is necessary to return part of this output to the grid circuit. This is known as "feedback." By placing a coil in the plate circuit adjacent to the grid coil (see Figure 3-5), voltage is induced in the grid circuit from the plate circuit.

As discussed later in this section, certain tubes amplify in a different manner depending upon the method of putting voltage on the grid. In this oscillator (if the tube is so constructed that the electron flow is very great when no voltage is on the grid), the tube will start itself, for at the time the circuit is closed, electron flow must be established immediately before oscillation can be realized. It is apparent that the characteristics of the tube determine the oscillatory value of the circuit; if in any way the tube loses its amplification qualities the oscillations will not take place. It is imperative that the time consumed by the electrons in traveling from cathode to plate be considered when very-high and ultra-high frequencies are employed for the phase relationships within the tube itself are of such a nature that the effective power output of the tube is greatly reduced. In the triode oscillator then, it must be remembered that generally, high-powered tubes operate on low frequencies. An increase in the frequency of the circuit results in a lowering of power output.

The vacuum tube oscillator mentioned here is the tickler-coil type. While not used generally today, it illustrates the vacuum tube type of oscillation. Other types of oscillators are as follows:

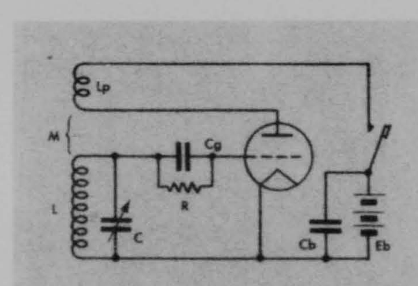

Figure 3-5 Tickler Coil Oscillator

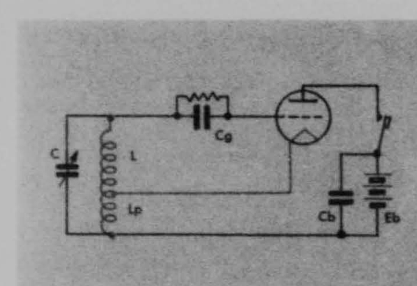

Figure 3-6 Hartley Oscillator

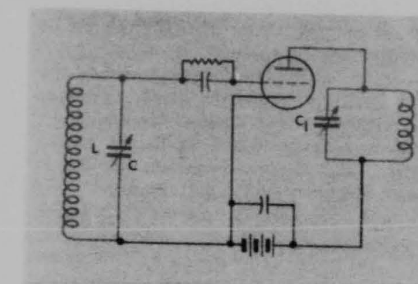

Figure 3-7 Tuned-Plate, Tuned-Grid Oscillator

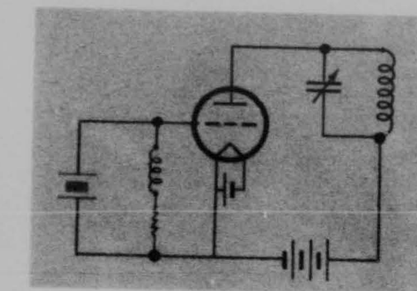

Figure 3-8 Crystal Oscillator

Hartley Oscillator. All oscillators are divided generally into types depending upon the method of feedback. The tickler-coil type accomplishes its replenishing of the circuit power by induction between the plate and grid coils. This method is widely used.

Another application of the induction method is found in the Hartley oscillator. It is to be noted (see Figure 3-6) that coil L in this case is two coils in one. The whole coil comprises the inductor part of the tank circuit while the bottom part is the feedback element, corresponding to the plate coil in the tickler-coil type. The values of L and C determine the frequency of the output signal. The key in this oscillator, as in all oscillators, is the manner of exciting the grid. In this oscillator, the grid receives its voltage through induction from coil L.

Tuned-Plate, Tuned-Grid Oscillator. Another type of oscillator depends upon the capacitance between the grid and the plate of the tube to couple the feedback to the tuned circuit. In Figure 3-7, an oscillator called the "tuned-plate, tuned-grid oscillator" is shown. There is an inherent capacitive effect in the triode tube which normally is reduced with a screen grid, however, at times the capacitance is utilized. This oscillator is a case in which the tube is so used. Here, the frequency of the circuit is established by the equal products of the L and C of the grid circuit and L_1 and C_1 of the plate circuit. The plate circuit is tuned to resonance; that is, it has the same frequency as the grid circuit. Coupling between the two is accomplished by the capacitive effect of the tube electrodes. In cases where the operating frequency of the oscillator is low, it is necessary to install a capacitor between the grid and the plate. Remembering that the capacity of the condenser is such that small capacitors work with high frequencies, it is apparent that lower frequency oscillations could not be accomplished with the tube capacitance alone because of the small size of the electrodes themselves.

Crystal Oscillator. Certain minerals possess the ability to convert mechanical stress into voltage values and conversely to produce mechanical motion when voltages are applied to them. In quartz, for instance, a mechanical stress applied to the crystal produces a dielectric stress between its outer surfaces. Application of electrical energy to the crystal produces a mechanical strain. This strain produces a dielectric stress or voltage across its face, producing a strain which in turn produces another voltage. The frequency of this action is determined by the thickness of the crystal. The mechanical and electrical actions of the crystal are self sustaining as long as there is an initial voltage potential established in the circuit.

This phenomenon permits the crystal to be used as an oscillator since it produces an alternating current of radio frequency. It serves as the oscillatory medium as well as the resonant circuit. In this case, feedback is accomplished in the tube itself, but the crystal serves to establish a frequency which will not vary as much as one set up with the conventional coil and condensor.

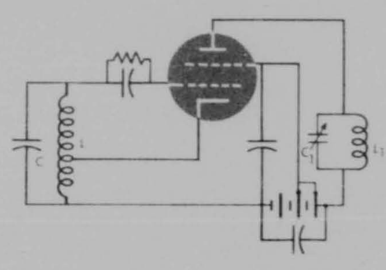

Figure 3-9 Electron-Coupled Oscillator

Electron-coupled Oscillator. Another oscillator using the tetrode likewise provides frequency stability. Oscillators by themselves are of no value unless they are coupled to a load or resistance. Just as an electric motor will slow down when a load is applied, so will an oscillator suffer frequency distortion when a load is applied unless proper coupling and shielding are employed.

In the electron-coupled oscillator, we have a combination oscillator and amplifier. The screen grid of the tetrode acts as a plate and with the cathode and grid acts as a triode. This "triode" serves as an oscillator. Electron flow within the tube varies according to the oscillations established by the resonant circuit. The tube output in the plate circuit is unimpeded. The structure of the screen grid is such that electron flow is controlled at a rate determined by the oscillatory action that takes place in the triode section of the tube.

Since the output is taken off across the tuned circuit (C_1 and L_1) coupling takes place within the tube itself. Since the screen grid serves to shield the oscillatory circuit from the load circuit, frequency stability is good in electron-coupled oscillators.

4. AMPLIFICATION

General

It has been stated previously that the outstanding ability of the vacuum tube is amplification. This term (amplification) is misused in a sense, for the vacuum tube does not take a small voltage and make it a larger one, but, instead, controls a high potential and current with a very small voltage impressed on the grid. The use of the term "valve" instead of amplifier would be more correct.

Since the grid voltage is a key factor in determining the amplification value of a tube, amplification types are categorized according to the method of biasing the grid. To illustrate the relationship between grid voltage, or bias, and plate current, graphs are used, showing the characteristic curve of the tube in question. The point along this curve at which the grid is biased, generally determines the class of amplification. These classes of amplification follow.

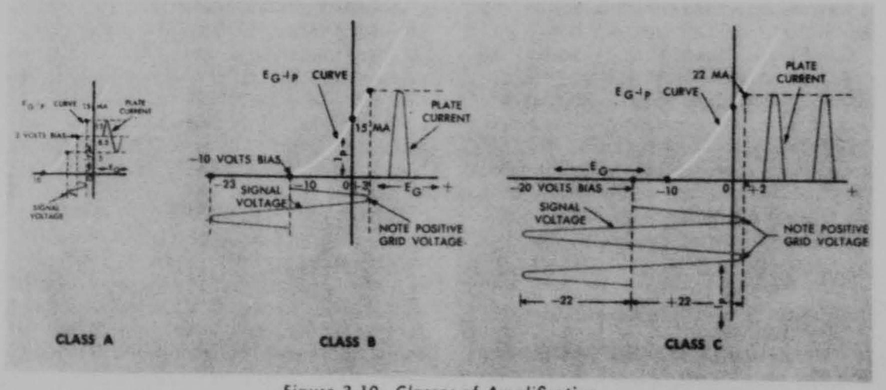

Figure 3-10 Classes of Amplification

Class A Amplifiers

All amplifiers which operate on the straight or linear portion of the plate current-grid voltage curve are known as "class A" amplifiers. These will give voltage amplification with high fidelity, that is, the input signal and the output signal are identical. The efficiency of this tube is low in that it draws plate current at all times. This amplifier is used extensively in those cases where fidelity of signal is paramount. It is occasionally used as a power amplifier.

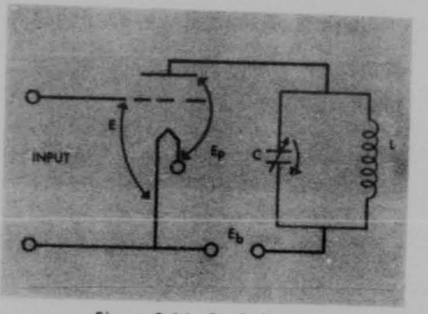

Figure 3-11 Tank Circuit

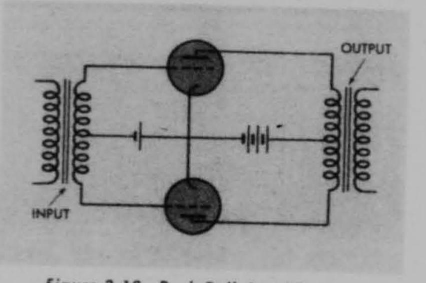

Figure 3-12 Push-Pull Amplification

Class B Amplifiers

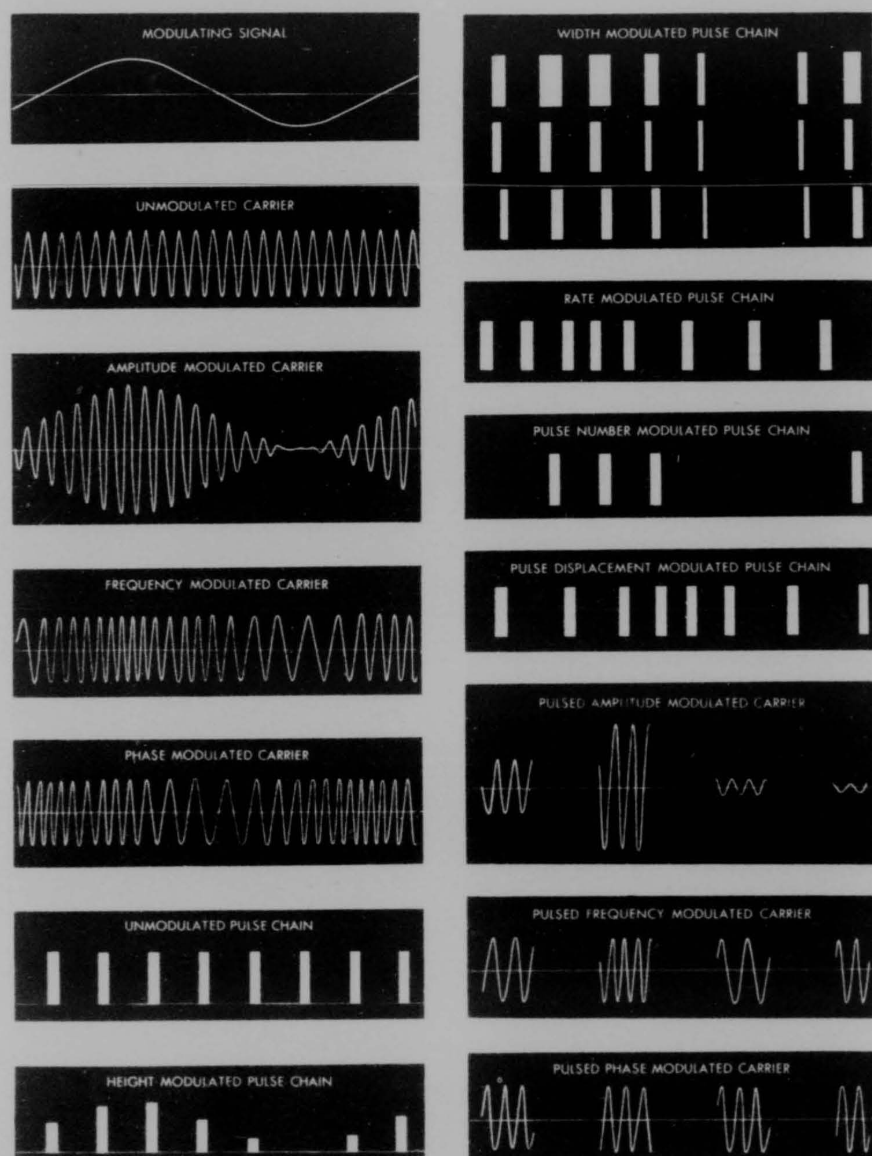
All amplifiers which operate on the lower portion of the characteristic curve of the tube are known as "class B" amplifiers. The grid is biased so that plate current flows only during the times when the grid or signal voltage is positive. The point at which the grid stops current flow in the plate circuit is known as the cutoff point. Class B amplifiers operate at cutoff permitting high efficiency to be realized since the plate is drawing current only half the time. Because of the fact that the plate current flows only half the time, the output signal is not symmetrical with the input signal. In radio transmitters, the class B amplifier can be used provided an oscillatory or tank circuit is used. (See Figure 3-11.) In this case, when the period in which the positive signal peaks are impressed on the grid, the potential across the filament and the plate causes a voltage to be applied to the tank circuit LC since it parallels the filament and plate. As soon as the positive peak of the plate current falls off, the condensor discharges through L (as shown by the arrow) and charges the other plate of the condensor. During this period no plate current is flowing as the input grid current is negative. Because of the electrical inertia of the charge built up in the tank circuit, current will flow in an opposite direction, completing the cutoff cycle. This is known as the "flywheel" effect. Thus the class B amplifier can be used in transmitting circuits without a loss of signal fidelity. Since the flywheel action supplies this necessary correction of the wave shape, class B amplifiers cannot be used in receiver circuits since the tank circuit is not employed. However, by using two tubes in parallel, the flow of current will be constant. So, in receiver systems, class B amplifiers can be used only in tandem or push-pull. (See Figure 3-12.)

Class C Amplifiers

All amplifiers which operate below the cutoff point are known as class "C" amplifiers. These amplifiers operate only on the high positive peaks of the grid potential. (See Figure 3-10.) Class C amplifiers are used only in transmitters having very high power efficiency but low power amplification, because the plate current flows but a small portion of the time.

5. MODULATION

Radio frequency waves are capable of carrying intelligence provided some method is employed to impress the intelligence upon the wave. The method is known as modulation. Discussion in this text will be limited to amplitude modulation (AM), frequency



modulation (FM), and pulse-time modulation since these are the principal types employed by the USAF. Modulation has been defined as the "process of producing a wave, some characteristics of which vary as a function of the instantaneous value of another wave, called the modulating wave."

Probably one of the most familiar cases of modulation is that of the carbon granule microphone employed in the telephone. The pressure of the sound waves against the diaphragm causes the resistance of the carbon granules to vary with time.

Amplitude Modulation

Amplitude modulation may be defined as the variation of the strength of the RF output of a transmitter at an audio rate (Figure 3-13). The RF energy has to increase and decrease in power according to the audio frequencies. If the audio frequency is high, the radio frequency must vary in amplitude mere rapidly than if the audio frequency were low. If the audio note is loud in volume, the radio frequency energy must increase and decrease by a larger percentage than if the audio note were soft. Thus, the RF variations must correspond in every respect with the audio frequency (AF) variations.

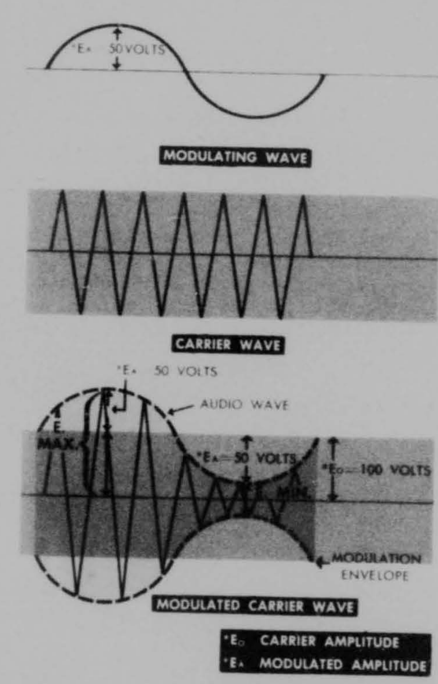


Figure 3-13 Amplitude Modulation

Carrier Requirements. The carrier frequency is the radio frequency upon which the modulating signal is impressed. For proper amplitude modulation, the carrier should be completely free from inherent amplitude variations such as might be caused by insufficient filtering of the power supplies and should be a pure sine wave of the desired frequency. Furthermore, it is essential that the carrier frequency be entirely unaffected by the application of the modulation frequency. In other words, the frequency of the carrier wave must not change when a modulating wave is applied.

Percentage of Modulation. The degree of modulation is expressed by the percentage of maximum amplitude deviation from the normal value of RF carrier. The effect of a modulated wave, as measured by receiver response, is proportional to the degree of percentage of modulation.

The percentage of variation of the total voltage of the final RF amplifier stage will depend upon the ratio of AF to the DC voltage. For example, if the DC plate voltage of the RF amplifier is 100 volts and the AF voltage is 50 volts, the two voltages will add (when they are of the same polarity) to give 150 volts. They will subtract (when they are of opposite polarity) to give 50 volts (Figure 3-13). The plate voltage of the RF amplifier will vary between 50 and 150 volts. Since the variation (50 volts on either side of the DC voltage) is one-half of the DC voltage of 100 volts, the transmitter is said to be modulated 50 per cent. The mathematical expression for degree of modulation is:

$$m = \frac{E_{max} - E_o}{E_o} \times 100 \text{ or } \frac{E_o - E_{min}}{E_o} \times 100$$

where m = per cent of modulation

E_o = Carrier Amplitude.

Thus percentage or degree of modulation may be defined as the percentage of variation of the modulated wave compared with the unmodulated wave.

It is important that the amplitude of the carrier wave be varied as much as possible because the output of a detector in a radio receiver varies with the amplitude variations of the received signal. This is why a comparatively low power station, well modulated, will often produce a stronger signal at a given point than a more powerful, but poorly modulated station located the same distance from the receiver. However, the maximum limit of modulation is 100 per cent.

Power in the Modulated Wave. Since power varies with the square of either the current or voltage (if the value of the resistance in the circuit remains constant), the instantaneous peak power of a 100 per cent modulated wave is four times that of the unmodulated carrier power. With a sine wave modulating signal, the average power of a 100 per cent modulated carrier wave is one and one-half times the unmodulated carrier power; that is, the power output of the transmitter increases 50 per cent with 100 per cent modulation.

Linearity. The amplitude of the carrier should follow faithfully the amplitude variations of the modulating signal up to the limit of 100 per cent modulation. When the modulated RF amplifier is incapable of quadrupling its power output at the peak of 100 per cent, modulation will cause distortion of the modulation envelope. A graph showing the relationship between the RF amplitude and the instantaneous modulating voltage is called the modulation characteristics. This graph should be a straight line between the limits of zero and twice the carrier amplitude. Curvature of the line between these limits indicates nonlinearity in the amplifier.

Modulation Capability. The modulation capability of a transmitter is the maximum percentage of modulation possible without objectionable distortion due to nonlinearity. The modulation capability should be as high as possible so that the most effective signal can be transmitted for a given carrier power. The maximum modulation capability is 100 per cent.

Over modulation. The carrier wave should never be modulated over 100 percent since this produces undesirable distortion in the transmitted signal. In the case of over 100 per cent modulation, the peak amplitude exceeds twice that of the carrier wave. This demands that the RF amplifier be capable of supplying more than four times the normal carrier power at rest and then will be completely shut off for other periods of time. The result is the appearance of the harmonics in the modulating signal.

Sidebands. (Figure 3-14). The modulated wave is a combination of several frequencies. A mathematical analysis is required in order to determine the frequencies present in the wave. As a practical example, if the RF carrier is 100 kilocycles and the audio frequency is 1,000 cycles or 1 kilocycle, the wave will contain the following frequencies:

Fundamental frequencies:	100 kc—1 kc
Second harmonic:	200 kc—2 kc
Sum frequency:	101 kc
Difference frequency:	99 kc

Harmonics other than the second are produced, but they are weak and easily dispensed. All these frequencies are present in the plate circuit of the final RF amplifier. The plate circuit is broadly tuned to 100 kilocycles so that only frequencies of 99, 100 and 101 kilocycles will be transferred to the antenna through the antenna coupling circuit. The remaining frequencies, such as the second and third harmonics, will be bypassed. Thus, instead of transmitting only one frequency, the antenna is transmitting three frequencies very close together.

These additional frequencies are known as "sideband frequencies," or "sidebands." These sidebands are separated from the carrier frequency by the amount of the audio

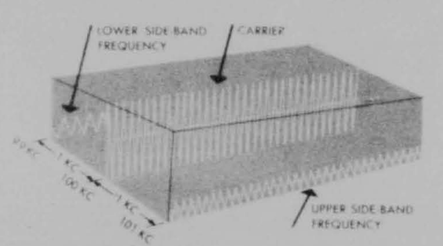

Figure 3-14 Carrier Wave and Side-Band Frequencies

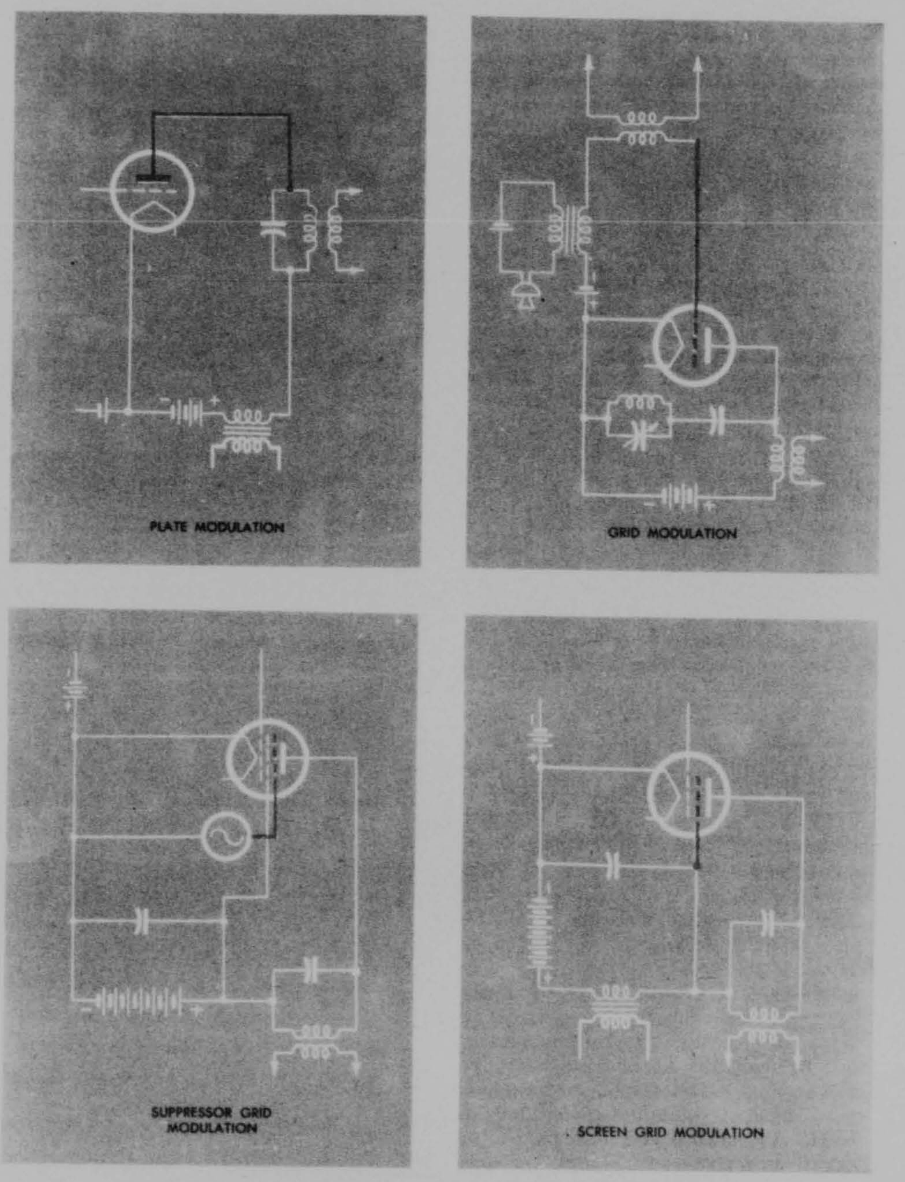

Figure 3-15 Methods of Amplitude Modulation

frequency. Thus, if the audio frequency had been 2 kc, the sidebands would have been 98 and 102 kilocycles. The higher the audio frequency the farther both sidebands will be from the carrier.

In actual speech, many audio frequencies are used to modulate the carrier wave. There will be a pair of frequencies (one upper and one lower) for each frequency present in the speech. The speech modulation will be made up of an entire band or group of frequencies.

The RF carrier varies in appearance only when it is being modulated. With zero modulation there are no sidebands. The additional power in a modulated carrier wave is supplied by the modulator and appears in the sidebands.

Methods of Amplitude Modulation. (Figure 3-15) There are various methods of amplitude modulation. The most common one is known as "plate modulation". In this method the AF modulating voltage is applied to the plate of the RF amplifier and causes the carrier output to vary in accordance with the audio frequency. Application of the AF voltage to the control grid of the RF amplifier is known as grid modulation or grid-bias modulation. Suppressor grid modulation is obtained by applying the audio frequency to the suppressor grid of a pentode power amplifier. Screen grid modulation may be accomplished by the use of a tetrode. Cathode modulation, in which the audio frequency is applied to the cathode circuit, is a combination of plate and grid modulation.

Plate modulation of the final RF stage of a radiotelephone transmitter is known as high-level modulation, since the modulation takes place at the highest power level of the system. If the modulation takes place in an intermediate stage with one or more high power amplifiers following, it is known as "low-level modulation." In low-level modulation, RF amplifiers which follow the modulated stage are operated as linear amplifiers, that is, their AC output voltage faithfully reproduce the applied grid voltages without distortion. In high-level modulation, the final RF power amplifier is always operated as a class C amplifier.

Frequency Modulation

Frequency modulation may be defined as "the variation of the frequency of the RF output of a transmitter by an audio signal" (Figure 3-16). The unmodulated frequency is called the "rest frequency." When a carrier wave is frequency modulated, the strength of the carrier wave is not varied but its frequency is changed or shifted from its rest frequency. This shift, known as "deviation," is proportional to the strength of the modulating signals. The rate at which the carrier frequency is varied is determined by the frequency of the modulating signal. The changes in frequency of the transmitter takes place within certain specified limits in accordance with the intelligence to be transmitted.

In military practice, the maximum deviation allowed for any channel is 40 kilocycles. This means that the strongest audio signal which can be used is limited to that value which will cause a maximum deviation of 40 kilocycles either side of the resting frequency. Weaker signals will vary the frequency by an amount less than 40 kilocycles. A total of 80 kilocycles, known as the "carrier swing," is available to each station for

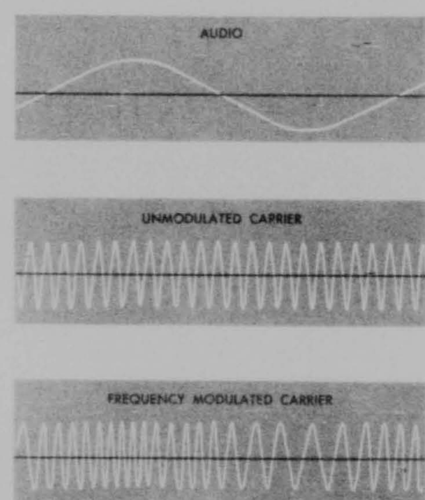

Figure 3-16 Frequency Modulation

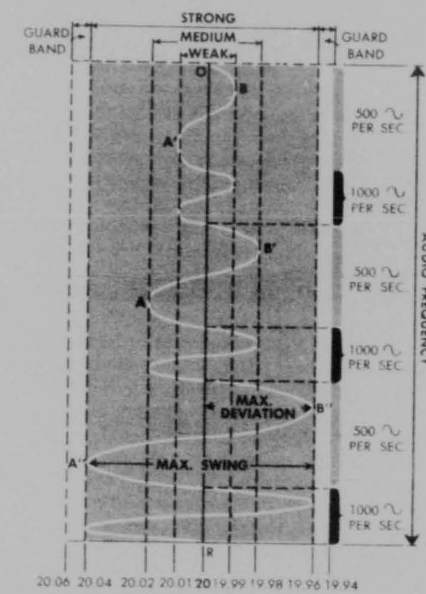

Figure 3-17 Graphic Review of Principles of Frequency Modulation

frequency variation during transmission. A band of 20 kilocycles is allowed for separation purposes between channels. This is known as the "guard band." Thus, the channel allotted to each station consists of two deviation ranges of 40 kilocycles each, plus half the guard band on either side, or a total of 100 kilocycles.

Linearity. A transmitter in which frequency deviation is directly proportional to the amplitude of the modulating signal is said to be "linear." It is essential also that the carrier amplitude remain constant under modulation, which in turn requires that the transmitter tuned circuits, as well as the antenna, have a broad enough response to handle audio frequencies without discrimination on the entire range transmitted. Normally, this requirement is easily met.

Sidebands. A circuit which is designed to produce a frequency modulated deviation of 40 kilocycles, may produce signals differing from the rest frequency by much greater amounts than the deviation. This is because in addition to the normal sidebands existing in amplitude modulated circuits, other sidebands differing from the rest frequency by multiples of 2, 3, 4, etc., of the modulation frequency exist. The spread of these frequencies becomes greater when the high modulation frequencies required in carrier telephone transmissions are considered. This characteristic is inherent in the circuit. The strength of the emissions on frequencies beyond the normal deviation, in general, do not decrease in strength in a manner directly proportional to the separation from the rest frequency. In some cases the strength of these emissions on a frequency greatly different from the rest frequency may be considerably stronger than the emissions on a frequency reasonably close to the frequency of maximum deviation. The mathematical solution of these emissions is beyond the scope of this text. These sideband frequencies may cause interference on other radio channels which are considerably removed in frequency from that of the offending transmitter. This is especially true if an excessively large modulation index is employed.

The modulation index may be likened to the percentage of modulation which is applied to amplitude modulated signals even though it is quite different in character. For the purposes of this text, it will be defined as the "ratio of the deviation, in relation to the frequency of the modulating signal." Figure 3-18 illustrates the signal strength that may exist on the various frequencies for several modulation indexes. It is apparent that the interference caused by a frequency-modulated transmitter on channels considerably different from its primary channel of transmission may be considerably reduced by a good choice of the range of modulation indexes which are to be employed in the transmitter. Regardless of this choice, however, the transmitter will not be free of higher order side frequency radiations. The following notes pertain to Figure 3-18.

Modulation frequency .... 10 kcs
Design deviation .... 40 kcs

Under these conditions side currents of still higher order exist but their intensities

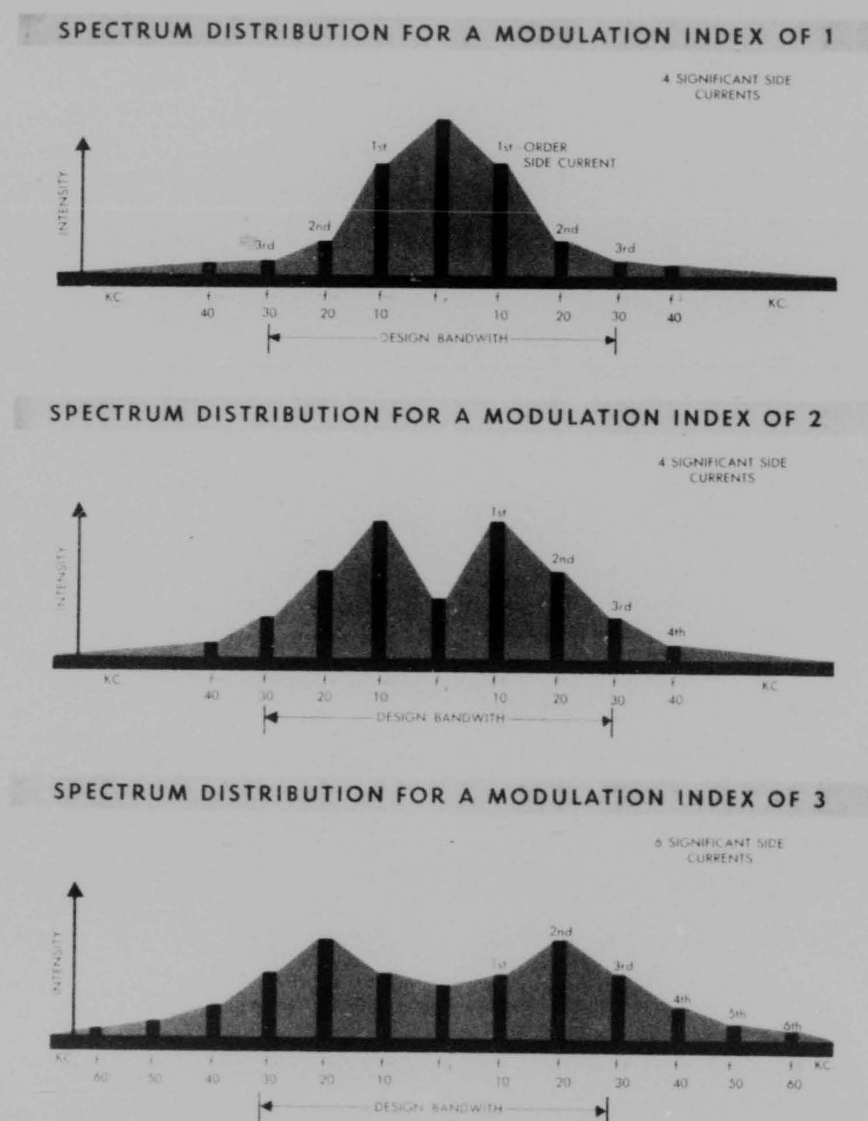

Figure 3-18 Spectrum Distribution for Modulation Indices

are too small to make a graphic comparison possible. However, these additional currents may cause transmitter-to-receiver interference when they are in close proximity.

When two or more modulation frequencies are employed (as is true, in general), additional side currents exist. Some of these currents have frequencies different from the rest frequency by greater amounts than those indicated.

Reactance-tube and Phase Modulation. A successful FM transmitter must fulfill two important requirements. The frequency deviation must be symmetrical about a fixed frequency, and the deviation must be directly proportional to the amplitude of the modulation and independent of the modulation frequency. See Figure 3-18. There are several methods of frequency modulation which fulfill these requirements. The two important types of frequency modulation used in military FM radio equipment are known as the "reactance-tube modulating system" and the "Armstrong phase-modulating system." The main difference between these two systems is that in the reactance-tube modulation method the RF wave is modulated at its source (the oscillator), while in phase modulation the RF wave is modulated in some stage following the oscillator. The results of these two systems are the same; that is, the FM wave created by either system can be received by the same receiver. The reactance-tube modulation system cannot be crystal-controlled as can the Armstrong phase-modulation system.

When it is desired to operate a transmitter with crystal control in frequency-modulation systems, it must be remembered that we will be operating in the very-high-frequency band, or higher. The oscillator in these units must be capable of delivering a signal of sufficient strength to excite the amplifiers used in the output stages. These high powers are injurious to crystals of the size required for very-high-frequency operation. Consequently crystals of the proper size can be used only if a small power output is required. For this reason, when large power output is required and high frequencies are used with crystal control, it is necessary to use thicker crystals which operate at lower frequencies. The output frequency must be increased before it is fed to the power amplifier.

Because certain amplifiers possess distortion characteristics, it is possible to utilize these characteristics since such systems are rich in harmonics. By adjusting the grid bias so that the plate distortion is high, it is possible to achieve the desired frequency increase and at the same time have the fundamental frequency crystal-controlled.

Reactance-tube Modulators. Frequency modulation in reactance-tube circuits is accomplished by utilizing the fact that a tube possesses inherent capacitance. (See Figure 3-19). Tube T2 is shunted across the oscil-

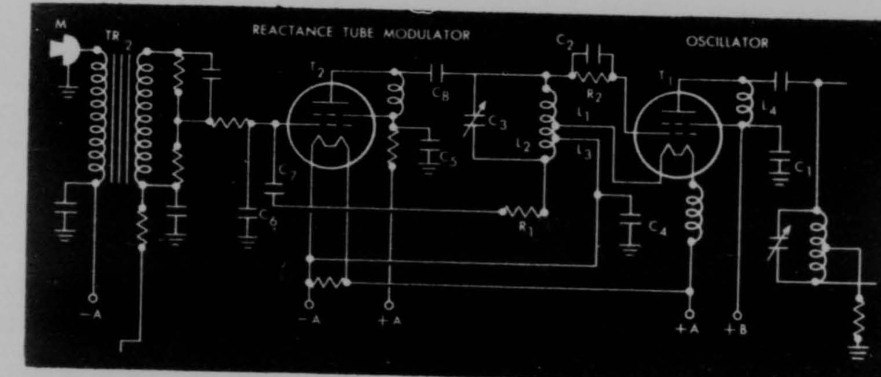

Figure 3-19 Reactance-Tube Modulator

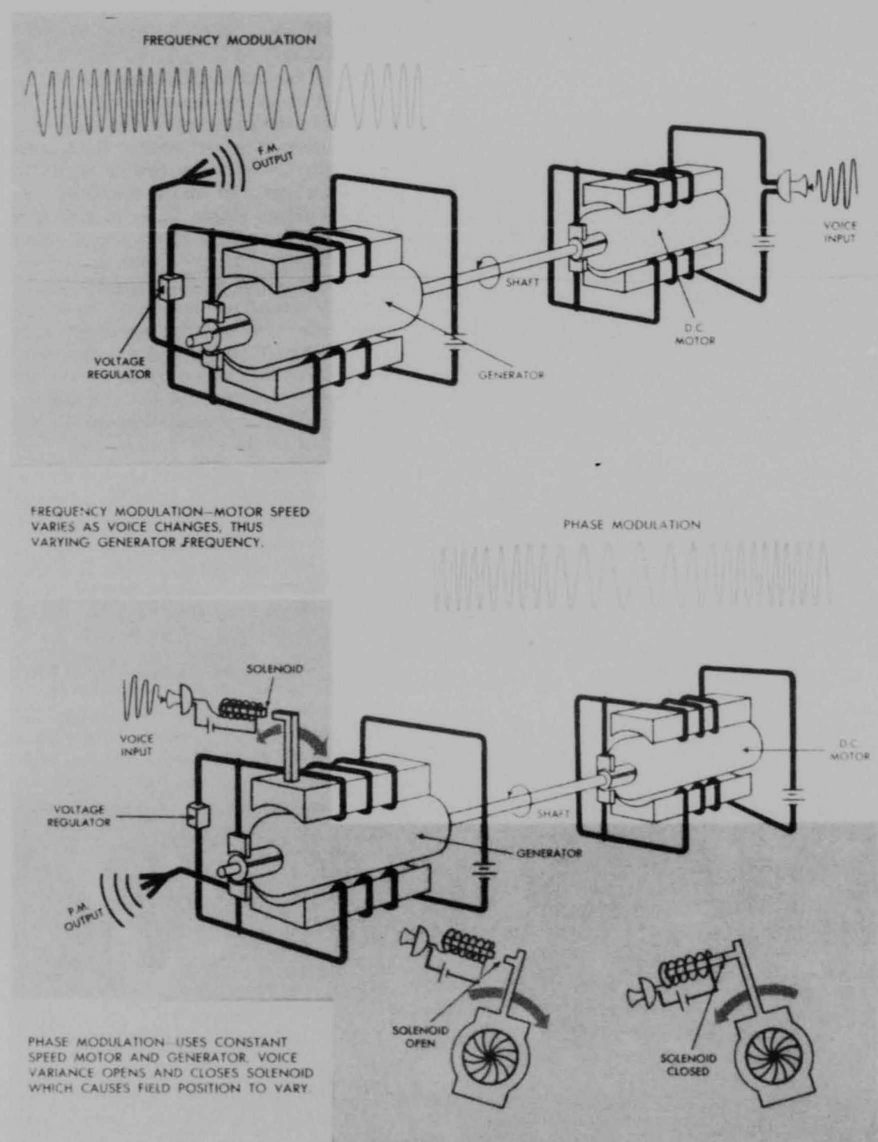

Figure 3-20 Comparison of Principles of FM and PM

lator tank through C8 and the filament circuit and is then made to act as a capacitor. By varying the amount of current flowing through this tube, its capacitive effect across the oscillator can also be varied. The audio-frequency voltage produced by microphone M is coupled through the transformer to the grid of the reactance tube T2. Thus the current through the tube will vary at an audio frequency and the capacitive effect of the tube will vary. This in turn varies the frequency of the oscillator.

Phase Modulators. To understand phase modulation, a form of frequency modulation, a brief review of coil saturation is needed since the principle involves the reactance of an inductance. When current flows through a coil, a magneto-motive force is set up about

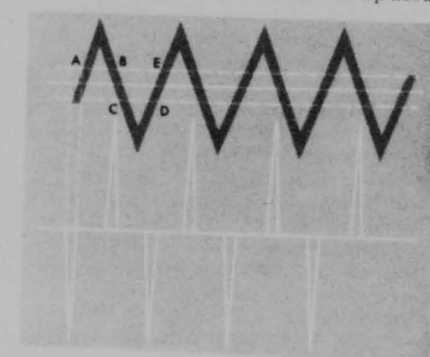

Figure 3-21 Voltage Pulses in Non-Linear Modulator Coil

the coil which varies according to the amount of current flowing through the coil. This magnetomotive force can be compared to voltage. This force sets up a flux about the coil which can be compared to current. The density of this flux depends upon the reluctance (comparable to resistance) of the core of the coil. Coils which have an air core have a reluctance that does not vary with current. Coils having a core of magnetic material will have a reluctance that varies with the current. In air core coils the flux density increases with current flow. In the other type of core, the flux density will increase to a certain point with current increase but beyond that point there is no further increase. If a core is made up of some material which gives a rapid rise in flux with a small change in current, its performance curve is non-linear. This accounts for the name "non-linear reactance coil." A sine wave voltage is applied across such a coil (See Figure 3-21) and as the current through the coil increases from zero to some value such as A, there is a rapid building up of flux as the core is saturated. As the current increases through its maximum to point B there is no further increase in flux. As it decreases through B to zero, there is a rapid change of flux but in the opposite direction. This forms voltage pulses which are 90° after the current peaks. From these voltage pulses, we will have average current values which will have a phase which varies according to the input signal. Such a coil (See Figure 3-21) operates in a circuit as follows:

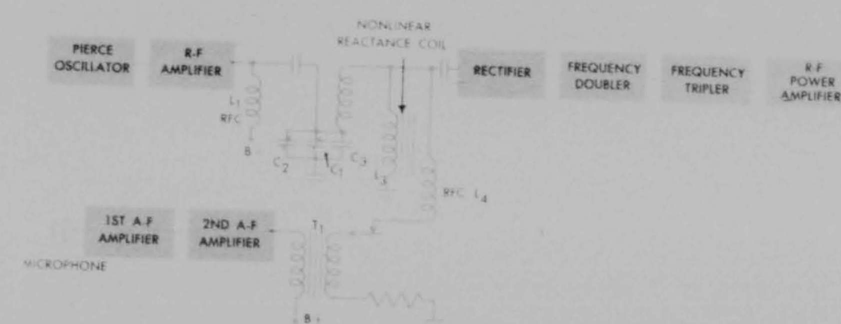

Figure 3-22 Circuit Diagram of FM Transmitter

THIS PAGE IS DECLASSIFIED IAW EO 13526

Amplifier is fed through coil L1. The frequency of the plate circuit is determined by coils L2 and L3 in series and C1 and C2. C3 is a temperature compensating device. Part of the RF voltage will be developed across L2 and part across L3. In addition to the input RF, the output of the audio section is applied through the RF choke L4 and grounded across L3 which is the non-linear reactance coil. Modulation of the RF is thus accomplished.

Pulse-time Modulation

Pulse-time modulation radio equipment currently employed by the Air Force, is designed for use as a radio link in a wire communications network which may consist of sections of wire lines, carrier telephone or telegraph systems. The set is composed of a pulse-modulated, microwave radio transmitter and receiver with facilities for providing eight two-way voice frequency channels over an unobstructed line-of-sight path. The radio sets are used in pairs, one being located at each end of the line-of-sight path. The average working range of the radio link is from twenty-five to fifty miles, depending upon the characteristics of the intervening terrain and the effective antenna height. Longer radio circuits may be set up by placing the sets in tandem as relay stations.

The conventional radio communications equipment transmits a continuous signal which is a faithful instantaneous reproduction of the audio frequencies superimposed on the carrier frequency. However, in pulse-time modulated radio sets, this is no longer the situation. The pulse-time radio system of communication samples the audio frequencies to be sent and then transmits only these samples. It readily may be seen that the major difference between the conventional radio system and pulse-time modulation system is in the amount of intelligence transmitted.

The receiver in the pulse-time modulation system sorts the received signals into the proper channel and then from the samples of the received signal reconstructs the original intelligence.

Method of Modulation. Existing military pulse-time modulated radio sets are capable of transmitting and receiving eight simultaneous voice channels by means of a single radio frequency (RF) carrier which is transmitted in pulses or short bursts of radio frequency energy. To explain the process by which a pulsed RF carrier may be modulated by one or more audio frequency channels, let us examine the functioning of a typical radio set—in this case the AN TRC-6.

In the time division multiplex, each channel to be transmitted is connected to the line in rapid succession either electronically or by means of a rotating commutator, thus the multichannel signal is composed of interlaced samples of the several channels being transmitted. A large number of these samples are transmitted per unit of time to permit reconstruction of the original signals at the receiver apparatus, where they are separated by another electronic or mechanical commutator synchronized with that at the transmitter.

When no modulation is present in any of the eight voice channels, the transmitted carrier wave is as shown in Figure 3-24. A 2-microsecond synchronizing pulse is followed by eight channel pulses, each of 0-4 microsecond duration, the first of which occurs approximately 6-microseconds after the synchronizing pulse with the remaining seven channel pulses following at approximately 12-microsecond intervals. The next synchronizing pulse occurs approximately 6-microseconds after the eight channel pulses. One synchronizing pulse and eight channel pulses constitute a frame or cycle, which has a duration of 100-microseconds. Ten thousand frames are transmitted per second.

The transmitter fires during the 2-microsecond interval of the synchronizing pulse, then rests, storing up energy until the proper time for a channel pulse to be transmitted. With no modulation signal present, each of the eight channel pulses recurs in the exact center of the 10-microsecond time interval allotted to that particular channel, as indicated by the dotted lines in Figure 3-24.

The process of superimposing voice frequencies on any type of radio frequency carrier is known as modulation. In the pulse-time modulation, the voice frequencies are applied to any single channel and varies the time of occurrence of the channel pulse, with

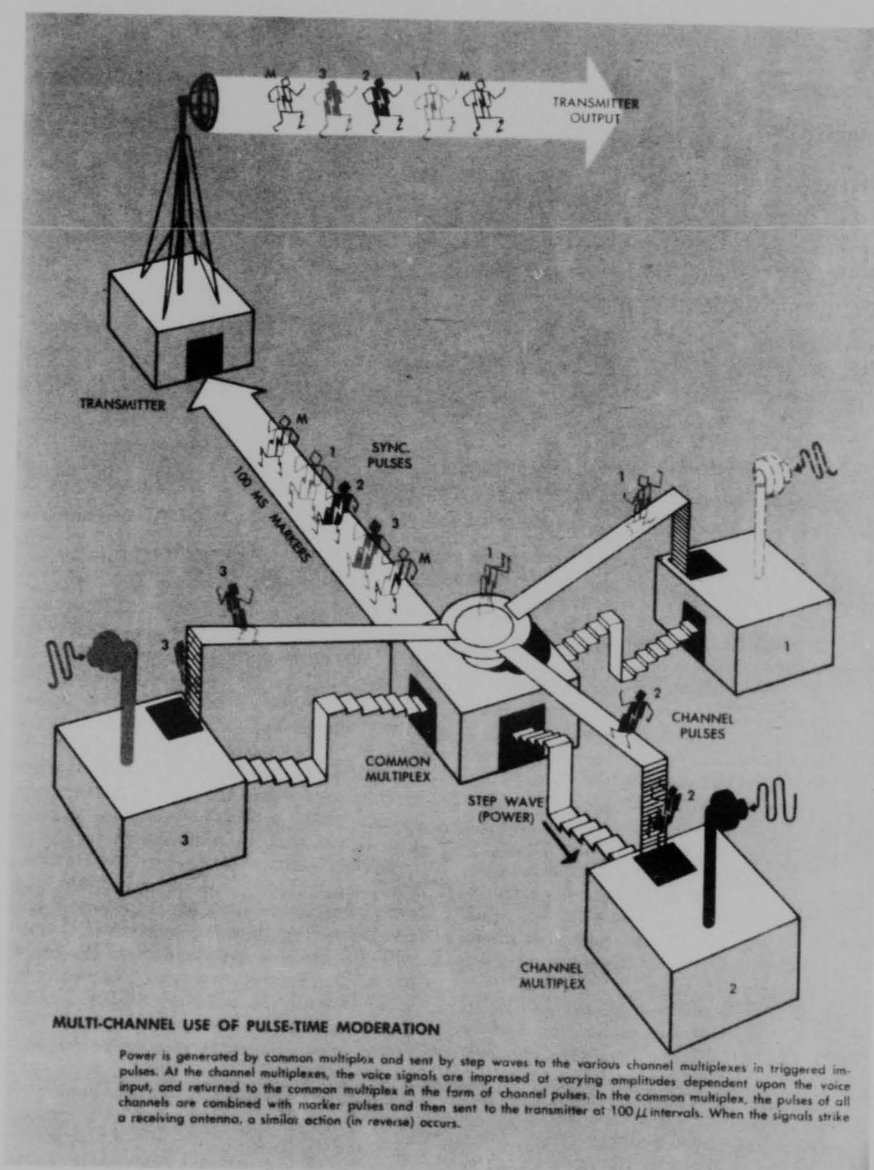

Figure 3-23 Pulse-Time Modulation

THIS PAGE IS DECLASSIFIED IAW EO 13526

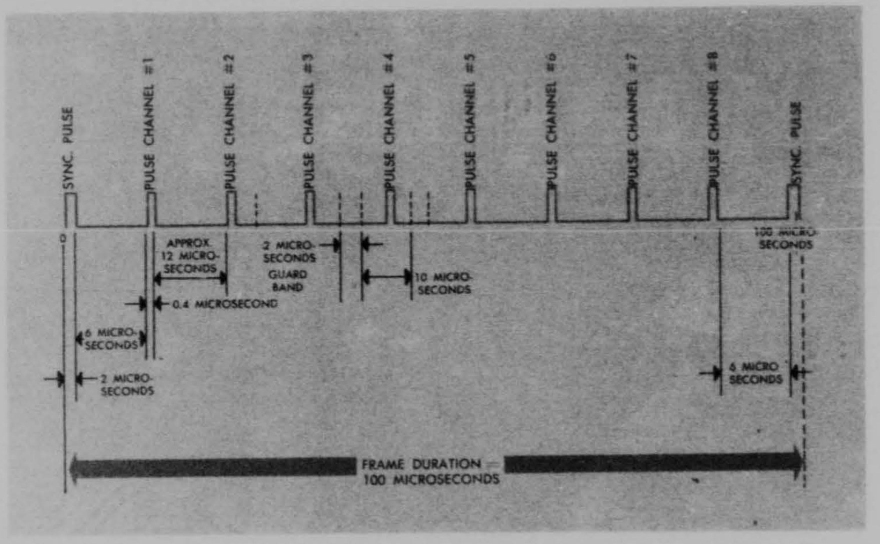

Figure 3-24 Graphic Representation of Pulse-Time Modulated Carrier Wave — No Modulation Present

respect to its unmodulated or rest position. The maximum deviation of the channel pulse from its rest position is plus or minus 5 microseconds. The extent of the deviation depends upon the instantaneous amplitude and polarity of the modulating signal, hence the term pulse-time modulation.

It is noted that the channel period is about 10-microseconds while the interval between channel pulses is approximately 12-micro-seconds. The 2-microseconds interval between the channels is a guard band which serves to separate the channels and reduce the possibility of interchannel crosstalk that might be caused by excursions of a channel pulse into an adjacent channel.

Figure 3-25 is a graphical representation of audio-frequency modulation applied to channels 2, 4, and 6, the remaining channels being unmodulated. The relative positions of the nine pulses which occur in channel 2 during one cycle of a 1,250 cycle per second sine wave are illustrated. Further consideration of channel 2 indicates that pulse A occurs at a time when the modulating signal has neither amplitude nor polarity; hence it is centered in the 10-microsecond channel. Pulse B approximately 100-microseconds later is retarded 0.707 x 5 microseconds, corresponding to the amplitude of the wave at 45 electrical degrees. Pulse C samples the peak amplitude of the wave and is retarded 5-micro-seconds. Pulses F, G, and H are advanced in time indicating that the polarity of the modulating signal has reversed. Channels 4, and 6 may be analyzed in a like manner.

Demodulation. At the receiver the synchronizing pulse is separated from the channel pulses and is utilized to generate eight 10-microsecond gates, synchronized in time with the channel assignments at the transmitter. Each gate is connected to the input of a different channel demodulator, so that the channel is operative only during the expected time of arrival of a pulse for that channel.

After being separated in this manner, the position-modulated pulses for each channel are converted to width-modulated pulses, from which the original modulating signal may be recovered quite easily by means of appropriate low-pass filters. This conversion

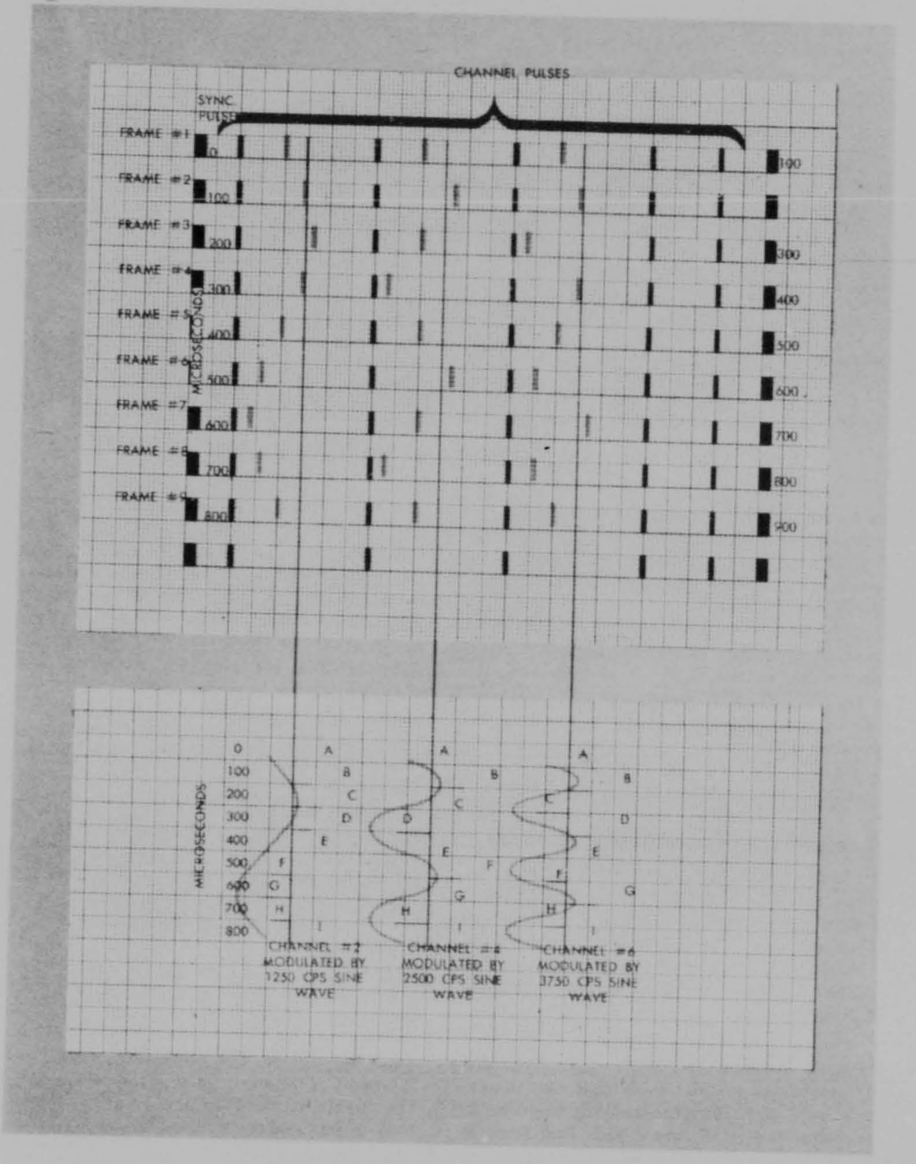

Figure 3-25 Graphic Representation of Pulse-Time Modulation

THIS PAGE IS DECLASSIFIED IAW EO 13526

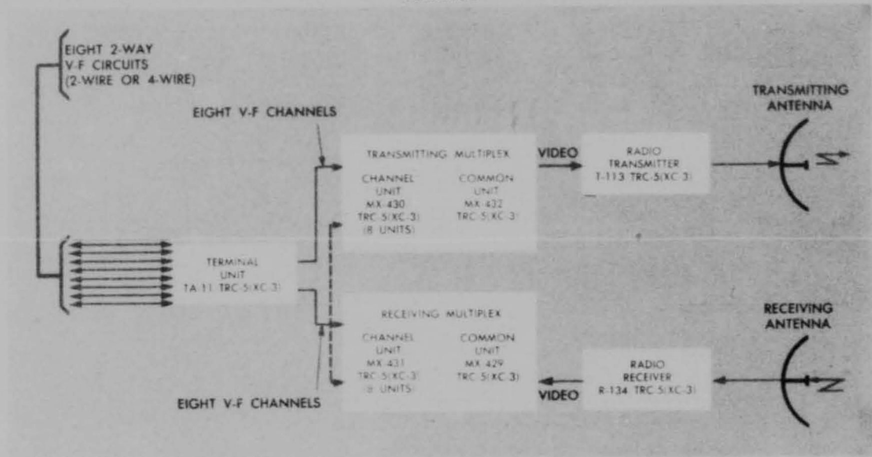

Figure 3-26 Block Diagram of Pulse-Time Modulated Radio Set

is accomplished by using the opening of the channel gate to trigger a flip-flop multivibrator which then conducts and continues to conduct until the incoming pulse arrives. Since the pulses may arrive at any time during the 10-microsecond interval that the gate is open, the pulses passed by the local circuit may vary in length from 10-microseconds when the pulse arrives 5-microseconds late to only 1-microsecond when the pulse occurs 5-microseconds early.

Figure 3-26 is a block diagram of a typical pulse-time modulated radio set.

Comparison of Modulation Methods

Each of the various types of modulation discussed in the text has certain advantages and disadvantages. It is impossible to say that any one type is the "best" since it is necessary to consider the employment of the radio frequency spectrum in which the set will operate.

Figure 3-27 briefly compares the three types of modulation. The principle advantage of amplitude modulation is that only a narrow band of radio frequencies is required to transmit the intelligence. This fact alone is sufficient to cause its use in the lower frequency bands where space in the radio spectrum is at a premium. Frequency modulation and pulse-time modulation require such wide frequency bands for the transmission of intelligence that they waste large portions of the radio frequency spectrum in the lower bands. Therefore, they are confined to the higher bands where there is less congestion in the spectrum. Frequency modulation permits the final RF amplifier to be operated always at its rated power output and is more efficient since no additional power is required when the radio is modulated. However, the final amplifier in an amplitude-modulated radio is less efficient since it operates at only one-fourth rated power output when unmodulated. It operates at full power output only when modulated to 100 per cent. At all other times, it is of some value between these two extremes.

Static either natural or man-made is a source of disturbance in any radio. Static, in general, is amplitude-modulated and contains few, if any, components of frequency modulation. Static is generally more intense at the lower radio frequencies and decreases quite rapidly as the radio frequencies are increased. Frequency modulation will reduce the effects of static to a very great degree, but, unfortunately cannot be employed in the lower frequencies, where the effects of static are most noticeable due to the wide band widths required for transmission. Since

COMPARISON OF MODULATION METHODS

	AMPLITUDE MODULATION	FREQUENCY MODULATION	PULSE-TIME MODULATION
SIGNAL LEVEL FROM TRANSMITTER.	Varies with modulation level.	Remains constant during modulation.	Remains constant during pulses.
AMPLITUDE OF MODULATING VOLTAGE.	Determines instantaneous change in signal level. Stronger the audio signal, greater the instantaneous change in carrier level.	Determines instantaneous deviation in frequency from resting carrier frequency. Stronger audio signal, greater frequency deviation.	Determines instantaneous deviation in time of channel pulse from rest position. Stronger audio signal, greater time deviation.
MODULATING VOLTAGE FREQUENCY.	Determines rate of change of amplitude of r-f wave.	Determines rate at which carrier frequency changes between high and low values.	Determines number of samples transmitted for each cycle of modulating voltage.
SIDE BANDS TRANSMITTED.	Width of transmitted side bands determined by frequency of modulating voltage. Present general limit plus and minus 5 kc each side of the carrier.	Width of transmitted side bands determined by amplitude of modulating voltage. Present limits in military are 40 kc each side of rest frequency. In addition, a 20 kc guard band is provided for separation of adjacent channels. Divided equally on both sides of rest frequency.	Width of transmitted band is determined by pulse width of transmitted pulses. Bandwidth is several times that required by a-m or f-m width may be aproximated of intelligence. The band to transmit the same amount by formula. Bandwidth in mc 1 pulse length in microseconds.
MODULATOR POWER.	One-half plate power input to modulated stage.	Negligible enough to supply plate loss in modulator tube.	Negligible enough to supply plate loss in modulator tube.
CARRIER POWER.	Final amplifier must be capable of supplying four times rated carrier power on 100 percent modulation peaks.	Final amplifier must be able to supply rated carrier power only.	Final amplifier must be able to supply rated carrier power only.
FREQUENCY LIMITATION.	None	Normal above 20 mc, practicable at 2 mc.	Above 1000 mc.
MODULATION SAMPLING.	Continuous	Continuous	Periodic

Figure 3-27 Comparison of Modulation Methods

the intensity of static decreases at higher frequencies, one of the great arguments for frequency-modulated radio stations begins to lose some of its weight.

The employment of pulse-time modulated equipment parallels that of frequency-modulated radio terminal and relay equipment. However, it has two major advantages over frequency modulated terminal and relay equipment:

1. Frequency-modulated terminal and relay equipment is capable of providing four two-way communication channels while the pulse-time modulation provides eight such channels.

2. The distortion between successive relay stations is greatly reduced.

The fact which limits the length of circuits employing frequency-modulated relay equipment is the amount of distortion introduced at each relay. With pulse-time modulated relay equipment, the circuit length is limited by cumulative maintenance rather than the cumulative distortion, which occurs with addition of relays.

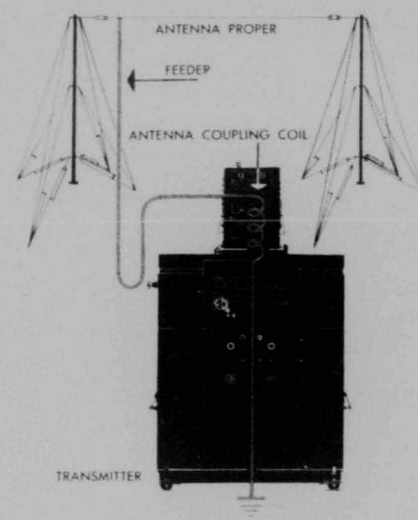

Figure 3-28 Typical Transmitting Antenna System

6. ANTENNAS

General

The device which performs the function of projecting radio waves into space is the antenna. The energy from the transmitter is radiated or sent into space by the transmitting antenna. This energy travels through space in the form of an electric field which cuts across the receiving antenna and induces a voltage in it. Receiving antennas for LF, MF, and HF, normally, are not very critical, and, therefore, do not require extreme care in design for satisfactory operation.

The proper design of the transmitting antenna system is important, as the antenna must be able to radiate efficiently the power supplied by the transmitter. This antenna must be very exact in its dimensions and must be properly constructed. Otherwise, low efficiency will result.

A complete transmitting antenna system consists of three distinct parts, as illustrated in Figure 3-28. These are the coupling device, for coupling the output of the transmitter to the feeder; the feeder, or transmission line which carries the energy to the antenna; and the antenna proper, which radiates the radio energy into space.

There are many shapes and sizes of antennas employed in radio transmission. A few of the many types are shown in Figure 3-29. Some of the factors which determine the type, size, and shape of the transmitting antenna to be used are:

The frequency of operation on the transmitter.

The amount of power to be radiated.

The general direction of the distant receiving station.

Relationship of Frequency and Wave Length

The wave length represents the distance traveled by the wave in a length of time corresponding to one cycle, assuming that a sinusoidal force produced the wave. Since the radio wave travels with the velocity of light, the relationship between wave length

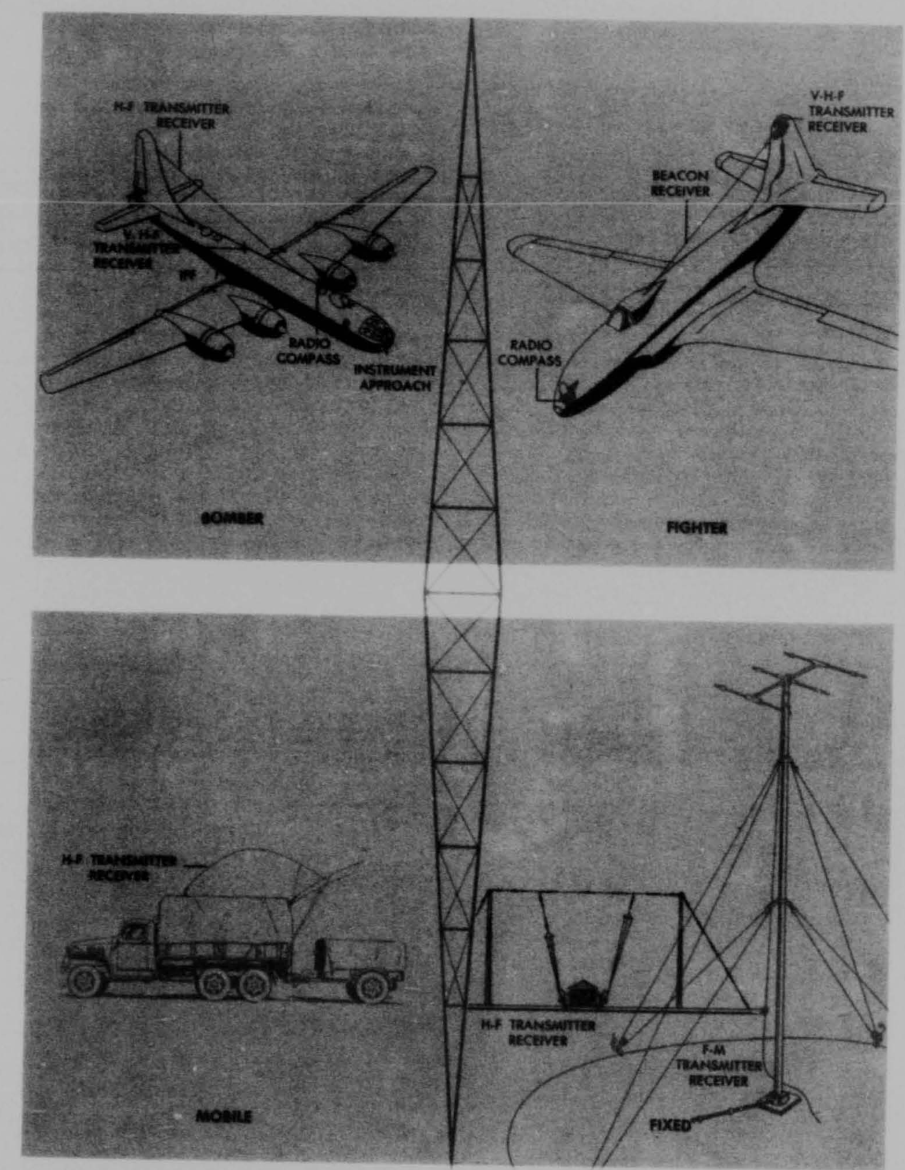

Figure 3-29 Types of Antennas

THIS PAGE IS DECLASSIFIED IAW EO 13526

and frequency exists. This relationship is:

$$\lambda = \frac{300,000,000}{f}$$

where:

λ = wave lengths in meters
f = frequency in cycles per second

or:

$$\lambda = \frac{186,000}{f}$$

where:

λ = wave lengths in miles
f = frequency in cycles per second

Generation of Electromagnetic Waves

The Infinite Line. An alternating voltage impressed on an open-wire transmission line of infinite length, causes an electro magnetic wave to be propagated along the line at approximately the velocity of light. The applied voltage causes an electrostatic field to exist between the wires. The current flowing in the wires causes magnetic lines of force to exist around the wires. Figure 3-30 illustrates the manner in which these two fields exist. The two fields are at right angles to each other and both are perpendicular to the length of the wire. The magnitude of each field is directly proportional to the amplitude of the force which produces it.

In order to explain the phenomenon of wave-travel more fully, assume that one cycle of a sine-wave voltage whose frequency is 186,300 cycles per second (wave length 1 mile) is impressed on an open-wire line of infinite length (Figure 3-31). Figure 3-31 A represents the condition of the line and the voltage generator at time zero. As the voltage starts positive from zero (B), a weak electromagnetic field is started down the line. The amplitude of the voltage increases until at one-quarter cycle (90°) it is at a maximum value at the source (C). At the same instant, the electromagnetic field has reached its maximum at the source. However, at this instant the weak electromagnetic field initially set up has traveled one-quarter wave length down the line. During the next quarter-cycle, the generator voltage decreases to zero and the electromagnetic field also diminishes to zero at the source as the first half-cycle is completed. At this instant, the leading edge of the electromagnetic field has traveled a distance of

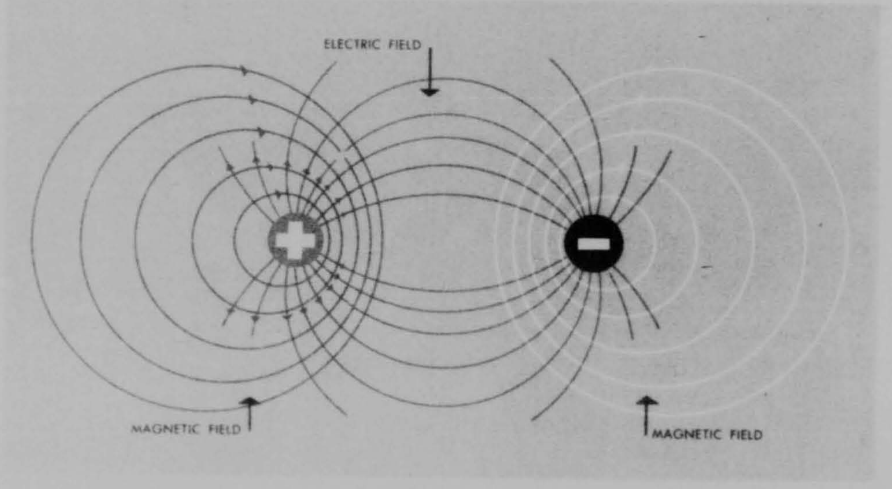

Figure 3-30 End-On View of a Transmission Line. (The Two Fields Constitute an Electro-Magnetic Wave).

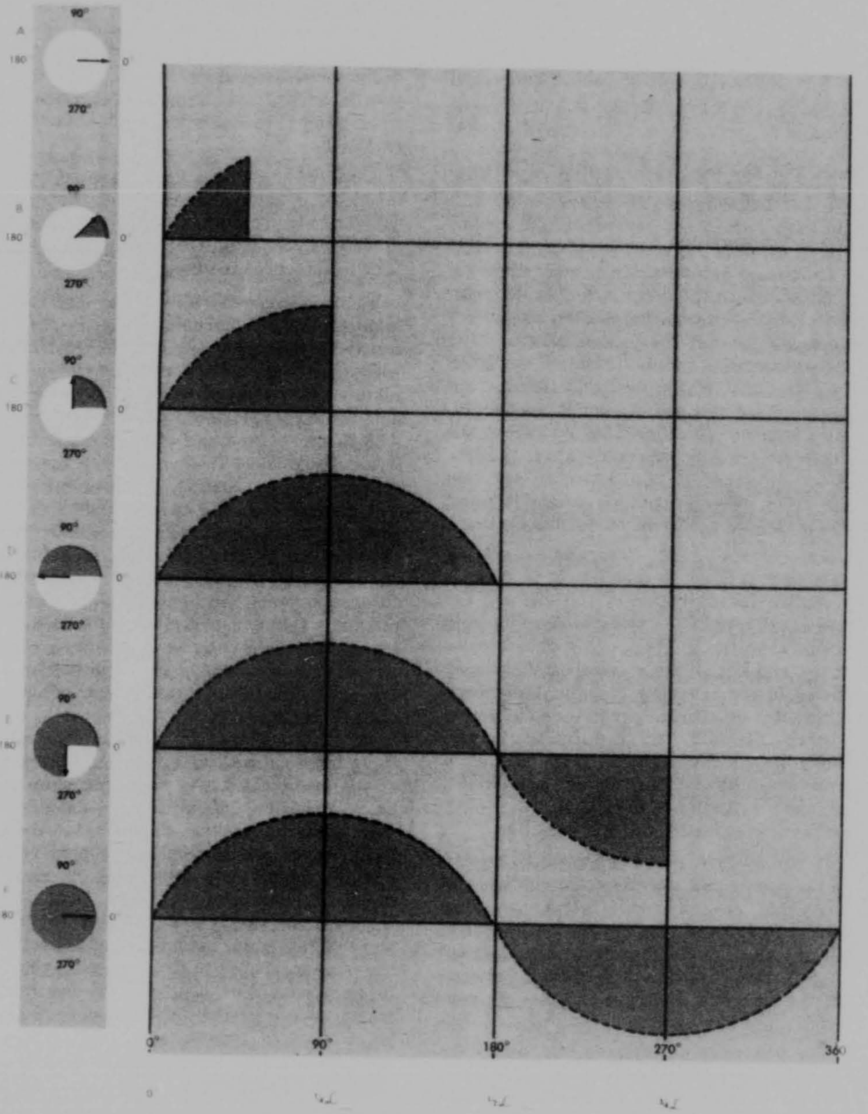

Figure 3-31 One Cycle of Alternating Voltage Impressed on an Infinite Line

one-half wave length down the line. Figure 3-31 D shows the wave at the end of this instant. Figures 3-31 E and F show the wave at the three-quarter, and one-cycle, points. As the voltage generator begins the second cycle, the same phenomenon is repeated. At the end of the second cycle, however, the first weak electromagnetic wave has traveled down the line two wave lengths, in this example two miles.

Wave Reflections

The preceding discussion is based upon the condition of an infinitely long line. In practice of course this is impossible, but a condition will be met in practice in which the transmission line appears to be infinite. When the impedance of the load and the line are the same, its behavior is as if it were an infinite transmission line. This results in the maximum transfer of energy along the line in one direction. It is a desirable condition and every effort is made to attain it, since this is the most efficient mode of operation.

Unfortunately, this condition is not always encountered in practice. It is difficult to match the impedance of the line and the load exactly, or if the transmission line conductor material is changed, a discontinuity occurs and not all the wave energy is transmitted in one direction. Some of the energy is reflected back to the sending end at points where a discontinuity or mismatch occurs. When an electromagnetic wave strikes a large discontinuity, such as an open circuit, complete reflection occurs since the wave cannot travel further in that direction.

In the study of wave reflection as related to radio antennas, we are interested only in lines that are electrically short. In other words, in lines which are only a few wave lengths along at the frequency of excitation. In this case, the line attenuation between the sending and receiving end may be neglected since it is small.

The traveling electromagnetic wave has its counterpart in hydraulics, in the case of a long straight canal. If a disturbance is made at one end of the canal, a series of waves will travel along the canal. If a series of floats were placed on the surface of the water and measurement of the instantaneous values of the heights were made as the wave passed, these values would be similar to the instantaneous values of voltage and current obtained in the infinite line. If, however, the floats were so arranged that they would remain at the maximum height after the wave passed, then a straight line would be obtained.

Now, suppose that a dam is placed across the canal in such a manner that the waves will strike it. There will then be a piling up of water at the dam which will start a wave back in the opposite direction.

In like manner, if an electric line is not infinitely long or terminated in its characteristic impedance but is open-circuited, then, when the wave strikes the end, it will be reflected. The electric wave in traveling has half of its energy stored up in the magnetic field (current), and half of the energy stored in the electric field (voltage). When the wave strikes the open circuit, the magnetic field will collapse, for the current must become zero. However, a changing magnetic field produces an electric field. This is the principle upon which all generators and transformers operate. The energy stored in the magnetic field will, therefore, be turned into energy in an electric field and will be added to the existing field, so that the voltage at the open circuit will be increased. This increased voltage will start a wave traveling back in the opposite direction, and, since there has been nothing to absorb any energy at the open circuit, the returning wave will be of the same magnitude as the original wave. As the electric field starts moving back, it will set up a magnetic field again, and the energy will once more be equally divided between the two fields. As the electric field has simply been doubled at the instant of reflection, the voltage of the returning wave starts out in the same phase as the original wave. The magnetic wave is in opposite phase to the incident wave at the point of open circuit, and, since the two voltages are equal and do not add to zero, they must remain in phase.

In Figure 3-32A is shown a plot of the two voltage waves which are present on an open-circuited line at some instant. The total voltage at any point on the line at that instant is also shown. It will be noticed that the reflected wave is obtained by folding back on the line, from the point of reflection, the initial wave as it would have been beyond the open circuit has the line continued on. In Figure 3-32B to I, this process is continued for later instants. When the two waves are added point by point, it will be seen that at some points the resultant wave is always zero. These points occur at odd quarter-wave lengths from the open circuit, because at such a position the reflected wave has traveled an odd number of half-wave lengths since it passed this point as part of the initial wave. At even quarter-wave lengths from the open circuit, the resultant voltage is always twice the value of either wave, since the two waves at these points are equal and in the same direction.

In Figure 3-32J, all the resultant waves obtained for the different instants are plotted on top of each other to permit a better comparison. It will be noticed that voltage varies with time and space. At every point along the line, the voltage reaches a maximum at the same instant, but the magnitude of this maximum voltage varies sinusoidally along the line. It should be noted in contrast, that on the line terminated in its characteristic impedance the maximum voltage occurs at different instants for different points on the line but is the same value for all points when there is no reflection. If a voltmeter is moved along the open-circuited line, a curve similar to Figure 3-32K would be obtained. The readings always will be positive since the meter cannot take account of phase. Waves which can be detected by a meter which records average results are called standing waves and are different from the traveling waves which were first discussed. The points of minimum voltage are called the "nodes" of voltage while the points of maximum voltage are called antinodes. The voltage at the nodes is not actually zero since there is always some loss caused by resistance as the wave travels along the lines. Since the returned wave is slightly smaller, it will not entirely neutralize the initial wave at these points, but at high frequencies there is a close approximation to this ideal condition. These curves also represent current on a short-circuited line since the current wave is reflected without change in phase in this case.

Figures 3-33, A to I, show the two waves of current on the line for different instants. It should be remembered that while a voltage wave and a current wave are discussed as though they were distinct, the voltage and current together are necessary for a physical wave, since one cannot exist without the other, but each can be considered separately in plotting results. It will be noted that the current has been reversed at the open circuit so that the two waves add up to zero at that point. As the instantaneous values are added point by point, it will be observed that there is also a standing wave of current. This wave is the same as would be obtained for voltage if the reflection had occurred a quarter-wave down the line, and the nodes of current occur at the antinodes of voltage and vice versa.

These curves also represent voltage on a short-circuited line since phase reversal occurs on reflection in this case also.

Electromagnetic Radiation

Now, consider the special case of resonant lines $\frac{\lambda}{2}$ long at the frequency of excitation. From Figures 3-32K and 3-33K, the voltage and current distribution along one side of this line would be as illustrated in Figure 3-34.

Little of the energy along such a line escapes even though much of the actual generated power exists in the electromagnetic field as evidenced by the standing waves of voltage and current. It is evident from a study of Figures 3-32 and 3-33 that the phase angle (θ) between the current and voltage waves in Figure 3-34 is 90 electrical degrees. The energy, in the form of an electromagnetic wave, flows into the parallel wire circuit and is transmitted along the line to the distant open end where it is reflected back toward the sending end. If the parallel wires of Figure 3-34 have negligible attenuation, then all the energy that is sent out will be reflected and the net power input to the line must be zero. The generator voltage at the sending end forces a current into the line, but since the power taken from the line is

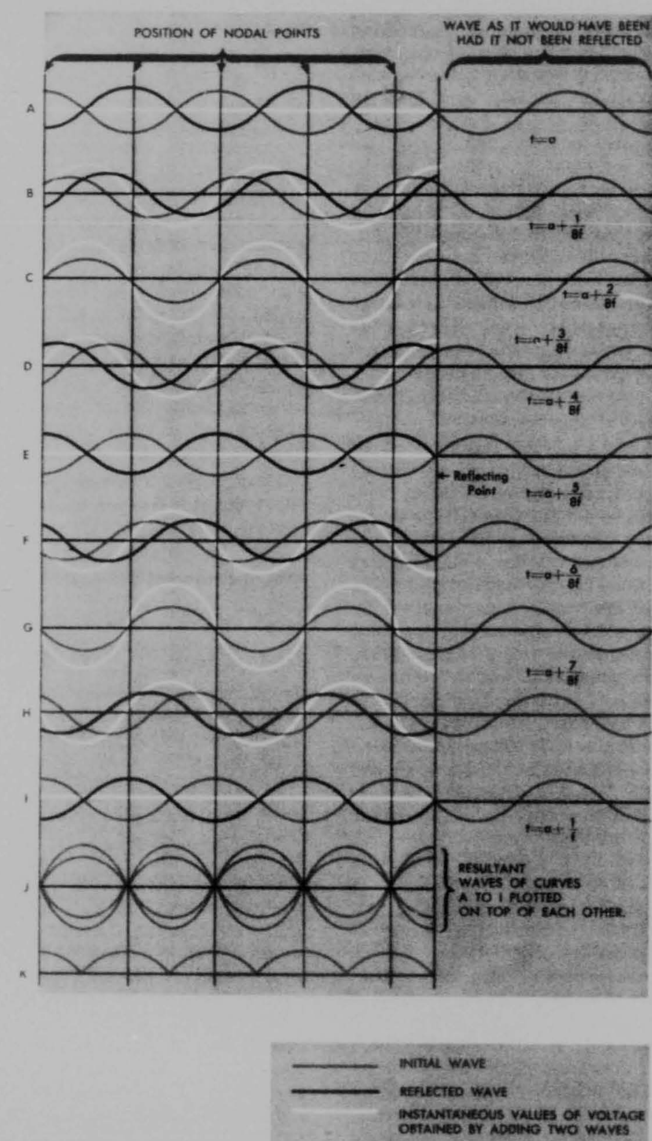

Figure 3-32 Instantaneous Distribution of Voltage on Open-Circuited Lines

Standing waves of voltage and current on one side of an open-circuited transmission line one-half wave-length long at the frequency of excitation.

Figure 3-34 Standing Waves of Voltage and Current

zero, the value of the power equation must, therefore, be zero. The power equation is:

$$P = EI \cos \theta$$

where:

P = power in watts
E = impressed voltage
I = current in amperes
Cos θ = power factor or the cosine of the angle between the voltage and current vectors.

An inspection of Figure 3-34 reveals that the voltage and current vectors have real value. Therefore, in order that the power be zero the value of cos θ must be zero. Cosine 90° is zero. This means that the voltage and current are 90 electrical degrees apart with respect to the time with which they pass through corresponding values.

In Figure 3-35, the instantaneous values of the voltage and current for a half-wave length line are plotted in the upper portion of diagram. The impedance for such a line is plotted below. This shows how the impedance varies as the distance from the open circuited end is varied, and, therefore, is a plot of impedance versus length of line. The input impedance of a half-wave length open-circuited line must be pure resistance.

Now suppose that the open ends of the half-wave line are separated as illustrated in Figure 3-36. It will be found that the generator now sends power into the line and that the input impedance is no longer pure reactance but contains a resistance component. The value of the power equation is no longer zero. In other words, the voltage and current are no longer ninety electrical degrees apart when they pass through corresponding values. The system is now dissipating energy. Since it has been assumed that the wires have no attenuation, where does the energy go? The answer is this: The magnetic and electric field components of the electromagnetic wave are no longer largely confined to a small region, but now excite a large volume of space and are starting to radiate electromagnetic waves into space. Imagine the electric and magnetic fields surrounding the line in Figure 3-34. It is readily

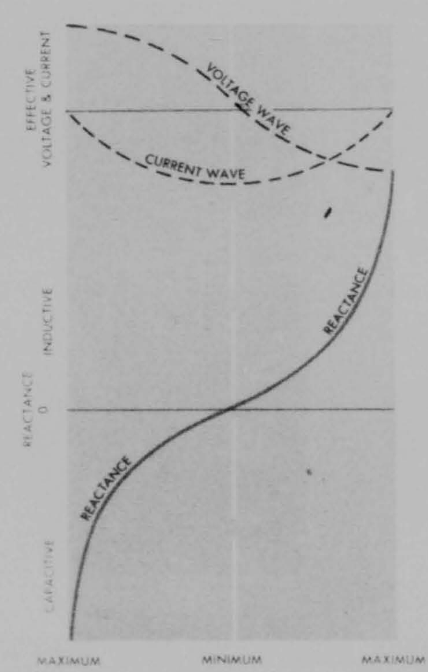

Figure 3-35 Variation of Impedance of an Open-Circuited Line One-Half Wavelength Long and Without Attenuation.

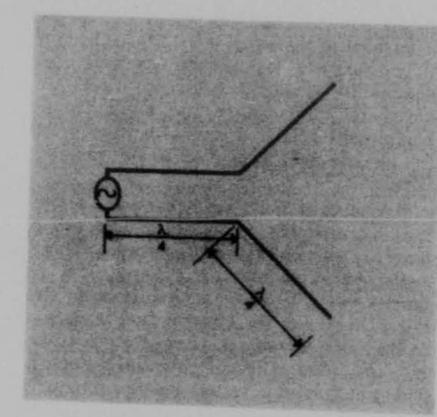

Figure 3-36 A Transmission Line Half-Wave-length Long with Open End of the Line Spread

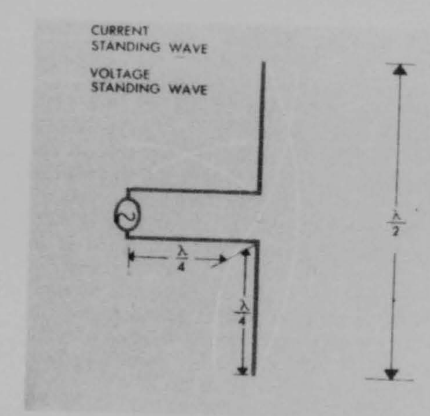
seen that the two fields are confined to a limited space. However, if the lines are now separated as in Figure 3-36, it is observed that the two fields will occupy a much larger space.

If the wires are further separated as in Figure 3-37, the system now becomes a quarter-wave resonant transmission line energizing a half-wave length antenna. The transmission line is energized at a point of high impedance and is terminated (at the antenna) at a point of low impedance. The length of the transmission line and of the radiating elements depend on the wavelength of the radio waves employed. If the lengths of the transmission line and radiating elements are proper, the entire system will be resonant at the frequency employed. In this case, a very small part of the power will be lost by the transmission line and practically all losses which occur in the system will be in the form of an electromagnetic wave radiated from the antenna.

To explain more fully how the radiation of energy actually occurs, suppose now that the radio-frequency generator (radio transmitter) is connected between points A and B in Figure 3-38. This gives the vertical radiator of Figure 3-37. Assume that the transmitter is impressing a pure sine-wave voltage on the antenna.

At that part of the cycle in which the upper generator terminal is negative, electrons in the antenna will be repelled and will flow up wire A. At the same instant, the lower generator terminal will be positive and will attract the electrons up from wire B. In conventional thinking, the direction of current flow is opposite that of the electron flow. Since the conventional current is flowing down the antenna the magnetic lines of force will encircle the antenna as illustrated by the solid circles. When the polarity of the generator reverses during the next one-half cycle, the direction current flow is reversed and consequently the magnetic lines of force will encircle the antenna in the opposite direction. Also, when the upper terminal of the generator is negative and the lower terminal positive, electric lines of force will be established as indicated by the broken lines between the two portions of the antenna. When the generator voltage is reversed during the next half-cycle, the electric lines of force will be reversed.

At frequencies below the radio frequency spectrum (below approximately 30 kc.), practically all of the energy in the two fields is returned to the source by the end of each



The half-wavelength transmission line by modification becomes a half-wave antenna energized by a quarter-wavelength transmission line.

Figure 3-37 Modification of a Half-Wavelength Transmission Line.

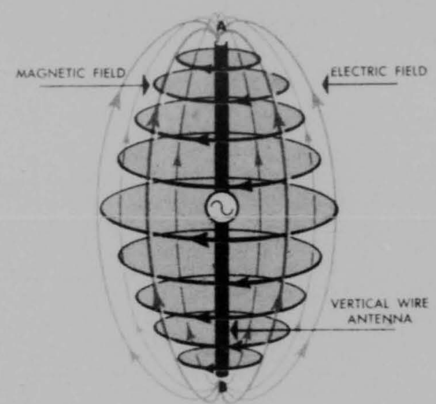


Figure 3-38 Electric and Magnetic Fields Around a Vertical Wire Antenna

half cycle, and before the fields of opposite polarity expand into the space around the wire. As the frequency of excitation is increased, however, the collapsing fields of one-half cycle of the applied voltage do not completely return to the wire before it is met by the expanding field, or opposite polarity, of the next half-cycle. For example, the collapsing field produced by the positive half-cycle does not completely return to the circuit by the time it is met by the expanding field produced by the negative half-cycle. This expanding field of the negative half-cycle forces a portion of the returning field from the positive half-cycle to propagate out into space and never to return to the source. Thus, some of the electromagnetic energy from each half-cycle of the impressed voltage is forced away from the antenna as an electromagnetic wave. This wave consists of two components; the magnetic field at right angles to the electric field. Furthermore, the wave travels away from the antenna with the velocity of light and in a direction perpendicular to the plane of the fields.

Polarity of Electromagnetic Waves

The direction of the electric field, i.e., the electric lines of force with respect to the earth, determines the polarity of a radio wave. A radio wave whose electric field is perpendicular to the earth is said to be vertically polarized and one whose electric field is parallel to the earth is said to be horizontally polarized. Vertical antennas radiate predominantly vertically polarized waves, and horizontal antennas radiate predominantly horizontally polarized waves. In other words, the electric field is parallel to the radiating wire.

Horizontally polarized waves are attenuated more rapidly in traveling over ground than are vertically polarized waves. This is explained as follows: A difference of potential exists between two points in an electric field. When the electric field is parallel to the earth, the earth acts as a short circuit between these points of potential difference. This short circuit causes small currents to flow in the earth's surface which results in the loss of radio energy from the wave.

If the electric field is perpendicular to the earth, as in the case of vertically polarized waves, the points of potential difference in the electric field are not in contact with the earth and no earth currents will flow since there is no point of potential difference on the earth's surface. Therefore, there are very small ground losses present. Radio waves traveling along the earth's surface tend toward vertical polarization regardless of the antenna polarization.

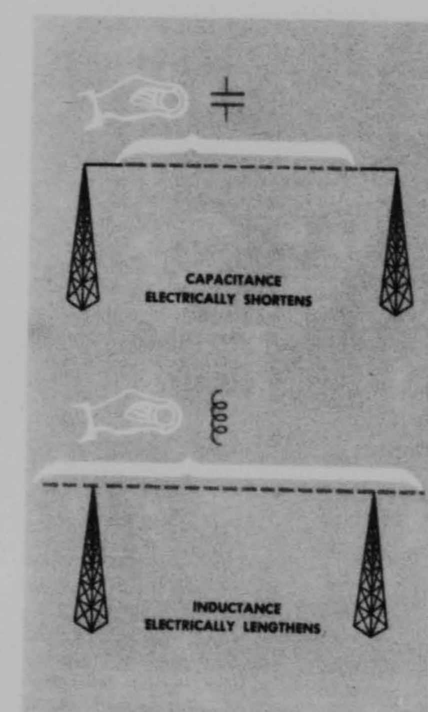
Antenna Dimensions as Related to Wave Lengths

The velocity at which an electro-magnetic wave travels through a medium depends upon the dielectric constant of that medium. At radio frequencies, the dielectric constant of air is unit. For all practical purposes, an electromagnetic wave is considered to travel with the velocity of light through air and the vacuum of space. However, the velocity will be reduced somewhat by other media, such as a wire, whose dielectric constant is greater than unity. When the dielectric constant is greater than unit, the velocity of propagation is reduced.

The addition of reactive elements (capacitance or inductance) at some point in the line or the antenna has the effect of electrically shortening or lengthening the line, depending upon the type of reactance added. The addition of capacitive reactance in series

with a given antenna causes it to be resonant at a higher frequency than the physical length of the wire would indicate. The line has been electrically shortened. On the other hand, the addition of inductance in series with a given antenna will cause it to be resonant at a lower frequency than the physical length would indicate. This line has been electrically lengthened.

If there were no inherent lumped reactance in antennas, their physical length could be found by dividing the velocity of light by the desired operating frequency. However, since antennas normally are supported by insulators at the antenna terminals, a small amount of capacitive reaction is present at these points. This capacitance normally is referred to as **end effect** and is compensated for in the frequency range from 1.5 to 30 mc by making the physical length of the antenna 0.95 that of the free space wave length.



A relationship can be found which will establish the length in feet of an antenna one half wave length long, or longer, to be resonant at any given frequency between 1.5 and 30 mc a follow:

$$L\ (\text{feet}) = \frac{492 \times (n - 0.05)}{f\ (\text{mc})}$$

Where 492 is a constant representing one-half wave length in feet at a frequency of one megacycle; N is the number of half-wave lengths in the antenna; and 0.05 is a constant which compensates for end effect and is sufficiently accurate for all practical purposes in this frequency range.

Free Space Radiation Patterns

The radiation from an infinitesimally small length of wire carrying a radio frequency current is a maximum in the plane perpendicular to the wire and minimum along its axis. The magnitude of the radiation field varies as the sine of the angle between the wire and a line from the wire through the point at which the radiation intensity is measured.

Next consider a wire of appreciable length to be made up of a chain of infinitesimal radiators. It will be found that the field strength is no longer distributed in the same way as for the elemental length. The total intensity of radiation at some point in space is now the vector summation of the intensities of all the elemental radiators at that point in space. For example, the radiation from one elemental radiator may reinforce the radiation from another elemental radiator if they arrive at the point **in phase**, i.e., their path lengths are the same or differ by any number of full wave lengths. Complete cancellation may occur in like manner if they arrive at the point **out of phase**, i.e., their path lengths differ by any odd number of half-wave lengths. These are the two extremes—one of complete reinforcement and one of complete cancellation. In between these two points, the intensity varies and is dependent upon the phase relationship between the intensities of the several elemental radiators concerned.

Now consider the radiation pattern for a

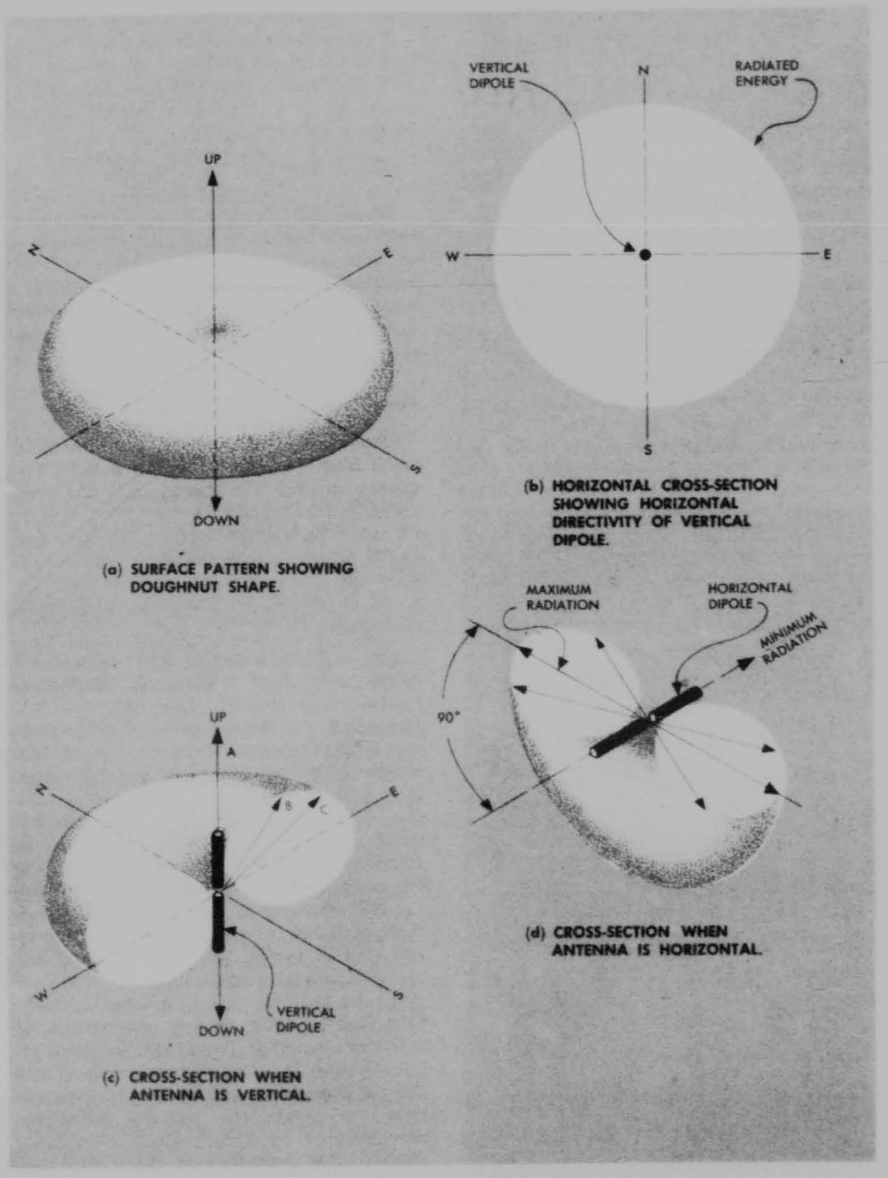


Figure 3-39 Radiation Pattern of a Half-Wavelength Antenna in Free Space.

half-wave antenna remote from the ground or any object that might influence its radiation pattern. Since the current is greatest at the center of the antenna, maximum radiation takes place at this point and practically no radiation takes place at the ends where the current is zero. The maximum radiation for this antenna would be in a plane perpendicular to the conductor. The shape of the radiation pattern resembles a doughnut with the antenna wire passing through its center, as illustrated in Figure 3-39. With a vertical antenna, the radiation pattern will be nondirectional in the horizontal plane, and with a horizontal antenna it will be nondirectional in the vertical plane. The points in the pattern where the radiation is zero are called "nulls" and the points on the pattern represented by the curved line (area between the nulls) are known as "lobes."

Modification of Free Space Patterns by Ground Reflection

The performance of an antenna, particularly with respect to directive properties is considerably modified by the presence of the earth. The earth acts like a huge reflector for those waves which are radiated from the antenna lower than the horizontal. The process of the reflection of radio waves by the earth is similar to that by which light is reflected from a mirror.

The value of the signal strength as measured at some point P (Figure 3-41) in space will depend upon the phase relationship of the direct ray and the reflected ray at point P, and will be the vector sum of the two rays. The factors which determine the magnitude of the resultant wave are the orientation of the antenna with the earth, the height of the antenna above the earth, its length (if vertical) and the characteristics of the reflecting surface.

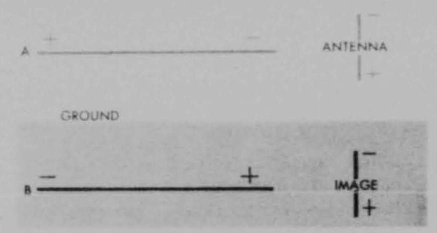
It is frequently necessary for the communications officer to predict the lobe pattern to be found in the radiation of a radio transmitter operating at frequencies above 30 mc in order to determine the performance of a communication set or a radar station. For this reason, ground reflection and the formation of lobe patterns will be presented in the manner they are employed in USAF communications.

For the purpose of studying the vertical angles at which radiation will be a maximum or minimum, it is convenient to consider that the reflected wave is generated by an image antenna below the surface of the earth. This concept is similar to that employed in studying the laws of mirrors.

In the case of a perfect earth (infinite conductivity), the magnitude of the reflected wave will be exactly that of the incident wave. This is the situation normally assumed by the communications officer, since it will provide results that are sufficiently accurate in most cases. The currents in corresponding parts of real antenna and the image antenna, i.e., parts lying on the same vertical line and at the same distance from the earth's surface, are of the same magnitude. The direction of current flow is such that the vertical component of the current in the image is in the same direction as the vertical component of the current in the corresponding part of real antenna. The horizontal component of the current in the image is in the opposite direction from the current in the corresponding part of the real antenna (Figure 3-40).

Since the reflected wave may be considered as being generated by the image antenna, it is apparent that it will be opposite in polarity to the wave generated by the real antenna. If the real antenna is horizontal and is instantaneously charged so that one end is positive and the other end negative, then the image antenna, also horizontal, is oppositely polarized. (Figure 3-40.)

The electric and magnetic fields existing in space above the earth, in the presence of a perfect earth, are exactly the same fields that would be produced in this region by the joint action of the real antenna and its image antenna with the earth removed. Since the total field in any direction represents the vector sum of the direct wave and the reflected wave, the total field will be maximum at vertical angles where the direct and reflected waves arrive in phase, and will be minimum at vertical angles where the direct and reflected waves arrive out of phase. The value of the field will have values between the maximum and minimum that depend upon the phase difference of the two waves at that point. If there were no phase shift in the



(A) illustrates the current distribution for the horizontal component of current in the image and corresponding parts of the actual antenna. (B) illustrates the vertical component of the current in the image and corresponding parts of the actual antenna.

Figure 3-40 Horizontal and Vertical Components of Current.

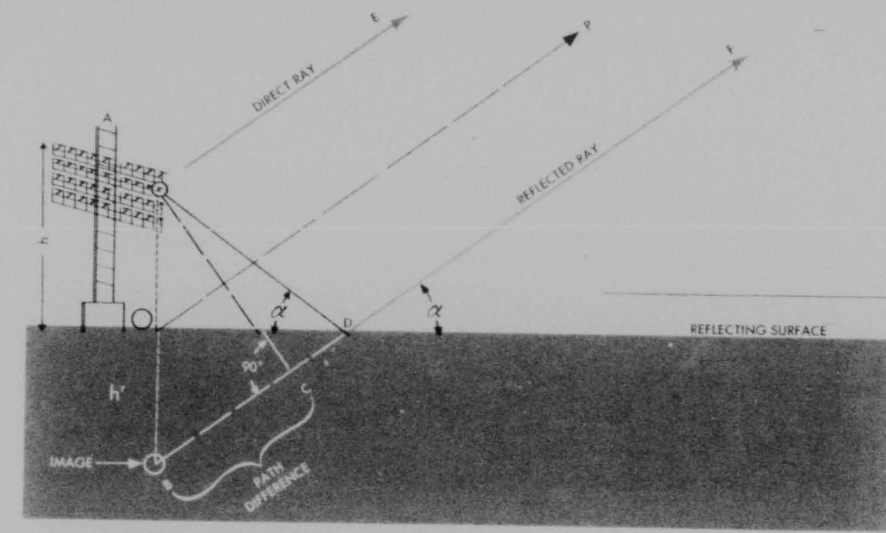
reflected wave at the point of reflection, the minimum field strength at some point P in space would occur when the path of the reflected wave was exactly one-half wavelength (or any odd number of half-wave lengths) longer than the direct path.

The case just discussed would be true if there were no phase shift of the wave at the point of reflection. However, when a radio wave is reflected from a reflecting surface having infinite conductivity, the angle of incidence equals the angle of reflection, the amplitude of the incident wave, and the reflected wave may have exactly the same or exactly the opposite phase of the incident wave. In practice, it may be assumed that the horizontally polarized wave will undergo a 180-degree phase shift at the point of reflection, while a vertically polarized wave will undergo practically no phase shift for angles of incidence useful in radio communications.

The following discussion for developing the vertical angles for minimum and maximum radiation is based upon the employment of horizontally polarized waves. The student communication officer is urged to develop a similar discussion for vertically polarized waves. Furthermore, in this discussion the curvature of the earth is neglected, in order to simplify the mathematics. This causes no appreciable error if the antenna is not more than 200 or 300 feet above the reflecting surface.

The radio waves from antenna **A** (Figure 3-41) may arrive at point **P** in space by way of two paths, the direct path **AEP** and the reflected path **ADFP**. The strength of the signal at point **P** is the resultant of the two waves reaching that point. The reflected wave (for horizontally polarized waves) undergoes a 180 degree (one-half wavelength) phase reversal at the point of reflection, and its phase is further delayed with respect to that of the direct wave because of the longer path that it must travel. The antenna **A** is **h** units above the earth and the image antenna is located at the same distance below the ground. The antenna and its image lie on a line which is perpendicular to the earth at point **O**. If the distance **OP** is very great compared to **h**, then path **AEP** may be considered parallel to path **DFP**. Construct the line **AC**, through point **A** and perpendicular to **BDFP**. Since paths **AE** and **DF** are assumed to be parallel, then geometrically, it is evident that the reflected path length is physically longer than the direct path by the amount **BC**. It is convenient to express this path difference in half-wavelengths. When the difference in the path length is equal to one-half-wavelength or any odd number of half-wavelengths the reflected wave arrives at point **P**, 180 electrical degrees behind the direct wave as a result of this extra path length. However, horizontally polarized waves undergo an additional phase reversal of 180 electrical degrees at the point of reflection-point **D**. Therefore, when the path difference **BC** is equal to odd half-wavelengths, the reflected wave will lag the direct wave by 360 electrical degrees (one wavelength or multiples thereof) in arriving at point **P** and the resultant field strength at point **P** will be maximum. Since both waves are of equal strength and in phase, the resultant field is the vector summation of the two waves at that point. It is evident that the resultant field will be double the value of the individual waves.

When the path difference is equal to one wavelength or any even number of half-wavelengths, the reflected wave lags the direct wave by an amount equal to the path difference plus one-half wavelength due to the 180 electrical degree phase shift at the



At any distant point P, the field strength will be the resultant of two rays, one direct from the antenna, the other reflected from the ground. The reflected ray travels farther than the direct ray by the distance BC, assuming the reflected ray originates, in effect, from the image antenna.

Figure 3-41 Direct and Reflected Rays

point of reflection. Therefore, the resultant field strength at point **P** will be zero since the two waves are arriving 180 degrees out of phase.

Critical Angles. Critical angles are those at which maximum or minimum radiation occurs and are measured from a line tangent to the earth at the base of the antenna. The mathematical relationship between the quantities may be derived from Figure 3-41 as follows:

Since the angle **BAC** is nearly equal to the angle of elevation **DOP** of point **P**, then as long as the mean path is very great compared to the antenna height **h**, the path difference **BC** may be expressed as:

$$BC = \frac{n\lambda}{2} = 2h \text{ sine } \alpha$$

$$\text{or sine} = \frac{nh}{4h}$$

For small angles, i.e., angles less than 10 degrees, the sine of the angle equals the angle itself expressed in radians (one radian equals 57.3 degrees). Than

$$d = \frac{n}{4h} \text{ radians}$$

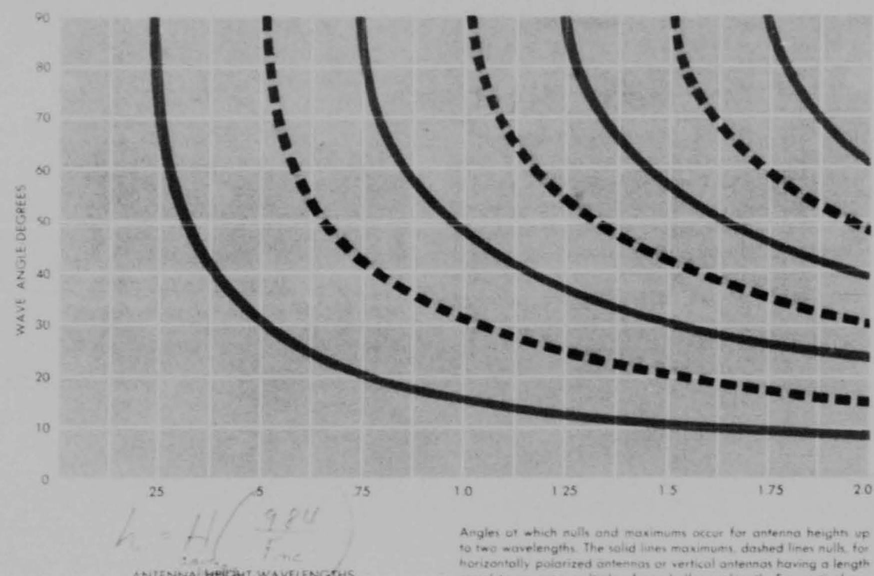
or

$$\alpha = 14.3\ n\lambda \text{ degrees}$$

Where λ = the wavelength in feet
h = antenna height in feet
n = the number of half wavelengths in the path difference.

For horizontally polarized antennas odd values of half-wavelengths (i.e., n-1, 3, 5, ...), the direct and reflected wave will arrive at point **P** and produce a maximum field strength, even values of n (i.e., 2, 4, 6, ...) will produce minimum field strength at point **P**.

Figure 3-42 shows the relationship between antenna height above ground and the wave angles for horizontal and vertical antennas.



Angles at which nulls and maximums occur for antenna heights up to two wavelengths. The solid lines maximums, dashed lines nulls, for horizontally polarized antennas or vertical antennas having a length equal to an even multiple of one-half wavelength. For vertical antennas an odd multiple of half waves long, the dashed lines are maximums and the solid lines are nulls.

Figure 3-42 Relationship Between Antenna Height and Wave Angle

Construction of Vertical Coverage Diagram. Once the mean antenna height above the reflecting surface has been determined, it is a relatively simple process to construct the estimated vertical coverage diagram from theoretical considerations. It has been shown that the field strength becomes a maximum or minimum whenever **n** in equation 10 is an integer. It can be shown that the curve containing all points at which the signal strength is a specified value is given by the expression

$$r = r\ max\ sine\ (90°\ n)$$

Where **r max** is the maximum range at which this value of signal strength occurs and **n** is essentially the angle of elevation in units of $\lambda/4h$ radians, employing equations 10 and 11 an estimated vertical coverage chart may be constructed.

Example: It is desired to construct an expected vertical coverage diagram for a radio set operating at 100 mc with the antenna 70 feet above the reflecting surface $\lambda = 9.82$ feet. Antenna horizontally polarized. Maximum range 200 miles.

Solution:

1. Compute α the angle of the first maximum for the given antenna height and operating frequency from equation

$$\alpha = \frac{14.3\ n\lambda}{n} = 14.3 \times 1 \times 9.82 = 2.0 \text{ degrees}$$

2. Draw through the origin a line at this angle of elevation above the reference line (the horizontal line drawn through a point directly underneath the antenna at the height of the reflecting surface). See Figure 3-43. Draw the line representing the first null in a like manner. Label each line to indicate a maximum or null. As many lines of maximum and nulls may be drawn as desired. Since the height scale is greatly distorted, the angle cannot be plotted with a protractor. It is convenient to remember that at a distance of 109 miles an altitude of 10,000 feet corresponds to one degree in angle of elevation. In the example, the first

maximum is plotted at 20,000 feet above the reference line at a range of 109 miles. The first null is 40,000 feet above the reference line.

3. Additional points on the coverage diagram may be obtained from equation 11. Divide into tenths the vertical distance between any two adjacent lines of critical angle just constructed. Number each division from bottom to top from N + 0.1 to N + 0.9 respectively. N represents the first digit of **n**, the multiple of the critical angle (N = O for the horizontal reference line). Prepare a table similar to Figure 3-44. Place a straight edge through origin and 0.5 in Figure 3-43, then refer to Figure 3-44 and under N — even find 0.5. The next column **r** gives the distance 140 miles at which this signal strength will occur. Plot this value in Figure 3-43. Repeat this operation for the other points and connect them with a smooth curve. The curve represents all points of equal signal strength in the first lobe and under the assumed conditions for a vertical cross section.

A horizontal coverage diagram is made by plotting contours of equal signal strength at given altitude versus range from the station. This information is gathered from several vertical coverage diagrams if the height of the reflecting surface varies in different directions. If the reflecting surface remains the same in all directions from the station, the horizontal coverage diagram is obtained by rotating the vertical coverage diagram about its vertical axis.

The communications officer should become thoroughly familiar with these coverage diagrams since they prove invaluable in estimating communications and radar equipment performance under given conditions. The method described is sufficiently accurate for military operations when used within its proper limits, i.e., not to exceed 10 degrees and the antenna height not to exceed 500 feet.

Size of Reflection Zone. Reflection from the earth's surface is caused by radiation from circulating currents induced in the ground by the lower portion of the radio wave. The reflected energy received at point **P**, Figure 3-41, does not come from point **D** alone but from a large elliptical area surrounding this point. This area, called the first reflection zone, is characterized by the fact that for all points within it, the distance from antenna to ground to the point in space exceeds the shortest reflected wave path by less than a half-wavelength. Thus the radiation contributed by all the currents within this zone give helpful contributions to the reflected field strength at point **P**. The dimensions of the ellipse vary with frequency, the antenna height above the reflecting surface, and the angle of elevation. For the angle of the first maximum above a flat earth, the base of the antenna to the near point of the reflection zone can be estimated from the expression (Figure 3-45):

$Pn = 0.7\ h^2$ feet

The distance to the far point is:

$pf = 23\ h^2$ feet

The width is:

$W = 5.6h$ feet

The distance from the base of the antenna to the point **D** (Figure 3-45) where the wave reflection occurs for the first maximum is:

$Pr = 4\ h^2$ feet

It is evident from equation 15 that the area of the reflecting zone nearest the antenna contributes more to the reflected wave than does the more distant portion of the zone.

The concept of the reflecting zone is useful for approximating the area over which the surface height should be averaged in order to determine the mean antenna height above the reflecting zone. It provides an idea of the area required for perfect reflction of radio waves. The large size of the reflection zone at low angles of radiation shows why minor irregularities of the earth's surface do not materially upset the regularity of the mirror-like reflection for the longer wavelength. However, the reflecting zone concept is not intended to give quantitative answers about the amount of reflection. Its sole use is largely qualitative. It should properly be used only to give an estimate on the order of magnitude for the areas of the reflecting zone necessary to provide the reflections.

The reflection zone is a large factor in the operation of relatively long-wave radar equipment—those operating below approxi-

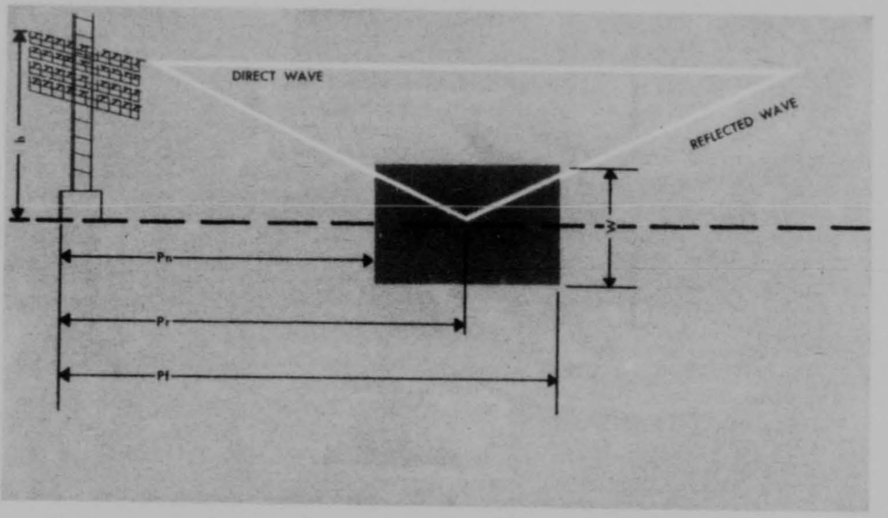

Figure 3-45 Dimensions of the Reflection Zone

mately 2000 megacycles. However, equipment operating above this point is not aided materially in its range capabilities due to ground reflection. This may be readily understood if the wavelength of the radio wave is compared to the physical dimensions of the ground irregularities. As the wavelength decreases, the reflecting surface appears increasingly rougher, and regular reflection no longer takes place.

The waves are now reflected at random and the scattering is so complete that no regular reinforcement occurs. In other words, the radiation patterns of microwave radiation approaches that of the free space pattern.

Characteristics of Half-wave Antenna Patterns. The antenna radiation pattern is that space about the antenna where the intensity of the resultant radiation (the vector sum of the direct and reflexed waves) is equal to certain fixed minimum standard. The envelopes of the radiation lobes are loci of points at which all measurements of radiation strength are equal and of the minimum fixed standard value. The standard of radiation intensity upon which the minimum fixed standard is based is some threshold value, usually expressed in microvolts per meter or in decibels above or below one microvolt per meter.

The radiation pattern for a half-wave antenna in free space is doughnut-shaped with minimum radiation along the axis of the wire and maximum radiation in a plane perpendicular to the wire (Figure 3-39).

Radiation patterns for vertical antennas are nondirectional and in the horizontal plane regardless of their length. The length of the vertical antenna and its height above ground determine the vertical angles at which maximum and minimum radiation occur. Figures 3-46 through 3-49 are representations of radiation patterns for a vertical half-wave antenna at several heights above ground. These are theoretical patterns assuming a perfect conducting ground. Except for the fact that the maximum radiation is not purely horizontal because of ground losses, they are fairly representative of actual practice. The practical result of ground losses is to curve the lower end of the pattern upward, somewhat as shown by the dotted lines. These diagrams illustrate the importance of height in relation to frequency. The higher the antenna the sharper the

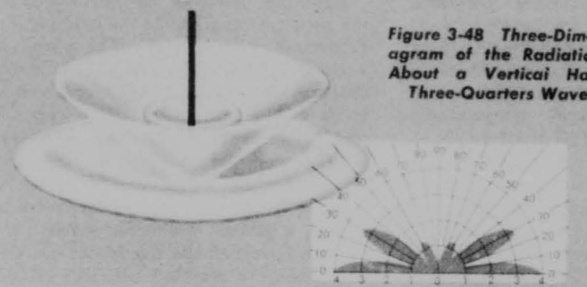

Figure 3-49 Three-Dimensional and Graphic Diagram of the Radiation Pattern Which Exists About a Vertical Half-Wavelength Antenna One Wavelength Above Ground

directive characteristics in the vertical plane. If conditions permit, a height should be chosen which concentrates the radiation at the vertical angle most suitable for the length of transmission path and operating frequency. At frequencies above 30 megacycles, when the space wave is the principal mode of propagation, it is best to have the antenna as high as possible, increasing the radio range, so as to clear the antenna of energy-absorbing objects in the vicinity. The height used, however, should be such that a null will not appear in the region of the most useful angles of radiation.

Radiation patterns for horizontal antennas are directional in the horizontal and vertical planes. The height of the antenna above ground determines its vertical directivity; its length determines its horizontal directivity. The shape of horizontal half-wavelength antenna radiation patterns are illustrated by Figures 3-50 through 3-55 for several heights above ground. Since horizontal half-wavelength antennas are directional in the horizontal plane, i.e., the horizontal pattern is not circular, it would take an infinite number of azimuth profiles such as these to give a complete picture of the vertical characteristics in all horizontal directions. In these figures, the shape of the vertical characteristics is shown for the plane of the wire, perpendicular to the wire, at the midpoint (maximum radiation). At intermediate azimuths, the vertical characteristics of the pattern will be an integration of the vertical characteristics of the two limits illustrated.

It is observed from these polar diagrams that the intensity of radiation is greatest in the plane at right angles to the center of the wire, and is minimum in the plane of the wire. This characteristic of horizontal half-wavelength antennas is more pronounced at low angles of radiation than at high angles of radiation, especially at frequencies of operation where the critical frequency is such that a wave leaving the antennas at almost vertical angles will be reflected from the ionosphere to modify, somewhat, the radiation pattern at high angles. Figure 3-56 is a horizontal polar diagram of a horizontal half-wavelength antenna pattern showing the modification in the shape of the radiation pattern at several vertical angles. The pattern represented by the dot-dash line represents the radiation intensity about the antenna at all azimuths for a vertical angle of 9 degrees. The solid line represents the intensity for a vertical angle of 15 degrees. The dashed line represents the intensity for a vertical angle of 30 degrees.

Characteristics of Long Wire Radiation Patterns. Vertical angles of maximum and minimum radiation for horizontal antennas one wavelength or more long are similar to those for horizontal half wavelength antennas, at equivalent heights. As the length of the antenna is increased to one wavelength or more in multiples of half wavelengths, the horizontal directivity changes. The radiation tends to concentrate more and more off the ends of the wire as the length is increased although some minor lobes appear and provide some radiation in other directions. Figure 3-57. It is apparent from the figure that the horizontal directivity of long-wire antennas depends upon the length of the antenna in multiples of half-wavelengths. Furthermore, the long wire horizontal antenna radiates more power in its most favorable direction. Figure 3-57 illustrates the variation in radiation resistance and power in the major lobe of long wire antennas. It may be seen that, as the length of an antenna is increased, the gain in favorable directions is increased over that of a half-wavelength antenna.

The term "gain" as applied to an antenna system is a measure of the directivity of the antenna radiation pattern as compared with a standard antenna. Quantitatively, the gain is a ratio of power which must be supplied to the standard antenna to deliver a particular field strength, in the desired direction, to the power supplied to the directional antenna system to obtain the same field strength in the same direction. "Gain" may be expressed directly or in terms of decibels.

Rhombic Antennas

The rhombic antenna differs somewhat in principle from the antenna previously described. The rhombic antenna has practically a uniform distribution of current and voltage

in all parts of the antenna. The types previously discussed operate under conditions which produce standing waves of current and voltage.

In its elementary form, such an antenna would consist of a single wire, grounded at the far end through a resistor having a value equal to the characteristic impedance of the antenna.

This termination, just as in the case of an ordinary transmission line, eliminates standing waves. The current decreases uniformly along the wire as the terminated end is approached, the decrease being caused by energy radiation and resistance loss in the wire. The energy remaining when the end of the antenna is reached is dissipated in the terminating resistor. For such an antenna to be a good radiator, it must be several wave lengths long at the frequency of excitation since the current in the wire is relatively small. Therefore, a longer antenna is necessary in order to radiate an amount of energy equivalent to that which would be radiated by a shorter antenna with standing waves. This type of antenna must not be so close to the ground that the return path through the ground will cause cancellation of the radiation. If the wire is sufficiently long, it will be practically nonreso-

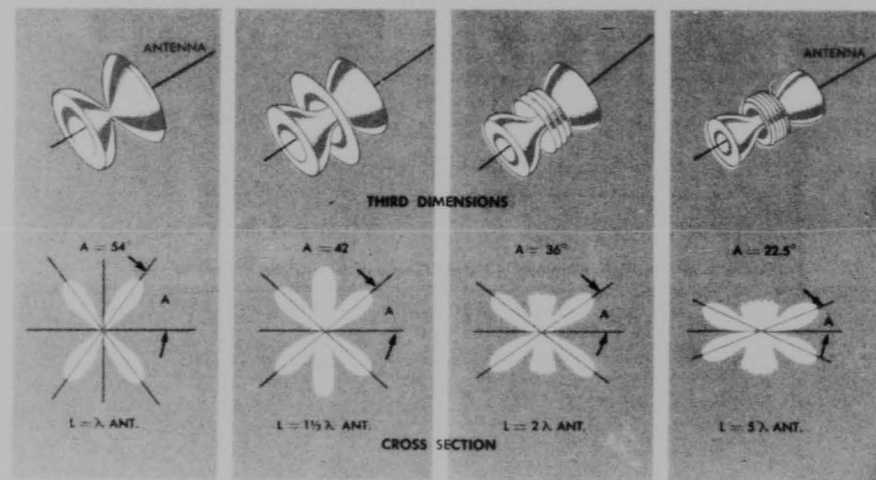

Figure 3-57 Three-Dimensional and Horizontal Cross-Section Diagram of Radiation Patterns for Long-Wire Horizontal Antenna

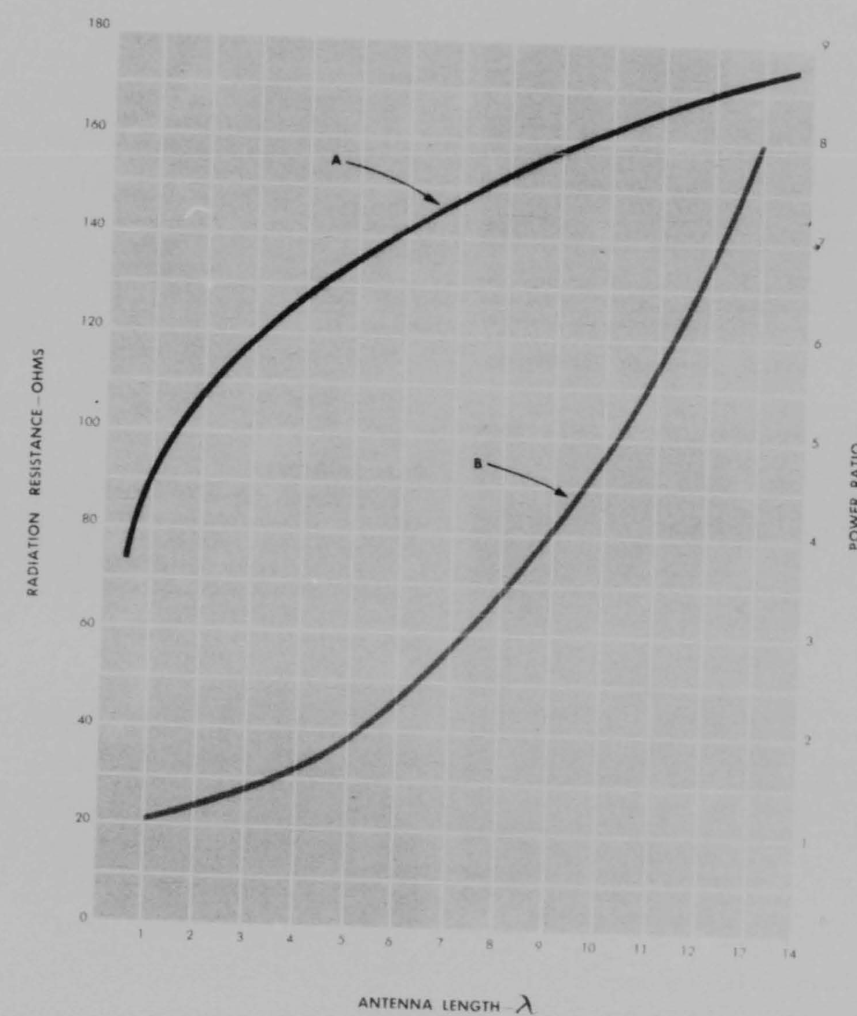
nant over a wide range of operating frequencies.

The directional characteristics of a nonresonant long-wire antenna differs from that of a resonant long-wire antenna in an important respect. The terminated wire is practically nondirectional, having the greatest signal gain in the direction in which the wire points, looking along the antenna toward the terminated end. The directional characteristics vary with the length of the wire, in a manner somewhat similar to the shift in directional characteristics of resonant long-wire antennas. Figure 3-60 illustrates some typical radiation patterns for rhombic antennas. It is observed that the back radiation is considerably less than the forward radiation. This condition results in a **figure eight** radiation pattern with a difference in signal intensity between the main lobes and back lobes. The free space radiation pattern of a nonresonant long-wire antenna shows directional characteristics as a result of reinforcement, or **in phase** radiation, in forward directions and cancellation, or **out of phase** radiation, in other directions.

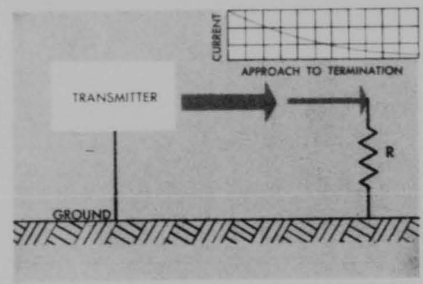
The angle which the main lobe makes with the wire depends on the antenna length, but because of the different types of current distribution, these angles are not the same for resonant (Figure 3-56) and nonresonant antennas of the same length. The difference is most marked for short wires. For a resonant one-wavelength antenna, the angle between the lobe and the wire is forty-five degrees, while the same angle for a nonresonant antenna is fifty-four degrees. However, for antennas two wavelengths or more in length the differences in this angle for resonant and nonresonant antennas is so small that it may be neglected. In the case of resonant antennas, the energy would radiate backward as well as forward. However, in nonresonant antennas the energy which would be radiated in the backward direction is absorbed by the terminating resistor. The rhombic antenna may be constructed either horizontally or vertically.

In designing a horizontal rhombic antenna which will give maximum radiation in a desired direction or maximum response to signals received from the desired direction, the wave angle (vertical angle of maximum ra-



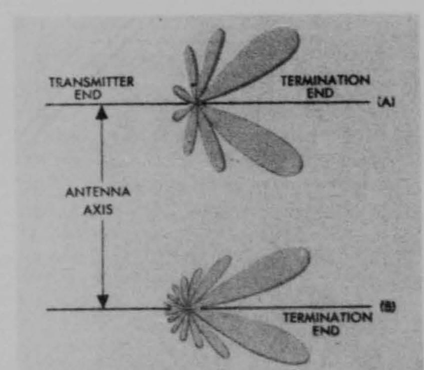
The variation in radiation resistance and power in the major lobe of long wire antennas. Curve A shows the change in radiation resistance with antenna length; curve B shows the power in the lobes of maximum radiation for long-wire antennas as a ratio to the maximum of a half-wave antenna.

Figure 3-58 Variations in Radiation Resistance and Power



This is the basis of nonresonant antenna design. The current falls off slowly from the transmitter and to the terminating resistor, but there are no standing waves.

Figure 3-59 Terminated Long Wire Antenna



Typical radiation patterns (cross section of solid figure) for terminated long wires. (A) length two wavelengths; (B) four wavelengths; both for an idealized case in which there is no decrease of current along the wire. In practice, the pattern is somewhat distorted by wire attenuation.

Figure 3-60 Typical Radiation Patterns

diation) must be first selected. Having selected the desired wave angle, the dimensions of the antenna, with the linear dimensions expressed in wavelengths, can be determined from the following formulas: (See Fig. 3-61).

$$H = 4\frac{\lambda}{4 \text{ sine } \triangle} \text{ (wavelengths)}$$

$$\sin \phi = \cos \triangle$$

$$l = \frac{1}{2 \text{ sine } \triangle} \text{ wavelengths}$$

Where:

H = antenna height in wavelengths
ϕ = angle of tilt (Figure 3-60)
l = length of each leg in wavelengths
$\triangle$ = selected wave angle

The dimensions in wavelengths may be converted to feet by the following expression:

$$\lambda = \frac{984}{f} \text{ (Feet)}$$

Where:

984 = length in feet of one wavelength at one megacycle.
f = operating frequency in megacycles
λ = wavelength.

Antenna Arrays

An antenna array is an antenna system with two or more elements arranged and energized in such a manner that the resulting radiation pattern has directional characteristics. It is beyond the scope of this text to discuss in any detail the numerous types of arrays that are possible.

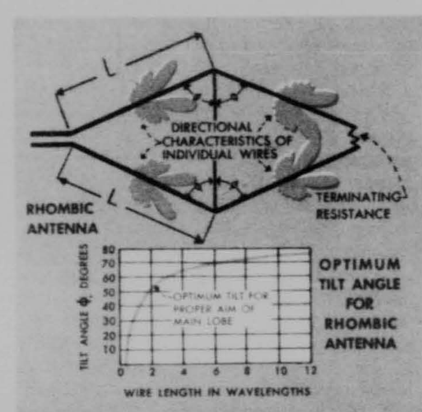


Figure 3-61 Schematic Diagram of a Rhombic Antenna Illustrating How the Optimum Wave Angle Varies With the Tilt Angle in Degrees.

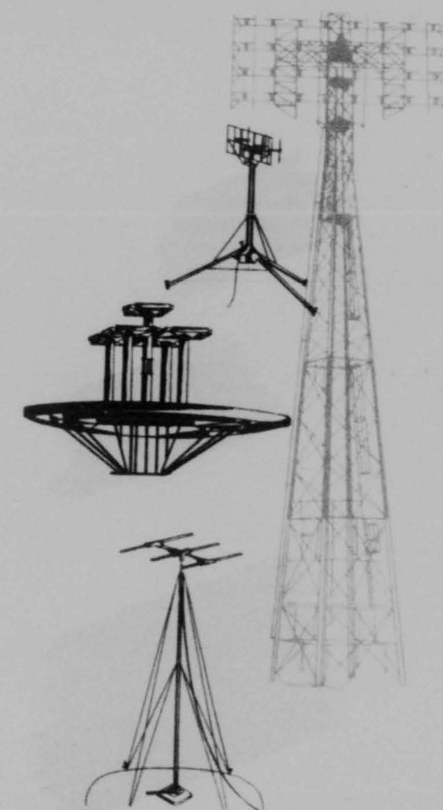

Figure 3-62 Some Typical Antenna Arrays

It is possible to obtain a very high signal gain in a favored direction or directions by employing a number of antenna elements in combinations so that the radiated signal from each of the separate elements combine in phase (reinforce) in certain favored directions and will combine out of phase (cancel) in other directions.

The resultant radiation pattern from such an array depends on the following:

The number of elements that make up the array.

The length of the elements and the geometric arrangement with respect to wavelength.

The manner in which the elements are energized.

The height of the array above the reflecting surface.

Figure 3-62 illustrates some of the many forms which antenna arrays may take.

7. FUNDAMENTALS OF RADIO WAVE PROPAGATION

General

Radio waves differ from other forms of electromagnetic radiation principally in the order of their wavelength, which ranges from about 30,000 meters to less than 1 centimeter. In general, their behavior is similar to that of light. They travel with the same velocity as light and may be reflected, refracted, or diffracted.

Radio communication is carried on by means of the radio waves which are composed of electric and magnetic fields. At the receiving antenna, the magnetic compoonent cuts it and the electric component impinges upon it, with a resultant voltage being induced in the antenna which causes a current to flow in the receiving equipment.

Larger voltages may be induced in antennas and at greater distances than those which can be transmitted over wires of reasonable dimensions. In other words, the attention in wire circuits is considerably greater than that caused by transmitting radio energy into three-dimensional space.

While the phenomena of the ionosphere and its effect on radio waves are subjects relatively unknown to man, research within the last few years has opened the doors to a new science, "frequency prediction and selection."

Frequency prediction and selection permits the communicator to take advantage of known changes in the ionosphere and to apply this knowledge in selecting proper frequencies for transmission. Likewise, a study of the behavior of the ionosphere permits adequate forecasting of the changes. As a result, poor or good transmission can be anticipated in time to make necessary adjustments in frequency selection.

For the next few years, the communicator will not be concerned with this science at the lower echelons. It is felt, however, that background knowledge of the ionosphere and wave propagation is necessary before the communications officer can understand properly the informational data on frequency prediction and selection which is sent to him monthly.

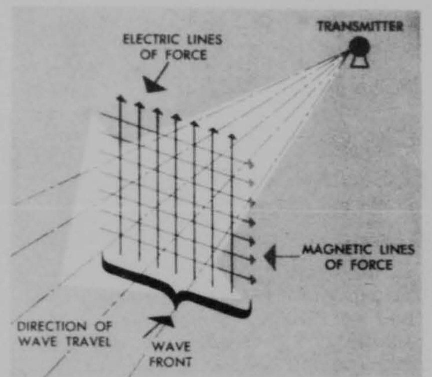

Figure 3-63 A Vertically Polarized Wave

Polarization

The electric lines of force and the magnetic lines of force are always at right angles to each other. Imagine, for instance, a latticework of horizontal and vertical strips in which the vertical strips are called the electric lines of force, then the horizontal strips will represent the magnetic lines of force. (See Fig. 3-63). The whole lattice, that is the plane containing the set of crossed lines, would represent the wave front, and the direction of wave travel is always perpendicular to the wave front.

The intensity of the waves is usually expressed in microvolts per meter, which is a measure of the dielectric stress produced by the electric field, or the voltage induced in a conductor one meter long, held at right angles to the magnetic field. While the intensity of the electric field is used to measure the strength of the radio wave, the energy contained in the wave is actually divided equally between its electric and magnetic waves.

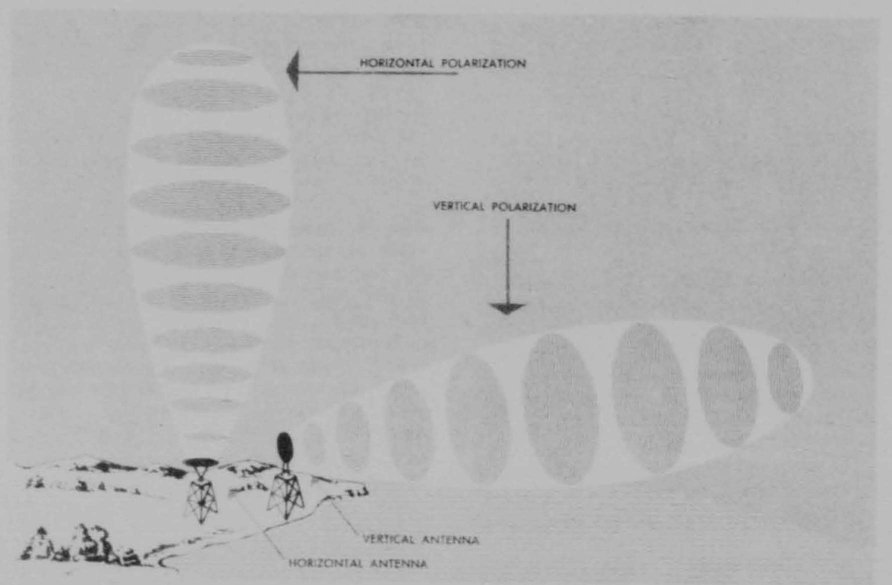

Figure 3-64 Horizontally and Vertically Polarized Waves

The polarization of a radio wave is taken as the direction of the lines of force in the electric field. If the plane of the electric field is perpendicular to the earth, the wave is said to be "vertically polarized;" if it is parallel to the earth, the wave is said to be "horizontally polarized." The electric field is parallel to the radiating antenna, therefore, a vertical antenna radiates a vertically polarized wave and a horizontal antenna radiates a horizontally polarized wave.

Horizontally polarized waves are weakened more rapidly in traveling over the ground than are vertically polarized waves. Therefore, waves of low frequency traveling along the ground usually tend toward vertical polarization regardless of antenna orientation. At high frequencies, the polarization usually varies, sometimes quite rapidly; often it is circular or elliptical because the wave splits up into several components which follow different paths.

The energy extracted from the arriving radio wave by the receiving antenna will be greatest when the antenna polarization is the same as the arriving wave. Therefore, antenna orientation (polarization) is of great importance if maximum efficiency is to be obtained from the radio equipment. Antenna orientation is most important at frequencies where sky wave transmission is involved. The polarization of the received wave seldom bears any definite relationship to the orientation of the transmitting antenna. This is due to the wave splitting up into several components which arrive at the receiving antenna by different transmission paths.

Reflection, Refraction, and Diffraction

Radio waves may be reflected, refracted, and diffracted in a manner similar to light waves. Radio waves are reflected from any sharply defined discontinuity of suitable characteristics and dimensions encountered in the medium in which they are traveling. Any conductor differing in dielectric constant from the medium through which the wave is traveling offers such a discontinuity and will cause reflection to take place if its dimensions are at least comparable to the wavelength of the radio wave. The surface of the earth, and the boundaries between dissimilar air masses in the lower atmosphere are examples of such discontinuities. Other examples of objects which cause reflection to take place if its dimensions are at least comparable to the length of the radio wave. The surface of the earth and the boundaries between dissimilar air masses in the lower atmosphere are examples of such discontinuities. Other examples of objects which cause reflection are aircraft, trees, and birds if the wavelength is small enough to be comparable to the size of the object. Radar depends upon the phenomenon of reflection for its operation.

When a beam of light passes from one medium to another, as from water to air, the path of the beam is bent. Similarly, a radio-wave is bent when it moves obliquely into any medium having a different refractive index from that of the medium which it leaves. Since the velocity of propagation differs in the two mediums, that part of the wave front which enters first travels faster or slower, depending upon the ratios of the indexes or refraction, than the part which enters last, and the wave front is turned or refracted. Radio waves travel slower as the density of the transmission medium increases. Since it requires a discontinuity in the transmitting medium to produce refraction, it is reasonable to expect that some reflection will also occur.

When a wave grazes the edge of an object in passing, it tends to be bent around that edge. This effect, called "diffraction," results in a diversion of part of the energy of those waves which normally follow a straight or line-of-sight path so that they may be received at some distance below the summit of an obstruction, or around its edges. This effect has no connection with atmospheric refraction since it occurs in a vacuum as well as the atmosphere. Figure 3-65 diagrams the reflected, refracted, and diffracted waves.

Types of Radio Waves

Radio waves may be classified according to the path along which they are propagated as **sky waves, tropospheric waves,** and **ground waves.**

The **sky wave or ionosphere wave** is that

THIS PAGE IS DECLASSIFIED IAW EO 13526

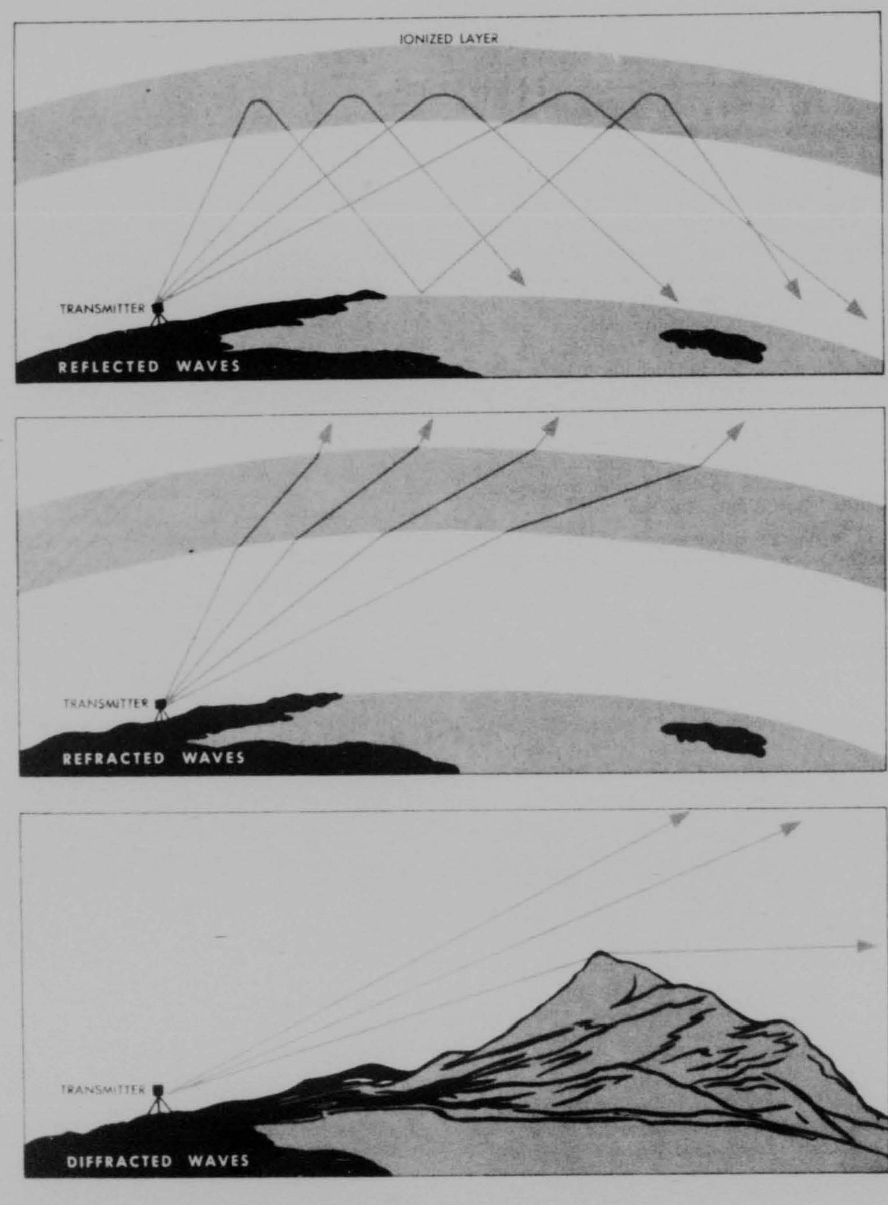

Figure 3-65 Reflected, Refracted, and Diffracted Waves

part of the radiation which is directed toward the ionosphere. Depending upon variable conditions in that region, as well as the transmitted frequency, the sky wave may be lost in space, or returned to the earth by the combined effects of reflection and refraction.

The **tropospheric wave** in that part of the total radiation which undergoes refraction and reflection in regions of abrupt changes of dielectric constant in the troposphere, such as at the boundaries between air masses of differing temperature and moisture content.

The **ground wave** is that part of the total radiation which is directly affected by the presence of the earth. The ground wave has two components. One of these is the surface wave, which is an earth-guided wave, and the other is the space wave. The space wave is the resultant of two components: the direct wave and the ground-reflected wave.

Ionospheric Propagation

The ionosphere is the upper portion of the earth's atmosphere, beginning about 30 miles, and extending to about 250 miles, above the surface of the earth, and containing layers of highly ionized air that are capable of bending or reflecting radio waves back to earth. The ionization in this region is principally due to ultraviolet radiation from the sun. The state of ionization which exists in this region would not be maintained for any length of time if it were not for the very low atmospheric pressures at the various levels concerned. Due to this, collisions between electrons and ions are relatively infrequent so the recombination to regain a normal stable state is slow. The ionization produced during the day is carried over into the night by some method which is not understood. The nighttime ionization, however, is not as strong as that observed during the day. There is a tendency for this ionization to become stratified into definite layers with each showing a maximum of ionization. For all practical purposes there are four of these layers, which are labeled, from the earth up: the D, E, F1, and F2 layers. Their average daytime heights are:

June Day

D — 30 to 55 miles
E — 55 to 85 miles
F1— 85 to 155 miles
F2—155 to 250 miles

December Day

D —30 to 55 miles
E —55 to 85 miles
F1—85 to 155 miles
F2—90 to 185 miles

The nightime F2 layer is a combination of the daytime F1 and F2 layers with a height ranging from 150 to 250 miles. This nighttime F2 layer remains relatively constant throughout the year.

While a complete understanding of the ionization phenomenon is lacking, there is sufficient knowledge to permit a fairly accurate prediction of the intensity of the ultraviolet radiation from the sun. From this knowledge, the degree of ionization in the ionosphere may be determined, and the behavior of the ionospheric radio waves may be predicted.

Although the ultraviolet light of the sun is the predominant cause of the ionosphere, certain other radiations and disturbances contribute to its formation in a somewhat lesser degree. Particle radiation is the transmission of ionized particles from solar bodies of which the sun is the principal source. Particle radiation is often associated with upheavals in the ionosphere called "storms."

The passage of meteors traveling at tremendously high speeds through the earth's atmosphere may cause local changes in the ionosphere. Such changes are predictable only in the broad statistical sense.

Little is known about the cause or nature of cosmic rays other than the fact that they have some effect on the ionosphere.

Communications between distant points by means of radio waves with frequencies between 3 and 30 mc depends principally upon the sky wave. Upon leaving the antenna, this wave travels upward from the earth's surface at such an angle that it would continue out into space were its path not bent sufficiently by the ionosphere to bring it back to earth. Each ionospheric layer consists of a central region of relatively dense ionization which tapers off in intensity both above and below.

Refraction, Reflection, Absorption. For a given density of ionization, the degree of refraction becomes less as the wavelength decreases. Therefore, the bending is less at higher frequencies than it would be for lower frequencies. If the frequency is raised to a sufficiently high value, a point is reached where the bending due to refraction becomes too small to bring one wave back to earth, even though it may enter the ionized layer along a path which makes a very small angle with the boundary of the ionosphere.

The greater the density of ionization in the ionosphere, the greater the refractive bending at any given frequency. Thus, with an increase in ionization shorter wavelengths may be bent sufficiently to permit long distance transmission. In other words, the maximum usable frequency for long distance transmission is increased.

In addition to refraction, reflection may take place at the lower boundary of an ionized layer if it is sharply defined, i.e., if there is an appreciable change in ionization within a relatively short interval of travel. For waves approaching the ionized layer at or near the perpendicular, the change in ionization must take place within a difference in height comparable to a wavelength; hence, ionospheric reflection is more apt to occur at longer wavelengths (lower frequencies).

The radio wave loses some of its energy in traveling through the ionosphere. This absorption loss increases with increasing ionospheric density. Unusually high ionization, especially in the lower strata of the ionosphere, may cause complete absorption of the wave energy. Nearly all of the absorption is the result of the wave entering and leaving the ionosphere.

Virtual Height. Although the ionospheric layer is a region of considerable depth, it is convenient to assign it a definite height, called the "virtual height." The virtual height is the height from which a simple reflection would give the same effect as the gradual bending which actually takes place. The wave follows the path **TBR** (Figure 3-66). It is noted that the bending takes place over a considerable distance and consumes a measurable period of time. The virtual height is the height of the triangle **TAR**. It is calculated on the basis of the angles at which the wave leaves and returns to the earth. The time required for a wave traveling with the speed of light to travel the path **TAR** is the same as that required by

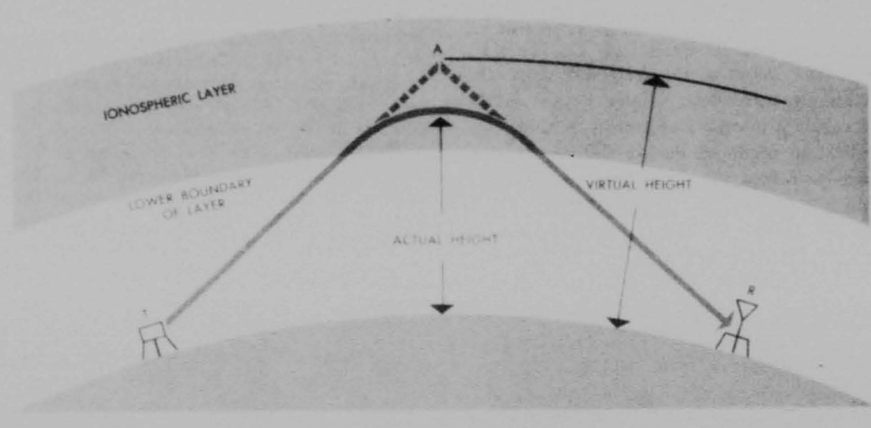

Figure 3-66 Virtual Height

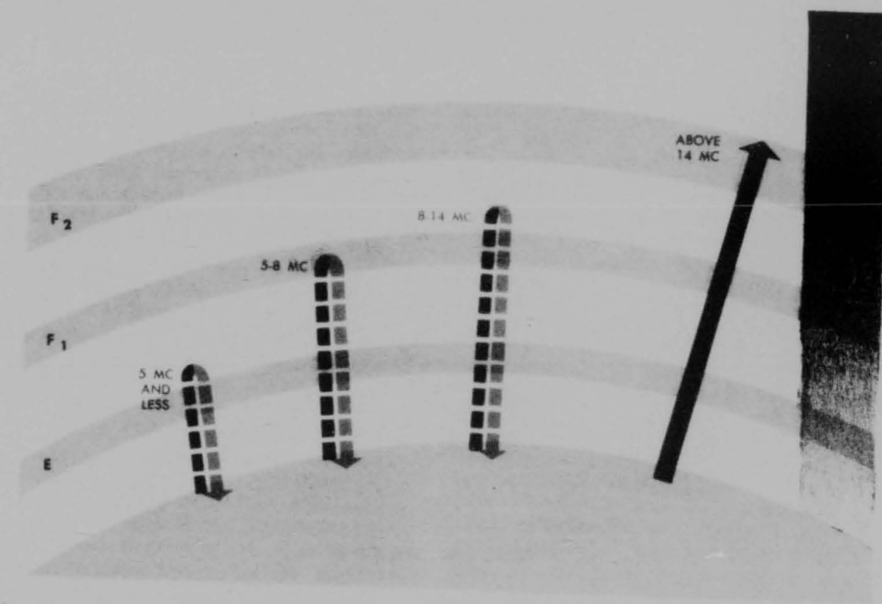

The highest frequency that will be reflected from a layer in a vertical path is the critical frequency for that layer.

Figure 3-67 Refraction Chart

the radio wave to travel the path **TBR**. Although the path **TBR** is shorter, the velocity of the radio wave is sufficiently reduced in the ionosphere to make up for the shorter distance.

Critical Frequency. When the frequency is sufficiently low, a wave sent vertically upward will be bent sharply enough to be returned to the starting point. The highest frequency at which such reflection can occur, for a given state of ionization of the ionospheric layers, is called the "critical frequency" for that layer. Figure 3-67 indicates the approximate critical frequencies that may be expected for E, F1 and F2 layers. Although the critical frequency may serve as an index of transmission conditions, it is not the maximum usable frequency, since other waves which enter the ionosphere at angles smaller than 90 degrees (less than vertical) will be bent sufficiently to return to the earth. The maximum usable frequency for waves leaving the earth at very small angles to the horizon is approximately three times the critical frequency. Besides being directly observable, the critical frequency is of more practical interest than the ionization because it includes the effects of absorption as well as refraction.

Maximum Usable Frequency. Radio waves shot vertically into the ionosphere (i.e., at vertical incident) are refracted almost vertically. These signals are returned to the earth in the vicinity of the transmitting antenna and hence have only limited application since we are interested more often in long distance radio communication. If the frequency of the radio wave exceeds the value of the critical frequency, the wave punches through the ionosphere and is lost into space. Waves A in Figure 3-68 represent a group of such waves.

To traverse the long distance often required in radio communication, the radio

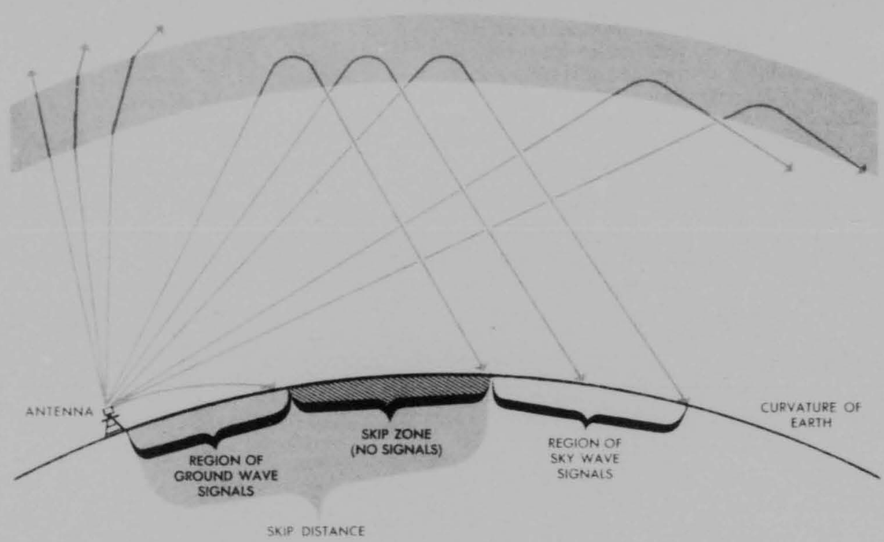

Figure 3-68 Skip Zone

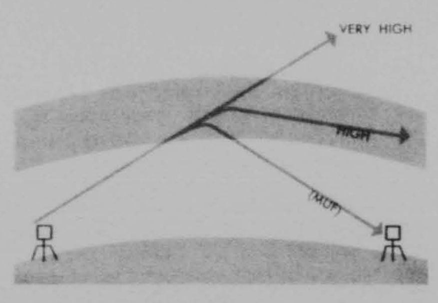
wave must enter the ionosphere at oblique angles, the exact value of which depends on the height of the layer and length of the transmission path. It will be observed that as the transmission distance increases, the grazing angle (the angle at which the wave enters the ionosphere) becomes smaller; until, at long distances, the signal path grazes the ionosphere at a very small angle. As the grazing angle becomes smaller, radio waves of higher frequency will be returned to the earth since less refractive bending is necessary to change the direction of the wave. At angles approaching vertical incidence, the path of the wave must be nearly 180 degrees to be returned to the earth. It is readily seen that a definite relationship may be established between the length of the transmission path and the highest frequency that will traverse the path. The highest frequency that can be used for a given path is called the maximum usable frequency (MUF). Frequencies above the MUF will either be lost in space, or will be returned to the earth at a more distance point. Frequencies excessively below the MUF are generally unsatisfactory, due to absorption and natural atmospheric noise.

Since greater bending is required to return the wave to earth when the angle of incidence is large, the refraction at high frequencies may not be sufficient to produce the required bending. Therefore, the angle of incidence must be smaller than a certain angle, known as the "critical angle," in order to produce sufficient bending to return the wave to the earth. The distance (determined by the critical angle) between the transmitting antenna and the receiving antenna is the shortest possible distance over which communications by normal ionospheric refraction can be accomplished.

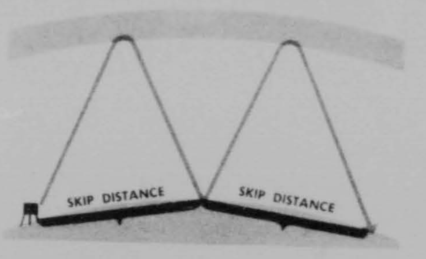


Skip Zone. The area between the end of the useful ground wave and the beginning of the sky wave reception is called the "skip zone." The extent of the skip zone depends upon the frequency employed and the state of the ionosphere. The higher the radio frequency employed, the greater the extent of the skip zone increases. For a given frequency and critical angle, the extent of the skip zone will vary with the height of the layer in which the refraction takes place.

The "skip distance" may be defined as the distance from the transmitting antenna to the point of first ground reflection or the distance between successive ground reflections. It is easily seen that the skip distance varies under the same conditions as the skip zone. (Figure 3-68)

Normally, the wave angles at the transmitting and receiving points are approximately the same for any given transmission path. It is readily possible for the ionospheric wave to pass through the E layer and be refracted back to earth by the F1 or F2 layer, as the critical frequencies are higher in these layers. Depending on the wave angle, frequency, and ionospheric conditions, it is sometimes possible to carry on communication via either the E, F, or F2 layers on the same frequency.

Optimum Working Frequency. The maximum usable frequency could be utilized for communications were it not for the fact that it contains no safety factor to take care of small unpredictable changes in the ionosphere. For example, a decrease in the intensity of the layer could cause the signal to not be returned to earth since MUF involves a critical frequency at a critical angle.



The MUF is considered to be reliable 50 per cent of the time. As the frequency of a wave is decreased there is an increase in the probability of the wave being refracted to earth. It is possible to achieve a reliability of 90 per cent by selecting a slightly lower frequency. This lower frequency is called the optimum working frequency (OWF) and its values are established by the following relationships:

F1 and E layers	OWF—MUF $\times$ 0.97
F2 layer	OWF—MUF $\times$ 0.85

It is observed that little correction is required for the E and F1 layers. This is due to the random variation in the ionosphere being confined mostly to the F2 layer.

Lowest Useful High Frequency. The optimum working frequency is the highest radio frequency that can be used for reliable communication along a given transmission path. However, to meet all the communications requirements of military situations, frequencies other than the OWF must be used. Since we know that, for a given transmission path, frequencies above the OWF cannot be relied upon for constant communication, the selection of additional frequencies must be made from those below the OWF. The problem here is to find how far below the OWF we may expect reliable communication. This lower limit is known as the lowest useful high frequency (LUHF).

A number of factors establish the LUHF, and its determination is usually the most difficult problem in frequency prediction. Some of the factors are:

Ionospheric absorption causes the radio wave to lose some of its energy as it passes through the ionospheric layers. This effect is greatest in the lower layers of the ionosphere.

Atmospheric or man-made noise in the vicinity of the receiver are important factors in establishing the LUHF. Most atmospheric noise is generated in tropical areas, mountains, and desert areas. The noise factor must be taken into account particularly in the design of highly directional antennas since such antennas may defeat their intended purpose should they beam the radio wave along a portion of the great circle path which passes through a zone of high atmo-

THIS PAGE IS DECLASSIFIED IAW EO 13526

spheric noise. In such cases a reciprocal path may be more satisfactory.

Radiated power of the antenna is another factor which must be considered in establishing the LUHF. As the upper limit of the high frequency band is approached, the atmospheric noise intensity decreases which permits the reception of weaker signals. However, toward the lower limits of the high frequency band the atmospheric noise intensity increases and requires that the signal intensity be greater so that reception may take place. For a given distance, the strength of the signal at the receiving point will be determined by the power radiated at the transmitting antenna. In other words, to increase the strength of the received signal, the power radiated by the transmitting antenna must be increased. The power radiated by the transmitting antenna should not be assumed to be the same as the power rating of the transmitter. It is not uncommon to have a transmitter with a high power rating, only a fraction of which is radiated by the antenna.

Radio waves are similar to light waves in that their intensity varies inversely with the square of the distance from the source. Therefore, if the transmission path is excessively long for a given radiated power, the signal may be too weak at the reception point to permit detection.

The skill or ability of the radio operator to reach weak signals is the least predictable of the factors which establish the LUHF, but it is sometimes the determining factor. It is well known that continuous wave signals may be received more easily than voice signals. One agency maintains that fifty times more signal strength is required for voice signals than for continuous wave signals. It is possible under unusual circumstances for the LUHF to have a higher value than the MUF.

Predictable Ionospheric Variations. Since the ionosphere exists primarily because of the ultraviolet radiation of the sun, it is evident that any variation in the strength of this radiation will cause a corresponding change in the make-up of the ionosphere. Some of the variations are periodic and their effects on radio frequencies may be anticipated. Others are unpredictable and while their effects are pronounced, there is little that can be done at the present time except to realize that they may occur. There are three types of normal variations: daily, seasonal, and sunspot.

The twenty-four hour rotation of the earth about its axis causes not only a variation in intensity of the visual light, but also a corresponding variation to the intensity of the ultraviolet radiation that passes through the ionosphere.

During the day, the ionosphere consists of four ionized layers. At night, however, only one weakly ionized layer exists; it is known as the "nighttime F2 layer." The nighttime F2 layer is formed by a combination of the daytime F1 and F2 layers which merge just inside the night area. If the same frequency is used for night transmission as for day transmission, the signal will force its way through the weakly ionized nighttime F2 layer. The critical frequency of the nighttime F2 layer, therefore, is lower than in the daytime. Consequently, the nighttime transmission frequencies must be lower than those employed in the daytime.

The seasonal variation in the ionosphere is due to the change in intensity of the ultraviolet light reaching the earth's atmosphere as the earth moves in its orbit around the sun. The earth is nearer the sun in December than in June; therefore, the ultraviolet light is more intense in December. This results in a more highly ionized ionosphere and higher critical frequencies in December than in June.

The third predictable variation is that of the sunspot cycle variation. Sunspots are so named because they resemble spots or craters when viewed through a telescope. Their cause is still obscure, but it has been ascertained that their number and intensity vary through a complete cycle, i.e., from maximum to maximum, within a period of nine to thirteen years, the normal period being eleven years. The ultraviolet radiation is more intense at a sunspot maximum than at a sunspot minimum.

Unpredictable Ionospheric Variations. The

unpredictable ionospheric variations are ionospheric storms and "sporadic E," (see definition below.)

An ionospheric storm is any marked or sudden deviation from normal conditions of layer height or critical frequency. Such storms may last for a few minutes or for several weeks and have a tendency to repeat every twenty-seven days, coinciding with the period of solar rotation. Some evidence tends to correlate these storms with solar activity. Ionospheric storms are most prevalent during unusually violent sunspot activity, when gigantic eruptions may be observed on the surface of the sun. The effects of ionospheric storms are most noticeable in the **auroral zones** (belts entering roughly around the north and south geomagnetic poles of the earth). During these storms, a normally reliable frequency may become unworkable and radio signals may weaken or disappear entirely. It is believed that these unusual disruptions of communications are caused by a tremendous increase in ultraviolet radiation of the sun, brought about by the eruptions on its surface. This strong ultraviolet radiation saturates the ionosphere to such an extent that radio signals are obsorbed rather than returned to the earth.

Another unusual condition that affects radio communication is **sporadic E.** Sporadic E consists of intensely ionized patches or clouds lying within the E layer of the ionosphere. The ionization in these patches is considerably above the ionization normally expected in this layer. It is not readily predictable, and therefore cannot be relied upon for dependable communication. It has been found to be more prevalent, however, during the early spring months in the northern latitudes. The greatest effect of sporadic E is to permit abnormally long distance transmission of VHF radio signals, sometimes as far as 1,500 miles. It may cause errors of 180 degrees in the signal path. This will be of great importance to the VHF direction finding and homing stations if sporadic E transmission is encountered during their employment.

Single and Multi-Hop Transmission. Since there is a definite limit to the heights of the layers, it may be shown geometrically

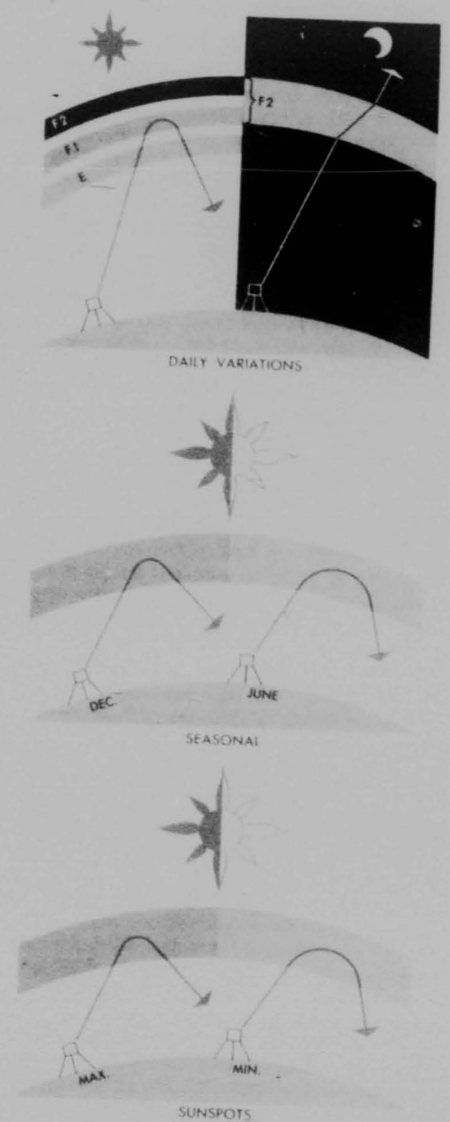


Figure 3-69 Predictable Ionospheric Variations

THIS PAGE IS DECLASSIFIED IAW EO 13526

that there is also a limit to the distance along the earth's surface over which a sky wave can pass in one "bounce." For the F2 layer this maximum distance is 2,500 miles, for the E layer, 1,250 miles. When the distance between the two ends of the transmission path is equal to, or less than, the maximum distance, the signal will traverse that distance in one bounce. This is known as single-hop transmissions. When the transmission path is greater than the maximum distance more than one bounce is required for the signal to be bounced, or refracted, back to earth. The point at which the reflection from the earth takes place is called the control point. In single-hop transmission, there is only one control point which is located at the midpoint of the transmission path. In multi-hop transmission, the signal may bounce between the earth and the ionosphere many times before reaching the end of its transmission path. This introduces the interesting possibility of many control points. However, in actual practice it is necessary to establish only two control points. These control points are located 1,250 miles from each end of the transmission path. It is the condition of the ionosphere at these control points which determines the maximum usable frequency for any transmission.

Fading. Two or more parts of a wave may follow slightly different paths in traveling to the receiving point, in which case the difference in path lengths will cause a phase difference to exist between the wave components at the receiving antenna. The field strength, therefore, may have any value between the numerical sum of the components (when they are all in phase) and a zero (when there are only two components and they are exactly out of phase). Since the paths change from time to time, this causes a variation in signal strength called fading. Fading also can result from the combination of single-hop and multi-hop waves, or the combination of a ground wave with a sky, or tropospheric, wave. Such a condition gives rise to an area of severe fading near the limiting distance of the ground wave with better reception being obtained at both longer and shorter distances where one component is considerably stronger. Fading may be rapid or slow, the former type resulting from rapidly changing conditions in the ionosphere, the latter occurring when transmission conditions are relatively stable.

It frequently occurs that transmission conditions are different for waves of slightly different frequencies, so that in the case of voice-modulated transmission, involving frequencies differing slightly from the carrier in frequency, the carrier and various side band components may not be propagated in the same relative amplitudes and phases they had in the transmitter. This effect, known as "selective fading," causes severe distortion of the signals, especially in the case of frequency-modulated signals received over other than line-of-sight paths. The distortion results from the fact that the instantaneous frequency of the FM signal is subject to continual variation, so that when two waves reach a receiving antenna by different paths, they differ in instantaneous frequency. The result is a combined wave in which components of both amplitude, and frequency modulation make up a new modulation at a frequency which is not harmonically related to the modulation impressed at the transmitter, but which depends upon the differences in transit time for the different paths traveled by the waves. The resulting distortion is greatest at high modulation frequencies and with high depths of modulation.

Tropospheric Propagation

The troposphere is that part of the earth's atmosphere occupying a space above the surface of the earth to a height of about six miles in which temperature generally decreases with altitude, clouds form, and convection is active. Variations in coverage of radio and radar equipment are caused by atmospheric factors which are in the troposphere. The influence of these factors are most noticeable in the VHF, UHF, and SHF bands.

The rapid and accurate evaluation of radio and radar signals is dependent to a great extent upon our knowledge and understanding of the effects produced by the variable conditions of the lower atmosphere.

U.S. warships in the Pacific, in several instances, have picked up targets by radar

at distances four or five times greater than those obtained under normal conditions. Enemy ships far beyond the horizon have been located and sunk by radar controlled gunfire. On some occasions, military coastal radars have tracked convoys twenty to thirty miles beyond normal radar ranges. Yet, a few hours later, these same radars have failed to detect targets clearly visible to the eye. While these conditions are unusual, they do occur frequently enough to cause considerable concern to the communications officer for he must be able to explain these unusual conditions and interpret them in any tactical situation that may occur. Serious errors and false evaluation of radar presentation, as well as VHF radio transmission may result, if the communications officer does not take into consideration the effects of weather and atmospheric conditions on radar ranges and VHF coverage.

The unusual conditions, which are caused by nonstandard atmosphere, might leave doubt as to the effectiveness of radar and VHF radio. However, understanding and allowing for these phenomena will make a useful instrument more effective, will make the weather work for, instead of against, radar and radio equipment.

These unusual ranges are caused by bending or refraction of the radio waves in the atmosphere. An important special case of refraction is the concentration of the wave energy in ducts within the atmosphere. The bending and duct formation is a direct result of the meterological factors involved and in many cases is peculiar to the locality and season. These factors will be discussed later.

Bending. It is usually assumed that VHF, UHF, and SHF radio waves travel along the line-of-sight from the transmitter to the receiver, and, in the case of radar, to and from the target. Experience has shown that this assumption, nearly true in many instances, may lead to serious errors or false evaluation if the meteorological conditions vary from those upon which the assumption is based.

Radio waves are bent from a straight line path as a result of refraction by the lower atmosphere. This bending, or refraction, is generally recognized as a property of light. It is equally a property of radio waves. The underlying principles are exactly the same.

The quality that determines refraction is called the index of refraction. Refraction occurs whenever there is a change of index of refraction, as at the boundary of two substances. In the interior of a homogeneous material, the index of refraction is constant and the rays travel in a straight line. The greater the difference in the index of refraction between two materials, the greater will be the change in the direction of the ray's travel.

Radio waves are refracted or bent in the atmosphere since the index of refraction changes with height. The properties of the atmosphere which determine the index of refraction and which change the height are temperature, pressure, and moisture content. These changes from one level to another are very small when compared to the change between that of water and air, and the resulting refraction is very small. Nevertheless, this refraction is of great importance in radar operations and radio communications at frequencies about thirty megacycles. It is only the exceptional case which permits communications to be carried on by means of the ionosphere, and, as already pointed out, these cases are unpredictable and, therefore, unreliable. The principal means of transmission at frequencies above thirty megacycles is the troposphere.

If the atmosphere were composed of a number of successive layers each having a different index of refraction, a wave passing across successive boundaries would encounter an abrupt change in direction at each boundary surface. However, the atmosphere does not exist in distinct layers, but, in such a state that the changes in its physical properties and index of refraction are gradually, but continuously, changing. Therefore, there is no sudden change in the direction of the wave, but a continuous gradual change in direction as the waves pass through the atmosphere. Radio waves passing through the lower atmosphere are normally bent downward.

Figure 3-70 illustrates the actual vertical pattern of a radar set. It is observed that the radio line-of-sight is somewhat greater

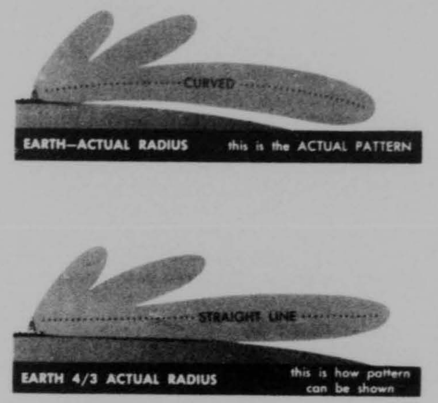

Figure 3-70 Radar Lobe Patterns

than the optical line-of-sight. This is due to the refraction of the radio waves by the atmosphere. Under average weather conditions, the horizon distance is increased approximately 15 per cent. However, at low elevations in the vicinity of the first lobe, the range increases will not be this great. The vertical dimensions in Figure 3-70 have been greatly exaggerated so that the earth's curvature becomes clearly visible. This figure depicts normal or standard propagation.

It is inconvenient to draw curved rays in constructing radar coverage and calibration diagrams. It would be very convenient if the radius of the earth could be increased to some fictitious value that would compensate for the refractive bending of the radio waves under standard conditions and permit the radio waves to be treated as if they traveled in straight lines. Analysis of the normal atmospheric conditions and the associated refraction has shown that if the earth's radius is increased by a factor of 4/3 this situation will exist. Figure 3-70 illustrates the lobe as it may be plotted using the radius of the earth as 4/3 of its true value.

Wave propagation will deviate from the norm under special weather conditions and is called "guided propagation," "trapping," or "super refraction"—sometimes referred to as "anamalous propagation." The principal feature of this type of propagation is an excessive bending of the radio waves due to refraction. This bending occurs principally in the lower portion of the atmosphere and mainly in the lowest few hundred feet. However, in certain regions, notably the warmer climates, excessive bending has been observed as high as 5,000 feet. The amount of bending in regions above this height is normally that of standard atmosphere. Figure 3-71 illustrates the normal radar pattern under normal atmospheric conditions. Figure 3-72 illustrates the shape that a radar pattern may assume under nonstandard atmospheric conditions.

The fact that atmospheric influences are effective only in the lower layers does not imply that the signal strength from the target will be affected only if it is in these layers. The greatest effects will be observed in the lower portions of the coverage pattern although variations in the pattern may be expected to extend to considerable heights. The excessive bending is suffered by the rays only while passing through the lower layers.

Two factors are operative in producing a rapid change of the index of refraction with height. They are variation of moisture with height and variation of temperature with height. Excessive refraction occurs when there is a rapid decrease of moisture with height **(moisture lapse)** and, to a lesser degree, when there is a rapid decrease in temperature with height **(temperature inversion)**. The most pronounced cases of excessive refraction occur when both of these conditions prevail, simultaneously. These conditions will be discussed later from the meteorological viewpoint.

Since the atmosphere is a very tenuous substance, the amount of refraction is very small and in no case exceeds a fraction of a degree. How then can these small effects influence radar operations? The answer is that they do not influence operations unless the angle between the wave path and the horizontal is very small. If a radar is used for fire control, search-light control, or ground-controlled interception, the targets are usually at medium or short ranges, and the angle between the line-of-sight to the target and the horizontal is usually greater

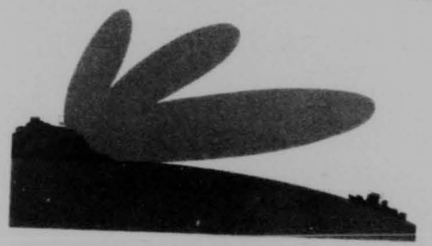

Figure 3-71 Radar Lobe Patterns in Standard Atmosphere

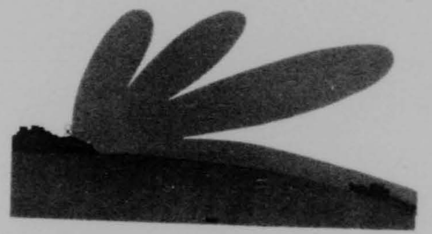

Figure 3-72 Radar Lobe Patterns in Nonstandard Atmosphere with Duct Formed

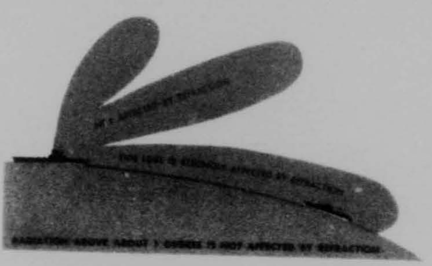

Figure 3-73 Refraction of Radar Lobes

than one or two degrees. Refraction has practically no effect on such radar applications. Figure 3-73 illustrates this point. Note that the height scale is greatly exaggerated in comparison to the range scale.

The same equipment, however, may be used for long-range search and then the picture is different. With long-range search radar the target may be an aircraft fifty or a hundred miles away, and flying at an elevation of a few thousand feet. In this case, the angle of elevation of the target above the horizontal, as seen from the radar, is only a fraction of a degree. The angle of elevation decreases as the elevation of the target decreases until the limiting condition of seaborne targets is reached. Thus, in this case, the atmospheric effects become operationally important. It must be kept in mind that only low-angle search is affected by meteorological conditions.

As a general rule, the operational characteristics of a radar observing targets with elevation angles exceeding one degree may be calculated on the assumption of a standard atmosphere, with confidence that all nonstandard meteorological effects are negligible.

Guided Propagation. Radio signals may be guided through the atmosphere much in the same manner as in waveguides if the proper atmospheric conditions are present. Within the duct there is less decrease of signal strength with distance than there is above the duct: (The waveguide in space is called a "duct.") Radar ranges on surface craft and low-flying aircraft located within a duct, similar to the one illustrated in Figure 3-72, are increased sometimes to two, three, or four times the normal ranges. Ground echoes will be increased at the same time and might partly or entirely obscure the echoes from the incoming aircraft. While this additional range is very desirable, operational procedures are rarely set up to take advantage of this condition since it is difficult to predict its occurrence and impossible to control.

In Figure 3-74, wave paths are illustrated as rays.

Ray No. 1 is bent so much that after some distance it returns to the ground; there it is reflected and then the same course is repeated. In this way, the ray may be reflected a number of times in succession, remaining always in the lowest layer. This superrefraction **traps** the rays in a **duct**, and results in guided propagation of the radar waves. Trapping does not occur under standard atmospheric conditions. A ray, under normal conditions, may be reflected by the earth's surface only once before it escapes into space.

THIS PAGE IS DECLASSIFIED IAW EO 13526

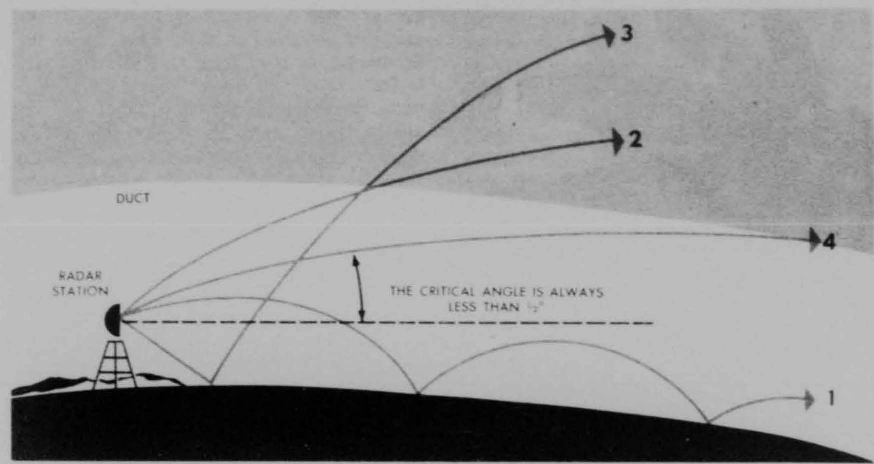

Figure 3-74 Guided Propagation

Ray No. 2 is also bent in the lowest layer, but not enough to keep it from escaping into the upper atmosphere whence it does not return to earth.

Ray No. 3 is similar to No. 2 except that it undergoes one reflection by the ground before it escapes into the upper atmosphere.

Ray No. 4 separates the two types of rays illustrated by rays 1 and 2. This ray becomes horizontal when it reaches the top of the trapping layer, or duct, and from there on travels along the same height. All rays are divided into two groups: those that leave the transmitter at an angle with the horizontal less than the critical angle and are trapped, and those that leave the transmitter at a larger angle and proceed into the upper atmosphere.

The critical angle is always small, practically never larger than ½°. Its magnitude may be taken as a measure of the intensity of guided propagation, that is, of the amount of radiation energy trapped within the duct. Rays that leave the transmitter at a somewhat larger angle are sufficiently deflected while passing through the lowest layers to distort that part of the radar coverage pattern lying just about the duct. Rays leaving the transmitter at a still larger angle are not appreciably affected.

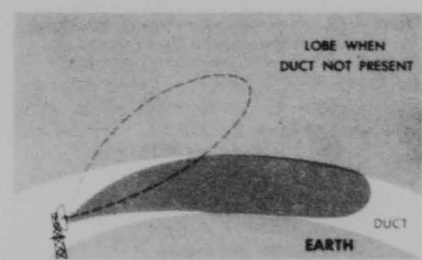

Figure 3-75 Ground-Based Duct

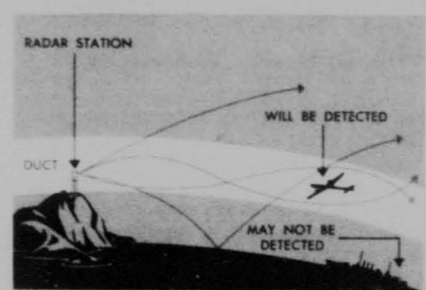

Figure 3-76 Elevated Duct

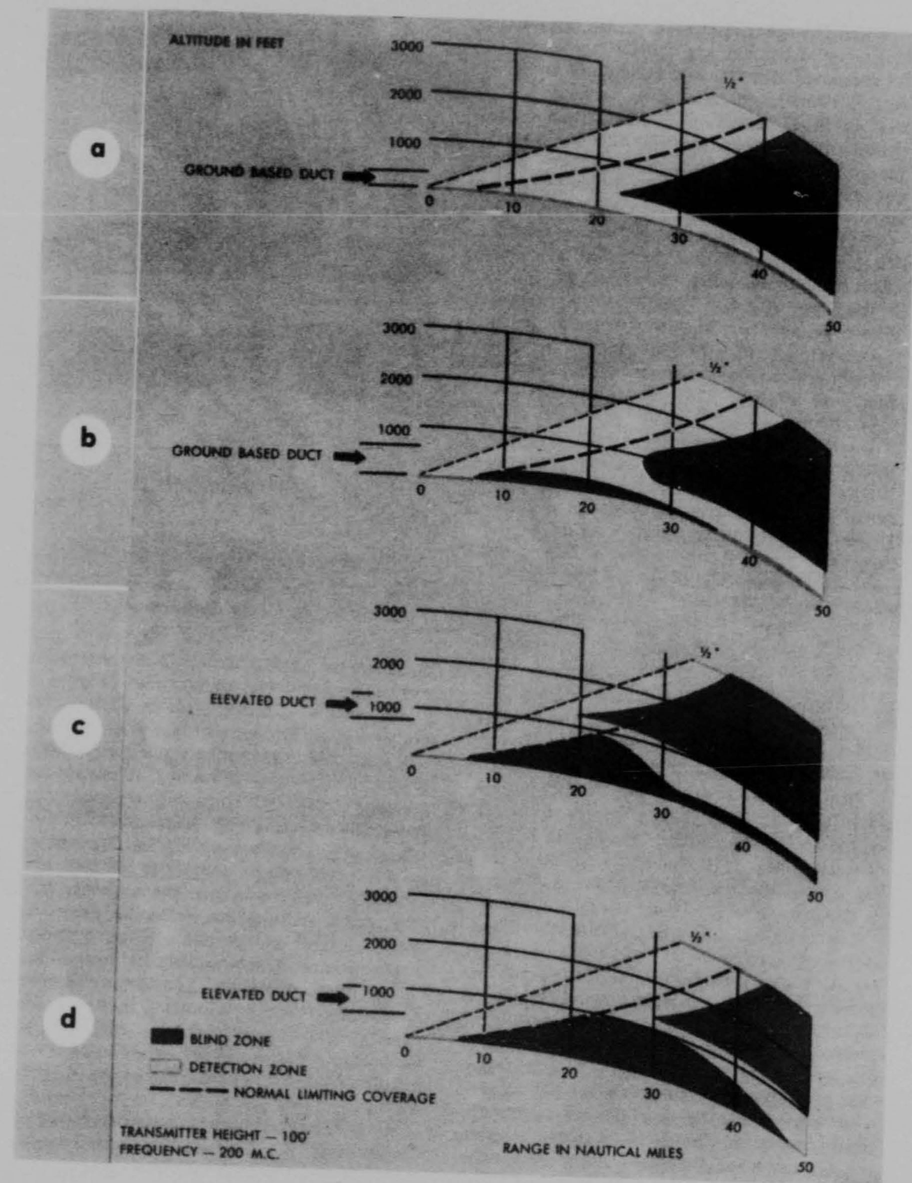

Figure 3-77 Deformation of Lower Lobes

When the radar is located within the duct, ranges on aircraft flying above the duct may be decreased slightly, and frequently the effective range may be slightly increased. If the angle of elevation of the aircraft is greater than one degree, the effects become inappreciable and failure to detect the target cannot be attributed to excessive refraction.

The guided propagation is noticed in the VHF, UHF, and SHF bands. The greatest effect is observed when the wavelengths are in the order of a few centimeters. However, guided propagation has been reported with wavelengths up to one and one-half meters.

Figure 3-75 illustrates the ground-based duct and Figure 3-76 illustrates the elevated duct.

Interference between the direct rays and the rays reflected from the ground, resulting in the well known lobe pattern of the coverage diagram, have not been mentioned. Under standard atmospheric conditions the position of the lobes depend only on the wavelength and the height of the antenna above the ground.

When a duct is present, the lowest part of the coverage diagram may be strongly distorted as is illustrated in Figure 3-77.

Meteorological Factors. In the troposphere the atmosphere is responsible for the normal and abnormal bending of the radio waves. In order to understand this phenomenon, it is necessary to consider the meteorological factors involved.

The refractive index of the atmosphere is defined as the "ratio of the velocity of radio propagation in vacuum to the velocity in the atmosphere." Under standard atmospheric conditions, there is a normal index of refraction which decreases gradually as the altitude is increased. Nonstandard atmosphere has an index of refraction which decreases gradually as the altitude is increased. Nonstandard atmosphere has an index of refraction which is different from that of standard atmosphere and which decreases more rapidly than normal as the altitude increases. The decrease depends upon the distribution of moisture and temperature in the atmosphere, particularly in the lowest few hundred or thousand feet.

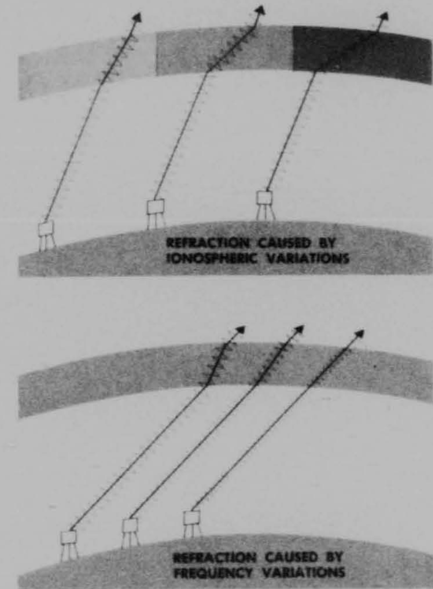

Figure 3-78 Refraction

Normally, the atmospheric temperature decreases at approximately 2 degrees centigrade per 1,000 feet of altitude. (Figure 3-79A). However, under some conditions, the air temperature may increase with altitude. Figure 3-79A shows a normal temperature gradient. Figures 3-79B and C illustrate two temperature distributions known as temperature inversions.

The moisture content of the atmosphere behaves in a manner similar to temperature. Under normal conditions, the moisture content of the atmosphere gradually decreases with increasing altitude. (Figure 3-80A shows normal moisture distribution.) When the moisture content of the atmosphere behaves other than in a normal manner, it is called a "moisture lapse." (Figure 3-80B and C illustrate two possible ways the moisture content of the atmosphere may be distributed.)

A moderate or strong moisture lapse almost always will produce the wave trapping which is necessary for guided propagation, while a temperature inversion will lead to trapping only if the moisture distribution

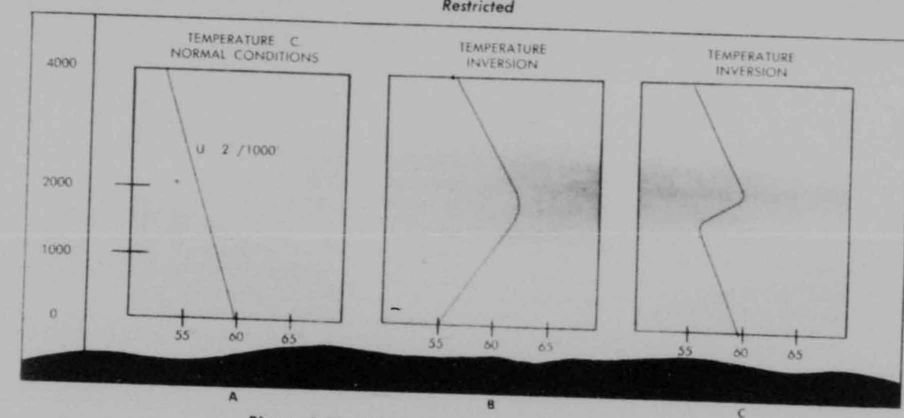

Figure 3-79 Atmospheric Temperature Distribution

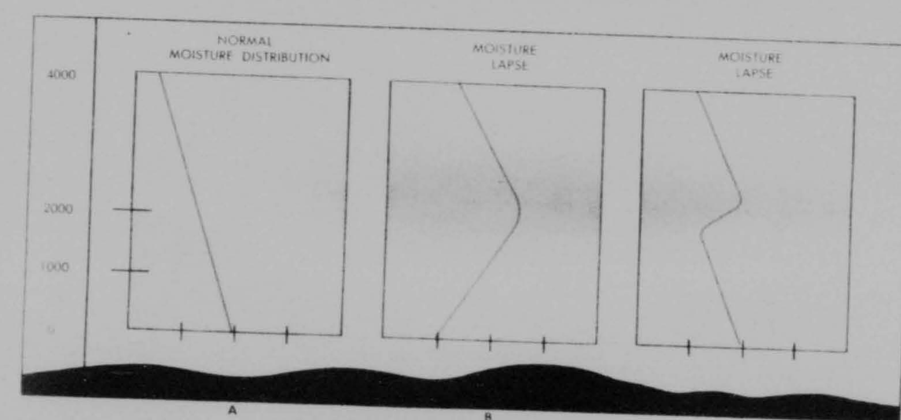

Figure 3-80 Atmospheric Moisture Distribution

is favorable. However, a combination of a moisture lapse and a temperature inversion within the same layer will usually produce trapping. This weather condition is one of the most common causes of guided propagation. An example in point is the Mediterranean, which to the south, east, and west is surrounded by dry land masses which produce a flow of dry, warm air over the water when the winds are blowing from land to sea across the eastern boundary of a continent. Land and sea breezes may influence radar operation across a coast line. The wind direction at a coast is often an important factor in determining propagation conditions and should be closely observed. Whenever unusual propagation is detected by coastal radar stations, a record of prevailing winds at the time is very helpful in the determination of anticipated performance.

Over Land. Temperature inversions are produced mainly by night-cooling of the ground. Trapping may occur when the moisture distribution in the lowest layers is such as to reinforce, or at least not to counteract, the effect of the temperature distribution—that is, when the moisture decreases not too slowly with height. Night-cooling is greatest with clear skies and is quite small under an overcast. Hence, guided propagation over land occurs at night almost exclusively with clear skies. This type of temperature inversion is strictly confined to land areas. It does not occur over the ocean because the sea temperature does not show appreciable daily variations. Temperature inversions caused by night-cooling are most pronounced over dry land (desert) but will occur almost anywhere over land with a clear sky and a not too humid atmosphere.

Another phenomenon favorable to trapping is **subsidence.** By "subsidence" is meant the slow downward motion, combined with horizontal spreading, of air above the lowest layers of the atmosphere (Figure 3-81). This process, which most frequently occurs in the area of barometric high pressure, will produce temperature inversions; the subsiding air moreover becomes relatively much drier than the unaffected air below. In general, the subsidence inversion is quite high (e.g., above 4,500 to 5,000 feet). In the light of present knowledge, it appears that high subsidence inversions do not generally affect guided propagation when the sets are situated at low altitudes. It appears, however, that such subsidence inversions might materially affect communications on airborne radar search. Lower subsidence inversions (1,000 to 2,500 feet) along the southwestern coast of the United States are known to produce stable duct layers affecting radar coverage at low angles.

Turbulence of the air has a distinct normalizing effect in that it tends to smooth out the temperature and moisture variations which are conducive to guided propagation. Moderate to strong winds produce a turbulent layer extending normally to a height of about 4,000 feet. The air is well mixed within this layer and consequently the standard type of refraction prevails. Regions of a barometric low pressure are characterized by strong to moderate winds and pronounced turbulence in the lower layers. In addition, low pressure areas usually have overcast skies. Hence, a barometric low pressure will as a rule, lead to standard propagation.

It is extremely difficult to estimate in general terms the frequency of occurrence of guided propagation, since statistical data is almost nonexistent at present, except for very limited regions in Europe, such as the North Sea. In the Central Mediterranean during the summer months of 1943, ducts were observed on nine days out of ten. Frequent trapping has also been observed in some parts of the Pacific. At other times and places, guided propagation might be an unusual occurrence, especially if the barometric pressure is generally low and the winds strong. It seems advisable to consult a weather officer with regard to any given locality.

In order to determine weather's influence upon radar in a quantitative way, the variation of refractive index with height must be determined. This requires accurate knowledge of the temperature and moisture distribution in the lowest few hundred or thousand feet of the atmosphere. The ordinary radiosonde is not well adapted to measurements of this type because the measured points on an ascent are usually spaced several hundred feet apart. Among the methods which have been developed for this purpose during the past two years, the one most generally adopted uses a captive balloon (or kite) which carries aloft electrical temperature and moisture measuring elements. These are connected to a meter on the ground by means of thin wires attached to the cable holding the balloon. This device permits measurements at such closely spaced intervals as may be desired. A psychrometer held outside the window of a slow-flying plane has been used with some success in the absence of more elaborate equipment.

The following is a summary of basic facts concerning propagation at VHF, UHF, and SHF frequencies:

Standard propagation results in a slight downward bending of the rays throughout the atmosphere, leading to an increase of the horizon distance compared to the geometrical value. It is taken into account operationally by the use of covering diagrams with a 4/3 earth's radius; on a diagram modified in this way the rays appear as straight lines.

Guided propagation occurs almost exclusively in the lowest 2,000 feet above the

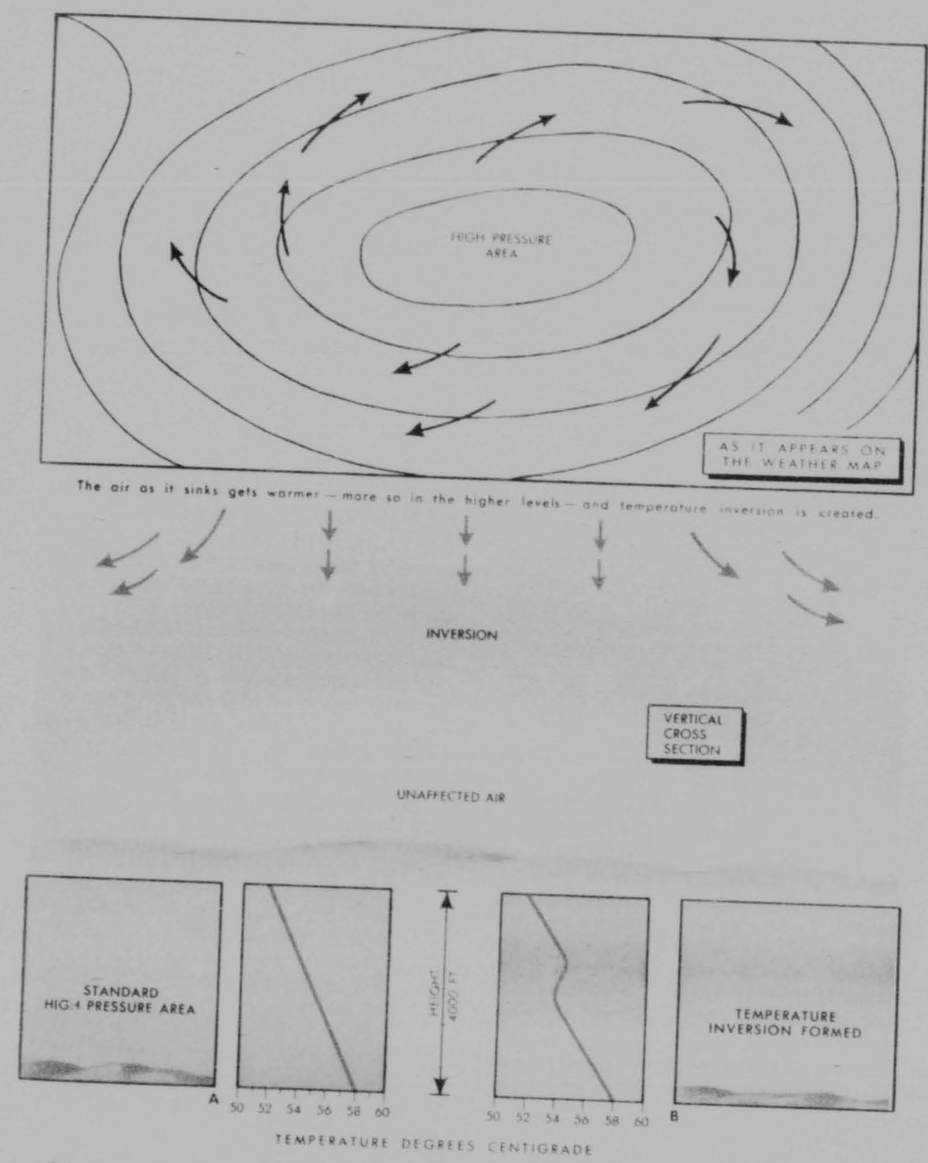

Figure 3-81 Subsidence (Sinking) in High Pressure Areas

THIS PAGE IS DECLASSIFIED IAW EO 13526

ground, and usually is confined to the lowest few hundred feet (except in warm climates).

Super-refraction resulting in guided propagation or trapping is produced:

a) By a pronounced decrease of moisture with height (moisture lapse), or

b) By a pronounced increase in temperature with height (temperature inversion), and

c) Particularly, by a combination of both of these two conditions.

Of the meterological conditions conducive to guided propagation or trapping, the most outstanding are:

a) Over sea—flow of warm, dry air over cooler water producing temperature inversions and evaporation into the lowest layers.

b) Over land—night-cooling of the ground with clear skies and calm air or light winds (if moisture distribution is favorable).

c) Over both sea and land—low level subsidence.

Conditions in a barometric high, including calm and clear skies and especially low level subsidence, favor trapping especially during the night (but do not necessarily produce it). Conditions in a barometric low, including strong winds, intense turbulence in the lowest layers, and overcast skies are conducive to standard propagation.

When the transmitter is within the duct, radar range is increased for surface targets (ships) and aircraft flying in the duct. At the same time there is an increase in fixed echo strength and consequently in ground clutter on the indicator. This may be accompanied by a change in the range of detection for craft flying above the duct.

When the transmitter is outside the duct, the range may either be increased or decreased from its standard value.

Effects of **nonstandard propagation** are negligible when the angle of elevation of the target is over 1°. Failure of detection at such angles must be attributed to other causes.

These echoes are caused by a reflection of the radar pulse from the rain drops in the clouds (or in rain storms). The amount of reflection increases rapidly as the frequency is increased. This occurs because the wavelength of the radio energy is approaching the same dimensions as those of the raindrop. Precipitation echoes are the exception at frequencies below 1,000 megacycles. In the application of microwaves to radar, these precipitation echoes at first appeared to be a nuisance. Recently, however, the precipitation echoes have been put to practical use in the field of weather observations. Storm detection radars are employed to chart the movement of storms and have proved successful in following the course of a storm.

Ground Wave Propagation

The ground wave is considered to be that portion of the radio wave which is affected by the presence of the ground and which would account for all the energy reaching the receiver if it were not for the ionospheric waves and tropospheric waves.

The ground wave can be divided conveniently into two components, a surface wave and a space wave.

Surface Wave

The surface wave is continuously in contact with the surface of the earth, and in cases where the distance of transmission makes the curvature of the earth a factor, extends its range by diffraction. The surface wave is practically independent of seasonal, dry, and night effects at frequencies above approximately 1,500 kilocycles.

The wave induces a current in the earth while traveling along its surface. If the earth were a perfect conductor, there would be no loss of energy, but the earth has appreciable resistance, and consequently causes an energy loss. This loss is made at the expense of the surface waves. Therefore, the range of the transmitted energy depends upon the characteristics of the earth over which it travels. Since sea water is a better conductor than the earth, a greater range will be attained. The losses, by attenuation, of the radio energy increase rapidly with increasing frequency so that at high frequencies the surface wave is unimportant, except for local communication. The surface wave range at frequencies in the vicinity of 2 mc is approximately 200 miles over average earth and perhaps two or three times greater over sea water for a transmitter radiating approximately 500 watts.

Space Wave

The space wave is the result of two component waves as illustrated in Figure 3-82, namely, a direct ray and a ground-reflected ray. When the transmitting and receiving antenna are both at the earth's surface, these two components of the space wave are equal in magnitude and opposite in phase thereby cancelling and leaving the surface wave as the only component of the ground wave. This is the case of **ground wave** transmission of broadcast frequencies, as the antenna heights are increased, however, the amplitude of the space wave rapidly increases, and soon becomes the principal part of the ground wave. This is the condition existing in the VHF and higher portion radio spectrum when the antennas are raised a few wavelengths above the earth.

The magnitude of the ground wave, and of its individual components, the space and surface waves, is influenced by the resistivity and dielectric constant of the earth, the frequency, the height of the transmitting and receiving antennas, the earth's curvature, the distance to the transmitter, and the variation of refractive index of the earth's atmosphere. The electrical constants of the earth affect the rate of attenuation of the surface wave, and also the reflection coefficient to which the ground-reflected wave is subjected. The height of the transmitting and receiving antennas affects the relative amplitudes and phases of the space and surface waves, and so influences the resulting field. The curvature of the earth makes it necessary for both the space and surface waves to diffract around the earth in order to reach a distant receiving point that is obscured by the curvature of the earth. The variation of density of the earth's atmosphere with height, (particularly the variation of moisture content), causes the refractive index of the atmosphere to decrease slowly with height above the earth. This causes the paths followed by the waves to be slightly curved, instead of straight as shown in Figure 3-82. This curvature is in the same direction as the curvature of the earth's surface, but is usually somewhat smaller in amount. However, if the earth's radius is assumed to be 4/3 its true value, then Figure 3-82 is correct since it takes into consideration the normal refraction.

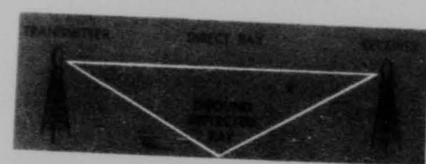

Figure 3-82 The Space Wave

The energy loss in ground absorption by a wave traveling close to the ground decreases rapidly with its height in terms of wave, therefore, can be relatively close (in wavelengths above the ground. A VHF direct physical height) to the ground without suffering the absorption effects which would occur at the same physical height with longer wave lengths.

Range Versus Height. Since the direct wave travels in practically a straight line, the maximum signal strength can be observed only when there is an unobstructed atmospheric path between the transmitting and receiving antennas. In other words, the antennas should be sufficiently elevated to provide such a path. On long paths, the curvature of the earth must be taken into consideration, as well as mountains or other obstructions.

Let us consider the height required to provide a clear line-of-sight over level terrain from an elevated transmitting point T (Figure 3-83) to a receiving point A on the earth's surface, neglecting for the moment the atmospheric refraction.

h = height of transmitter
d = distance between transmitter and receiver.
R = Radius of earth (4,000 miles)

The problem is to find h in the terms of the other quantities.

$$(R + h)^2 = R^2 + d^2$$
$$R^2 + 2Rh + h^2 = R^2 + d^2$$

The term h^2 is small compared to 2RH and, therefore, may be neglected without causing appreciable harm.

Then: $d^2 = 2Rh$ or $d = \sqrt{2Rh}$

In the practical application of this formu-

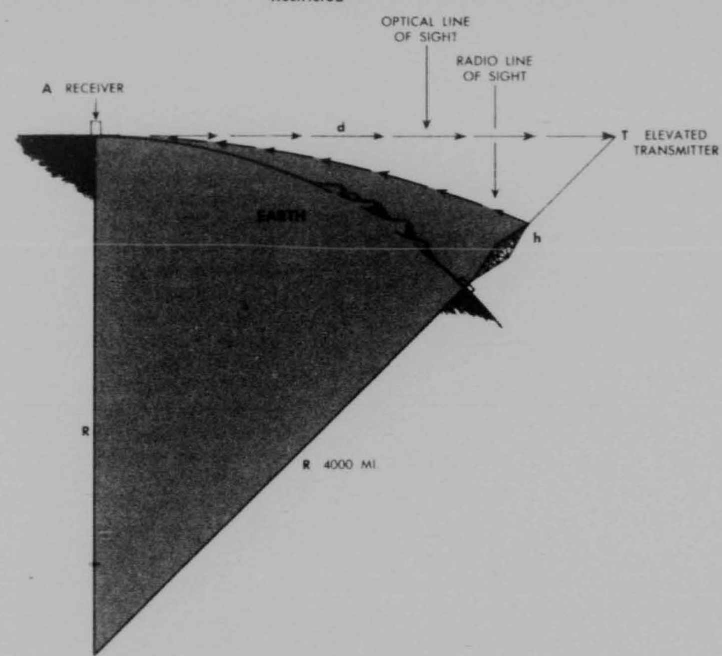

Figure 3-83 Curved Earth Geometry

la, it is desirable to express d in miles and h in feet. When this is done, the equation becomes:

$$d = \sqrt{1.51\,h}$$

However, when normal refraction is considered, the earth's radius then becomes 4/3 its true value and equation 22 then becomes:

$$d = \sqrt{2h}$$

When the transmitting and receiving antennas are both elevated, the maximum direct wave distance to ground level can be determined separately for each. Adding the two distances thus obtained will give the maximum distance over which direct wave communication may be had.

$$d = \sqrt{2h_1} + \sqrt{2h_2}$$

Where:

d = total distance in miles between transmitting and receiving antennas

h_1 = transmitting antenna height in feet

h_2 = receiving antenna height in feet

The subject of ground reflection and lobe formation has been discussed earlier in this section.

8. RECEPTION

General

The radio receiver has the function of converting radio waves into the original intelligence. Regardless of the type of modulation employed at the transmitter, the purpose of the receiver is to perform this conversion.

The receiver accomplishes this purpose by:

Collecting the transmitted signal.
Selecting the desired frequency.
Amplifying the radio frequency.
Detecting the signal.
Amplifying the detected signal.
Reproducing the signal from electrical current to sound waves.

Collecting the Signal

Just as the transmitting antenna acts as a radiating coil to generate magnetic waves, so does the receiving antenna act as a coil to intercept the magnetic waves. The magnetic waves produce a flow of current in the antenna which are brought into the receiver. For maximum efficiency, the receiving antenna should have the same polarization as the transmitting antenna, and the higher the frequency the more critical the size of the antenna.

Selecting the Signal

The first stage of the receiver is normally a series resonance circuit, that is, a coil and condenser in series with the antenna. The series resonance circuit is so designed that impedance is at a minimum only at one frequency. After the signal is established, succeeding circuits are parallel resonant circuits in which the impedance is highest at the desired frequency. This is necessary because each of the circuits feeds into high impedance vacuum tubes. The circuits must have an input which matches the impedance of the tubes.

Amplifying the Radio Frequency

All radio frequencies are of such low value when they reach the receiver that it is necessary to amplify them before it is possible to convert the signals to sound through detection and reproduction. Radio frequency amplifiers are normally class A.

Detecting the Signal

The purpose of the detector is to extract or recover from the modulated radio frequency the audio frequency which in turn can be converted to sound waves—the radio frequency signal does not carry an audio frequency component. The signal as transmitted through space is merely in the form of amplitude, pulse position, or frequency variations of the carrier wave, in no way is an audio component transmitted as such.

In the detection of radio signals superheterodyne, AM, or FM types are used.

A typical amplitude modulation type detector is the diode detector. (See Figure 3-84A). In this circuit, the cathode and plate are tied together and are connected at ground potential. No potential other than that of the impressed signal is on the plate. When the positive signals of the incoming cycle are applied to the grid, electrons will flow through L_1, R_1 and R_2 returning to the cathode.

An EMF across R_2 is built up through this process which charges C_2. Negative signals produce no current flow in the tube so the built-up charge leaks off through the resistors. This results in a series of voltage pulses (see Figure 3-84B) which produces a flow of current. The radio frequency component of these voltage pulses is removed by the filtering action of R_1C_3.

Diode detection provides high quality distortion-free signals with a sacrifice of amplification.

The output of the detector stage is amplified, normally, before it is fed into one of the receiving or converting devices which change current variations into sound impulses. With the exception of refinements of manufacture, radio receiving devices are similar to telephone receiving devices.

The typical amplitude modulation-type radio receiver consists of an RF amplifier,

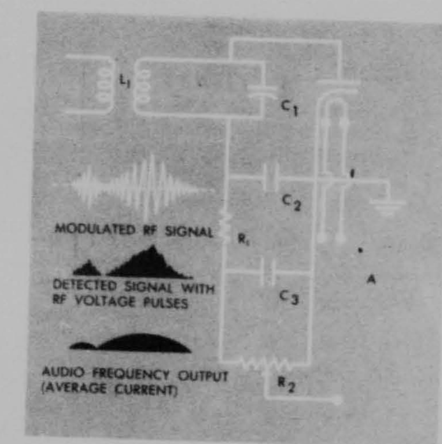

Figure 3-84 Diode Detection

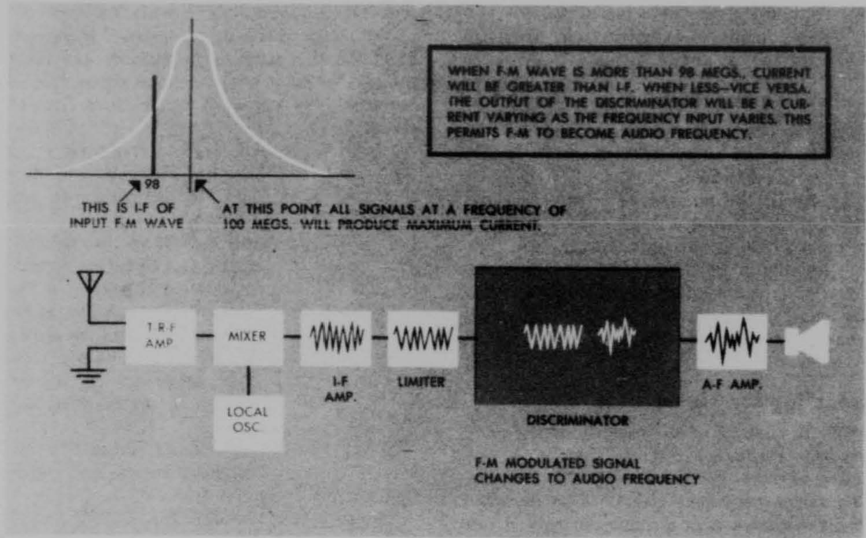

Figure 3-85 Discriminator Circuit

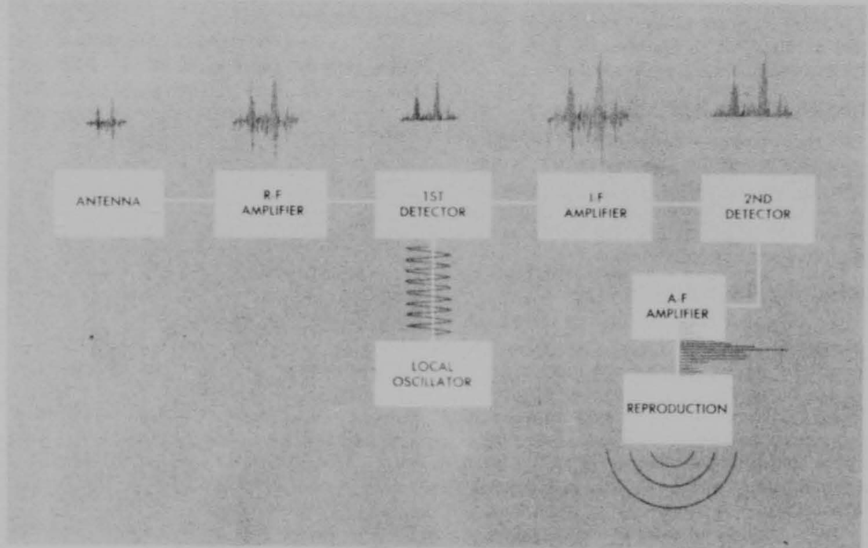

Figure 3-86 Block Diagram of Superheterodyne Receiver

local oscillator, mixer, IF amplifiers, detector, and AF amplifiers. This is shown in Figure 3-86. By adding the necessary components to this type of receiver, it is possible to convert it to a frequency or pulse-time modulation receiver.

The additional components necessary to demodulate frequency modulated signals are the **limiter** and the **discriminator.** A basic requirement of the FM receiver is that it be able to pass the required band of frequencies created by the transmitter. This band width might be as much as eighty kilocycles. A second requirement, and one which is necessary if the full noise-reducing possibilities of the FM system are desired, is a limiting device to remove all amplitude variations of the received signal, so that the signal varies only in frequency before it reaches the detector. A third requirement is that the detector or discriminator be capable of converting frequency variations into amplitude variations.

The **limiter** is a vacuum tube circuit so designed that the circuit will not pass currents above a certain amplitude. This is accomplished by means of tubes having a low plate potential. This low plate potential reduces electron flow regardless of the amplitude of the input signal.

The **discriminator** operates on the principle of applying the incoming frequency modulated signal to a circuit tuned to a slightly different frequency from that of the signal. A higher frequency will cause an increase in the current in the tuned circuit and a lower frequency will cause a decrease in current. (See Figure 3-85).

The additional components necessary to provide reception of audio frequency signals from pulse-time modulated transmitters are so complex in nature that a detailed discussion of the subject is not feasible in this text. The principles involved, however, are simple. Equipment used for this purpose should have the following characteristics: a sensitive receiver which uses the received pulses to activate the multiplex units, similar to those used in the transmitter; the multiplexes which take the pulse variations from the receiver and use them to trigger new pulses which are converted to sound. This conversion is accomplished by varying current flow in accordance with the pulse position.

The Superheterodyne. It is desirable in the receiver to have maximum sensitivity and selectivity. Because of the high bandwidth requirements of all radio systems, maximum sensitivity and selectivity can be obtained only by making a separate circuit for each frequency band. This is somewhat impractical, but it is the only way to achieve maximum efficiency in all stages.

The development of the superheterodyne circuit has substantially alleviated the difficulty. In this circuit, the incoming signal frequency is mixed with the local oscillator frequency. The resulting frequency called the **intermediate frequency** (IF) remains constant, regardless of the frequency of the incoming signal. Consequently, by engineering the following stages of the receiver to give maximum efficiency at this intermediate frequency, we are able to achieve great selectivity, great amplification, and better circuit stability.

The superheterodyne circuit accomplishes this by incorporating a well-shielded oscillator in the set. The output of this oscillator is varied directly with the frequency of the input signal. It is this direct variation that causes the resultant frequency to stay constant regardless of the incoming frequency.

This mixing normally occurs in what is called the **first detector.** The output is amplified and again detected. In effect, the intermediate frequency is a modulated current at a lower radio frequency. In some commercial sets, the local oscillator, detector, and amplifier are combined in one tube, called the "pentagrid converter." In Air Force equipment, the practice is to use a separate oscillator, the output of which is fed to a separate detector or mixer.

Audio Frequency Amplification. The output of the final detector will be a direct current at an audio frequency which by itself has no sound. Because most of the sound reproducing devices utilize varying currents of a fairly high value, it is necessary to amplify further the audio output. This amplification is normally class A or B in push-pull.

THIS PAGE IS DECLASSIFIED IAW EO 13526

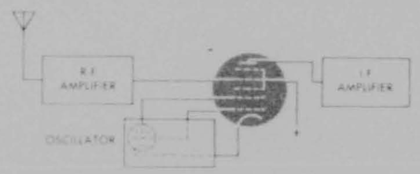

Figure 3-87 Pentagrid Converter

Sound Reproduction. The output of the audio frequency amplifier is ready for conversion into sound waves. Just as the microphone converts sound into electrical energy, so does the reproducer convert electrical energy into sound.

The headset of a radio receiver is identical with that of the telephone in operating principle. A permanent magnet is employed. About this magnet is a coil through which the audio-frequency amplifier output is sent. The variations of current will cause a diaphragm to vibrate and since the variations are at an audio rate the vibrations will be at an audio rate.

The headset does not permit much volume. For this reason a larger unit known as the "loudspeaker" is used. These are identical in principle with the headset differing only in size. The permanent magnet loudspeaker provides its own magnetic field; the dynamic speaker has a field coil which requires an external source of current to supply its magnetic field. The operation of these is identical.

Continuous-wave Reception. The receiver for continuous-wave transmissions must be constructed in the same manner as those receiving voice or tone-modulated signals. It must be realized that the CW transmissions are unmodulated, and, therefore, possess no audio characteristics. For this reason, the audio component must be added to the signal in the receiver itself. This is done with a device known as the **beat frequency oscillator** (BFO). This generates a radio frequency which, when mixed with the incoming signal frequency, produces a frequency that is at an audio rate. This permits an audio frequency to be fed to the final audio amplifier from which point it is fed to the reproducer.

Automatic Volume Control (AVC). Because the strength of radio signals will increase or decrease in transmission, it is necessary to provide a device which will insure a constant volume level. Without such a feature, the operator would be forced to sit at the set and continually operate the volume controls to adjust the output.

A typical simple automatic volume control is shown in Figure 3-88. In the diode detector, the more positive the plate the greater the current flow. Resistor **R** makes **X** negative in respect to **Y**. Therefore, the more positive the current flow on the plate, the more negative point **X** becomes. The grid in the radio frequency amplifier receives its bias from this point **X**. Thus, the greater the signal impressed on the plate of the detector, the more negative the bias on the radio frequency amplifier which in turn reduces the original amplification. Likewise, weak signals allow the grid to become less negative, permitting greater amplification. In this manner, an automatic control of volume is attained.

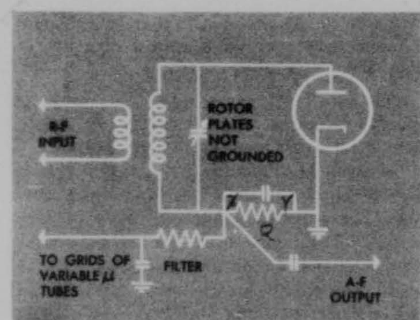

Figure 3-88 Automatic Volume Control

SECTION 3 - MILITARY APPLICATION OF RADIO

1. GENERAL

In conforming to the **six principles of communications**, namely, **reliability**, **security**, **speed**, **economy**, **flexibility**, and **system integration** it is apparent that radio, in its various applications, affords a suitable answer to four of these principles, speed, economy, flexibility and system integration.

In discussing the agencies of radio communication, it is appropriate to consider the reasons for selecting various bands of the spectrum for specific purposes, and their application to Air Force functions.

2. EMPLOYMENT OF THE RADIO FREQUENCY SPECTRUM

The radio frequency spectrum extends, for all practical radiation purposes, from **30 kcs** to **30,000 mcs**. As equipment ranging from huge transoceanic transmitters to miniature pack-carried sets utilize this spectrum, a discussion of the characteristics of each of the frequency bands is essential to an understanding of the various types of radio.

Low Frequency

Low frequencies are used in a few instances by the Air Force, principally for the radio range. Inasmuch as the radio range is a widely used piece of equipment, a discussion of low-frequency equipment is appropriate.

The low frequencies extend from 30 to 300 kcs. It is general practice, however, to extend the low-frequency band to include the wave lengths from 10,000 meters to 600 meters.

Low-frequency radio equipment has certain characteristics which are of sufficient importance to be considered. They are briefly:

a) Ground wave propagation is the best transmission method for low frequencies. Therefore vertical antennas are used.

b) Low frequencies travel great distances over water when vertically polarized. This is because of the high conductivity of water.

c) The easy absorption of low frequencies requires high powered transmission to attain the desired coverage.

d) Because of the long wavelengths used and high power required, low-frequency sets are very heavy and in most cases are used only when permanent installation is feasible.

e) Low frequencies are easily affected by static, limiting their use as a voice communications means.

f) Skywave propagation is of no importance since the ionosphere absorbs low-frequency signals. Global reception of low frequencies cannot be expected at all.

Except for specialized use in the Arctic regions, low-frequency transmissions are of limited value under most conditions.

Typical Low-frequency Equipment. Although low-frequency equipment was used in the early days of radio for communication purposes, the development of higher frequency techniques has resulted in its restricted use. The principle use of low frequency in the Air Force is in the **range stations.** A typical low frequency range transmitter has these characteristics: amplitude modulated, 50-300 watts output, very high vertical antennas, large AC or DC power supplies, and a range of from 30 to 100 miles, increasing greatly over water.

Radio ranges use low frequencies for these reasons:

a) Ground waves are more dependable and provide a steady wave in all directions.

b) Absorption of sky waves prevents reception of spurious signals by the pilot.

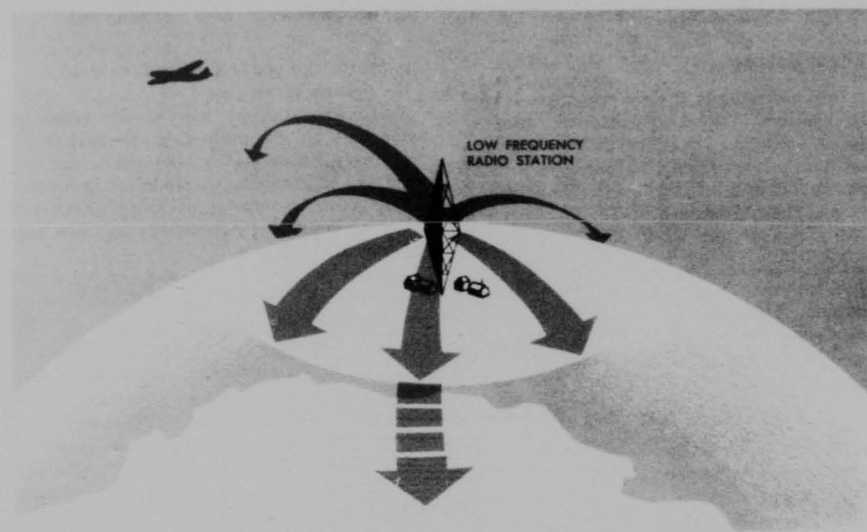
c) When transmitted over water, low frequency gives excellent coverage for very long distances.

(The theory of ranges will be discussed later in this section.)

Medium Frequencies

Medium frequencies (300 kc-3000 kc) provide a band of highly useful frequencies which are used extensively in commercial broadcast work. They have good ground wave range extending to about 100 miles and a nighttime sky wave range in excess of 1000 miles or more.

THIS PAGE IS DECLASSIFIED IAW EO 13526



High Frequencies

High frequencies are in the band from 3000 kcs to 30,000 kcs. Although the present trend of radio communications is toward greater use of the spectrum beyond 30,000 kcs, certain characteristics of high frequencies make the band best adapted for long range radio communications.

Between the low and high frequencies are the medium frequencies in which are included the commercial broadcast stations. For purposes of discussion, these may be considered as being in the high-frequency band.

Disadvantages of High Frequencies. Principal disadvantages of high frequencies are as follows:

a) Ionospheric changes cause fading, sporadic absorption, and seasonal variation in signal reception.

b) Antenna requirements restrict vehicular use. Although high frequency is used for mobile radio equipment, much of the power is lost in loading the antennas which usually are shorter than the required lengths. A compensation device is required to take up this difference in length with a consequent loss of power.

c) Crowded conditions in the high-frequency spectrum require peak frequency stability in high-frequency equipment.

d) Ground wave propagation is of little value in the tropics because of extremely high signal absorption; thus, close range communications must be accomplished by means of sky wave transmission.

e) Power requirements are high and equipment is heavy.

f) High-frequency signals are subjected to distortion caused by static. Storms of an electrical or auroral nature often cause a black-out in communications.

Advantages of High-Frequency Communications. Despite these disadvantages, the backbone of most point-to-point radio communications is high frequency. No other band affords these advantages:

a) Good range under most normal conditions.

b) Extremely long range under favorable conditions.

c) Manner of polarization is not critical unless extreme distance sky wave transmission is desired.

Very-High-Frequency

It can be said without exaggeration that the development of equipment using frequencies from 30-300 megacycles has led to the advancement of much of the tactical employment of radio. It is this band of frequencies, as we shall see later, that has made radar a practicality.

The list of points favoring very high-frequencies over high frequencies is extensive, and many new uses for very-high-frequency equipment will undoubtedly be developed within the next few years. Already we find the high-frequency command radio supplanted by a very-high-frequency unit and within a period of years the low-frequency radio ranges will be replaced by very-high-frequency units.

Advantages of very-high-frequency are as follows:

a) Small power requirements facilitate the use of lighter sets and thus contribute to greater mobility.

b) Line-of-sight operation permits the same frequency to be used in many areas with a minimum of interference.

c) VHF offers better security than does high frequency, because of the line-of-sight factor.

d) It is less susceptible to atmospheric interference then the lower frequencies.

e) It is unaffected by normal ionospheric changes.

f) Because the antennas used are small, it is possible to achieve high gain in a particular direction with a small reflecting device; a similar device is impractical for high frequencies.

g) Because the antennas are small, it is possible to get good results whether the set is mobile or stationary.

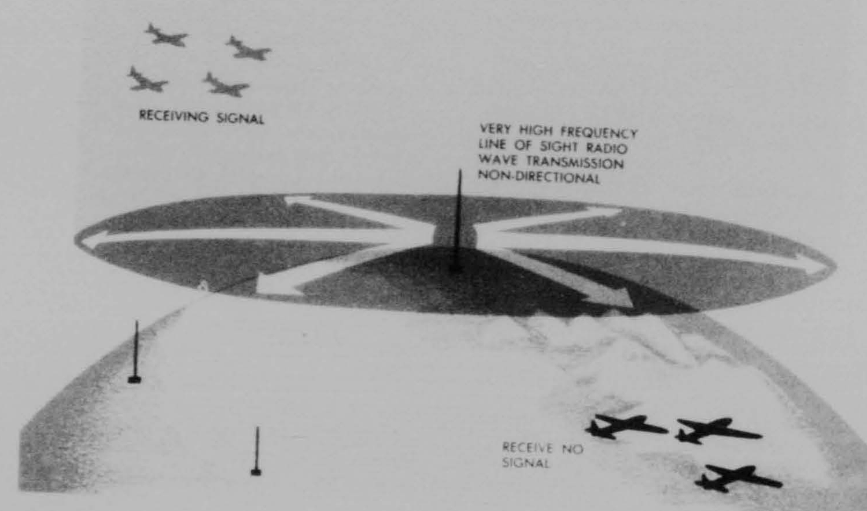
Above Very-High-Frequency

Above 300 mcs are found the range of frequencies used extensively in radar and in pulse-time modulation equipment. At these frequencies conditions are similar to those of very-high-frequency except that power requirements decrease, antenna gains are better, and the susceptibility to static drops. In this band, line-of-sight decreases effective transmission distance.

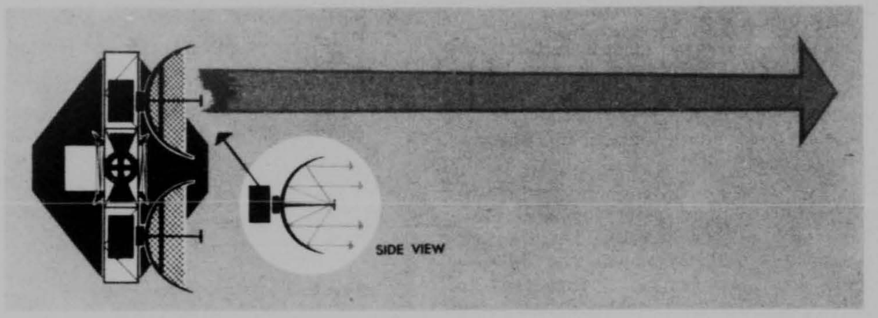
3. GROUND RADIO COMMUNICATION

General

The employment of radio under field conditions is a problem that is often faced by



THIS PAGE IS DECLASSIFIED IAW EO 13526



the communications officer and requires considerable planning in order to achieve the desired results. In order that a proper site be selected, it is necessary to consider several factors which will affect the end result. These factors include: technical requirements, cover and concealment, and local communications.

A radio station should be located in a position which assures communication with all other stations in the radio net. In order to obtain the most efficient operation for transmission and reception, certain features of the existing situation must be considered.

One of the most important features is that of the terrain surrounding the station. Hills and mountains rising between two stations will reduce the range of communications when ground wave or line-of-sight propagation is employed. When operating in hilly or mountainous terrain, sites should be selected relatively high upon the slopes. Locations at the base of a cliff or in a deep ravine or valley.

Dry ground has low conductivity and therefore reduces the range of transmission. It is desirable that a site be chosen near moist ground, since the value of conductivity is greater resulting in an increase of range. Water, particularly salt water, greatly increases the range expectancy.

Trees are to be avoided since the foliage absorbs radio energy and greatly reduces the range of transmission. Deciduous trees have a more adverse effect upon radio transmission than do evergreens. The antenna should be clear of all foliage and dense brush in order to attain the greatest possible efficiency.

Man-made obstructions are another source of interference with radio communications. It is inadvisable to select a position in a tunnel, beneath an underpass, or a steel bridge. Under these conditions, reception will be impossible since a large amount of the energy will be absorbed by the steel structure. Buildings between radio stations will hinder transmission and reception in much the same way as will hills and mountains. Steel and reinforced concrete buildings are worse offenders in this respect than wooden buildings.

All types of pole wire lines, such as telephone, telegraph, and particularly high voltage power lines, should be avoided in selecting a radio site. Such wire lines absorb power from the radiating antennas located nearby. They also introduce hum and noise into the receiving antenna.

Locations adjacent to heavily traveled highways are to be avoided. In addition to the noise and confusion caused by the traffic, ignition systems in the motor vehicles may cause local interference with the radio receiver and make reception under certain circumstances impossible. Battery charging units and other electrical generators should not be located too close to a radio station since they are potential sources of radio interference.

Care must be taken to see that radio stations are not located too close together since this is a potential source of interference between adjacent stations. Radio stations radiate harmonic frequencies as well as the fundamental frequency. A near by station may be able to detect and amplify these harmonics which cause interference within its assigned receiving frequency. Great care must be exercised with the placement and selection of operating frequencies assigned to frequency-modulated radios because of the interference explained above.

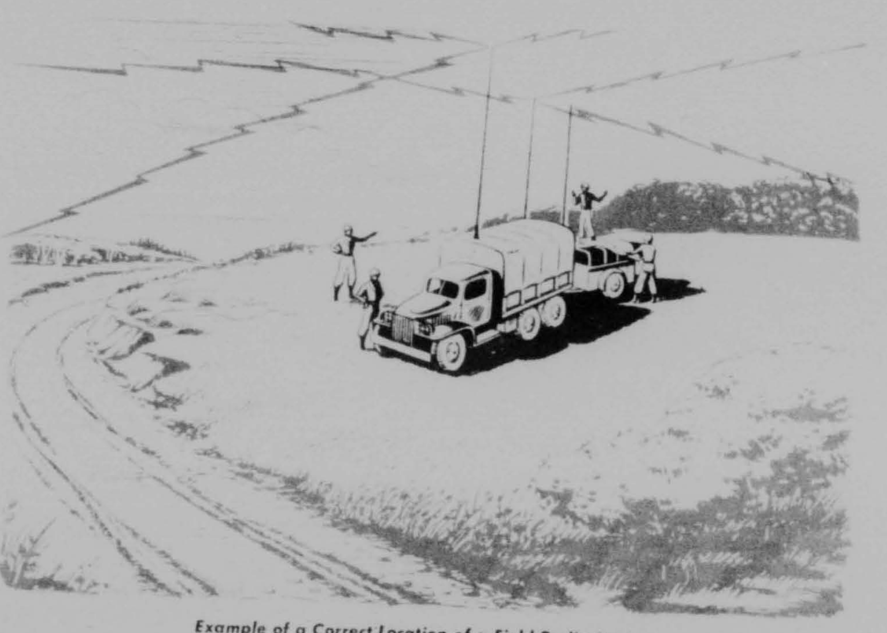
In addition, it is necessary to consider the local command requirements in the selection of radio station sites since they must always serve that headquarters adequately. The stations should be close enough to provide the required service but not so close to attract undue attention to the location of the friendly headquarters. (The minimum allowable distance between headquarters and the radio station is 200 yards.)

Sites should be selected so that the maximum cover and concealment consistent with good transmission and reception is available. The open crests of hills and mountains, although providing good transmission characteristics, should be avoided since the equipment is then silhouetted against the sky and makes an excellent target for enemy fire. A slightly defiladed position just behind the crest of the hill will provide better concealment without sacrificing too great an amount of radio transmission range.

In many cases, it is possible to install the transmitters and receivers in underground shelters, thereby enabling the communications to be carried on under severe battle conditions. The antenna is the only portion of the radio that must remain in the open.

Radio Call Signs

Radio call signs are employed to identify individual radio stations. A call sign consists of characters used to afford a short and secure means of conveying the identity



Example of a Correct Location of a Field Radio Station

Example of an Incorrect Location of a Field Radio Station

of stations, commands, and commanders. These call signs are the only identification employed between radio stations. The call sign may consist of a three-letter or a combination letter and number group when International Morse code is used. Call signs between voice radio stations normally consist of one or two words. Call signs are changed frequently in order to afford the desired degree of security. The proper call signs and their use are prescribed in the Communication Operation Instructions (COI) for each unit.

Interference and Jamming

There are few receiving locations entirely free from either natural or man-made static and such interference may be extremely troublesome at times. Under these conditions of static, the following steps should be taken to minimize and improve the reception.

a) If the receiver is equipped with a crystal filter, much of the extraneous noise frequencies on either side of the desired frequency may be eliminated. The crystal filter is a highly selective device and may be tuned so that much of the undesirable noises may be removed from the incoming signal. This device always should be employed first since it is the most effective one at the disposal of the operator.

b) The receiving antenna should be checked to determine that it is free from all obstructions and contact with trees and shrubs which will cause objectionable noises in the receiver.

c) If the antenna is provided with an external connection, the length of the antenna should be varied. Increasing or decreasing the length of the antenna may result in better reception of the desired frequency. This operation is largely an experimental one and it may take considerable time before the correct length is discovered.

d) The volume control on the receiver should be adjusted to the lowest level at which the desired signal can be heard.

e) Headphones should be employed in preference to a loudspeaker since it is possible to detect a weaker signal with a headphone than with a loudspeaker.

Jamming is the transmission of radio signals with the intent of blocking out or interfering with radio communication for the purpose of causing disorganization among opposing troops. Deliberate jamming of radio communication by the enemy must be expected.

Jamming is more or less effective, depending upon the power of the jamming transmitter and the type of interference being radiated. Jamming signals may consist of keyed continuous waves, tone, voice, music, imitation static, or other types of noise signals. The jamming signals may be undamped, amplitude-modulated, frequency-modulated, or a combination of these. Frequency shifts, made by the operator, may be employed to alleviate this condition. A number of jamming transmitters may be used simultaneously in order to cover some radio frequency band.

The effectiveness of radio jamming may be reduced if it is anticipated and planned for accordingly. The COI should include additional, widely separated, frequencies with instructions on their use in case of radio jamming. Changing frequency will often give sufficient time to complete the message or messages before the enemy can find the new frequency and change his jamming transmitter. Enemy jamming on one frequency may be discontinued if it is thought that the channel is no longer in use; therefore, it is good policy to maintain dummy transmissions on this channel in the hope that the enemy will continue to jam this channel rather than put his equipment to work on another channel.

The best defense against jamming is the proper training of radio operators to cope with the interference. Operators must be trained to operate through heavy interference of all types. It has been found that in general, tone modulation is more readable through jamming than CW or voice modulation. In general, the operator may reduce the effectiveness of jamming by performing the following operations:

a) Use the crystal filter of the receiver to tune out as much as possible of the undesired signal.

b) Authenticate all incoming messages since the enemy may intersperse jamming with false messages.

c) Change call signs and frequencies as directed in the COI.

d) Eliminate preliminary calling, requests for reports on signal strength, and other routine messages which are not necessary for conduct of the traffic.

Above all else guard against the possibility of panic at the first signs of jamming since this is the result desired by the enemy. Expect jamming and have the determination to get the message through under any conditions.

Transportation of Ground Radio Equipment

Radio equipment is comparatively delicate and its serviceability is governed to a great extent by the care with which it is packed for transportation. Operating equipment will be packed and loaded to protect it from dust and dirt, weather, shocks of the road, and from injury from other articles loaded in the same vehicle.

Representative Types of Ground Radio Equipment

Figures 3-89 through 3-92 are illustrations of typical ground radio equipment employed in the United States Air Force. A brief technical description of each set shown, and of others, is included in Appendix IV. These do not represent all the equipment of this nature employed in a military operation as space does not permit a more detailed discussion of all the sets that may be encountered in the field.

4. AIRBORNE RADIO COMMUNICATION

General

The principles involved in airborne radio communications are the same as those employed in ground radio. The important difference is one of design. The radio for airborne communications is handicapped by several features that are not imposed upon

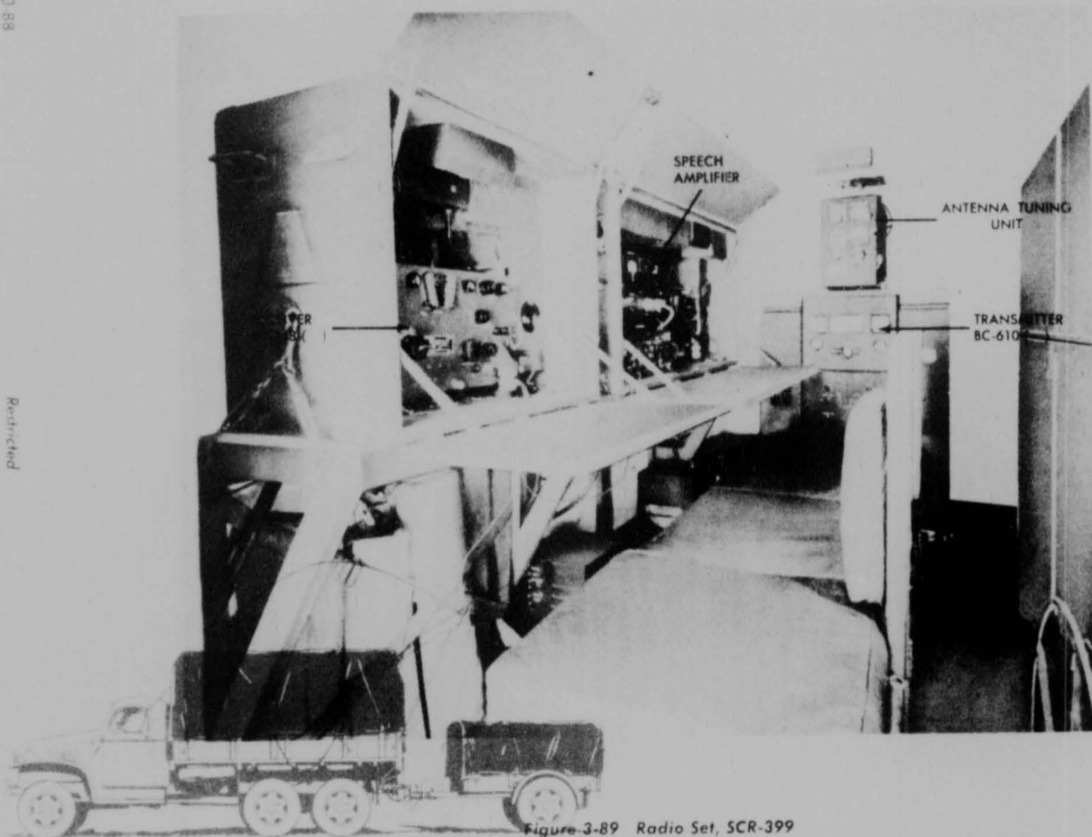


Figure 3-89 Radio Set, SCR-399

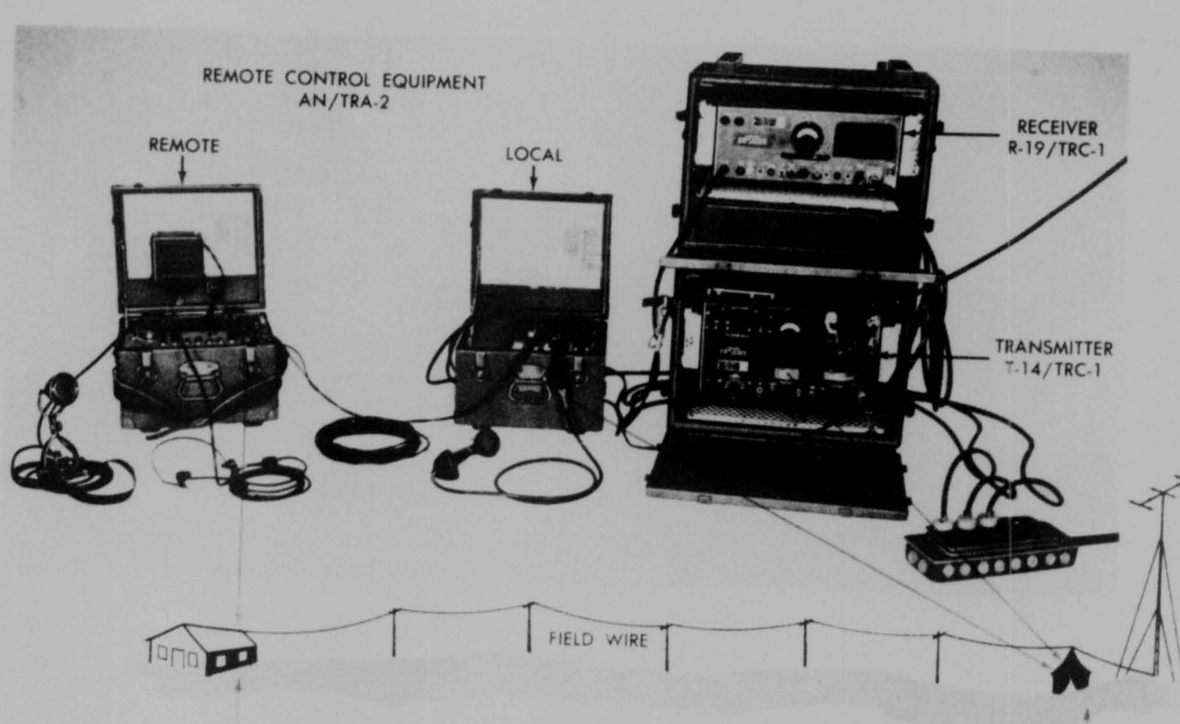

Figure 3-90 Radio Set, AN TRC-1

THIS PAGE IS DECLASSIFIED IAW EO 13526

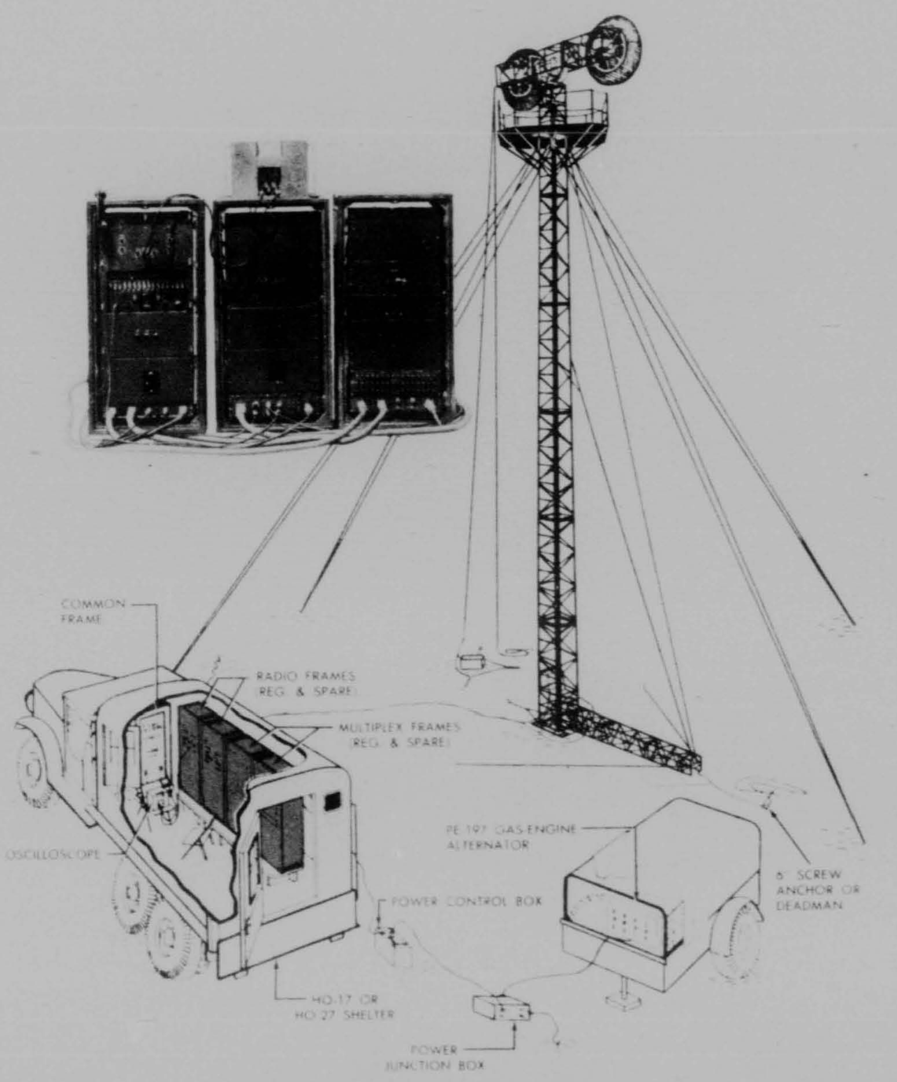

Figure 3-91 Radio Set, AN TRC-6

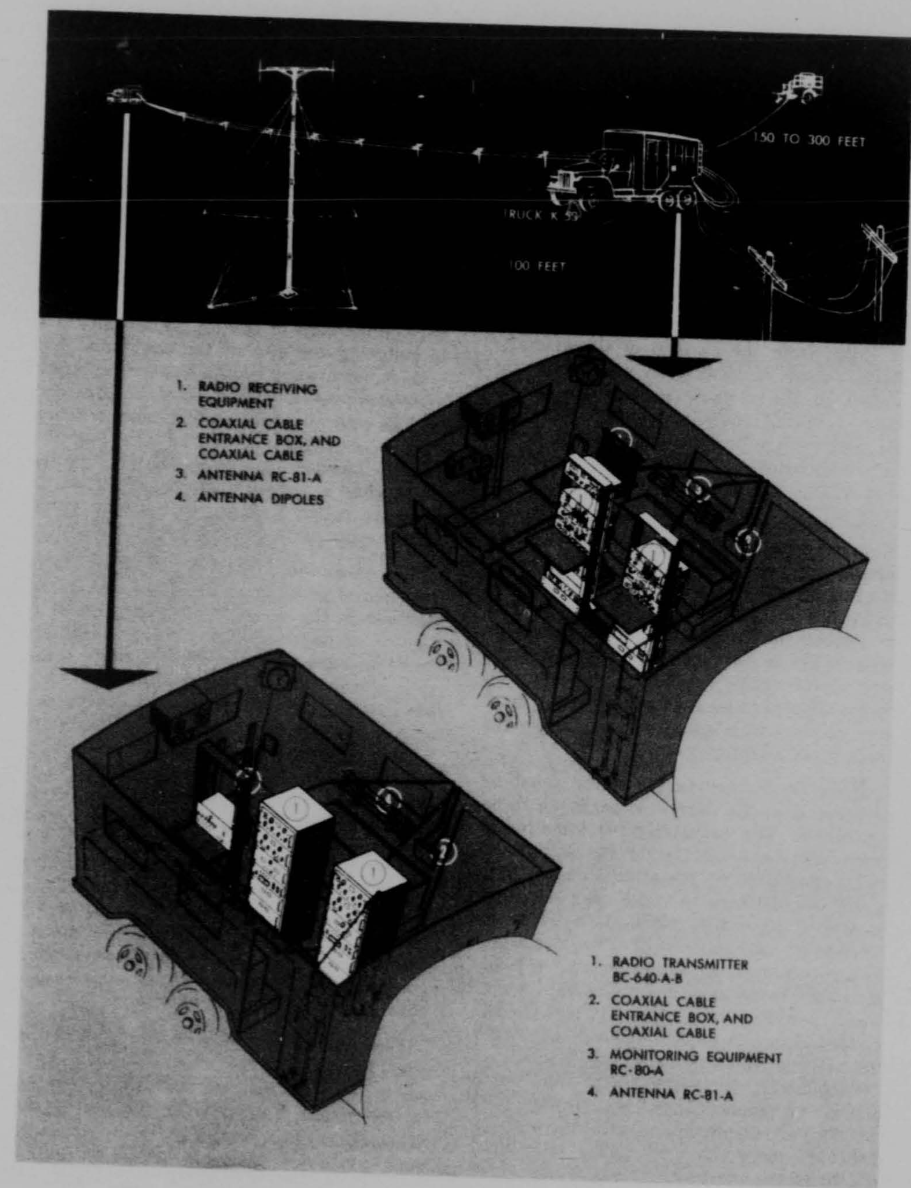

Figure 3-92 Radio Sets, SCR 573-574

ground radio equipment. The factors of weight, space, altitude, and antenna design must be considered in the construction and employment of airborne radio equipment. At first glance, these items may not appear to be serious, but after some consideration, it is apparent that they will impose great limitations upon performance. These factors do not play such an important part in the design and construction of ground equipment.

Weight is an important item when it is considered that for each pound of equipment installed in the aircraft, a pound must be taken from the payload of the aircraft. Each pound of additional equipment installed in the aircraft reduces the maximum potential fuel and bomb load. Each piece of such added equipment must prove its worth before it is considered for inclusion in the aircraft.

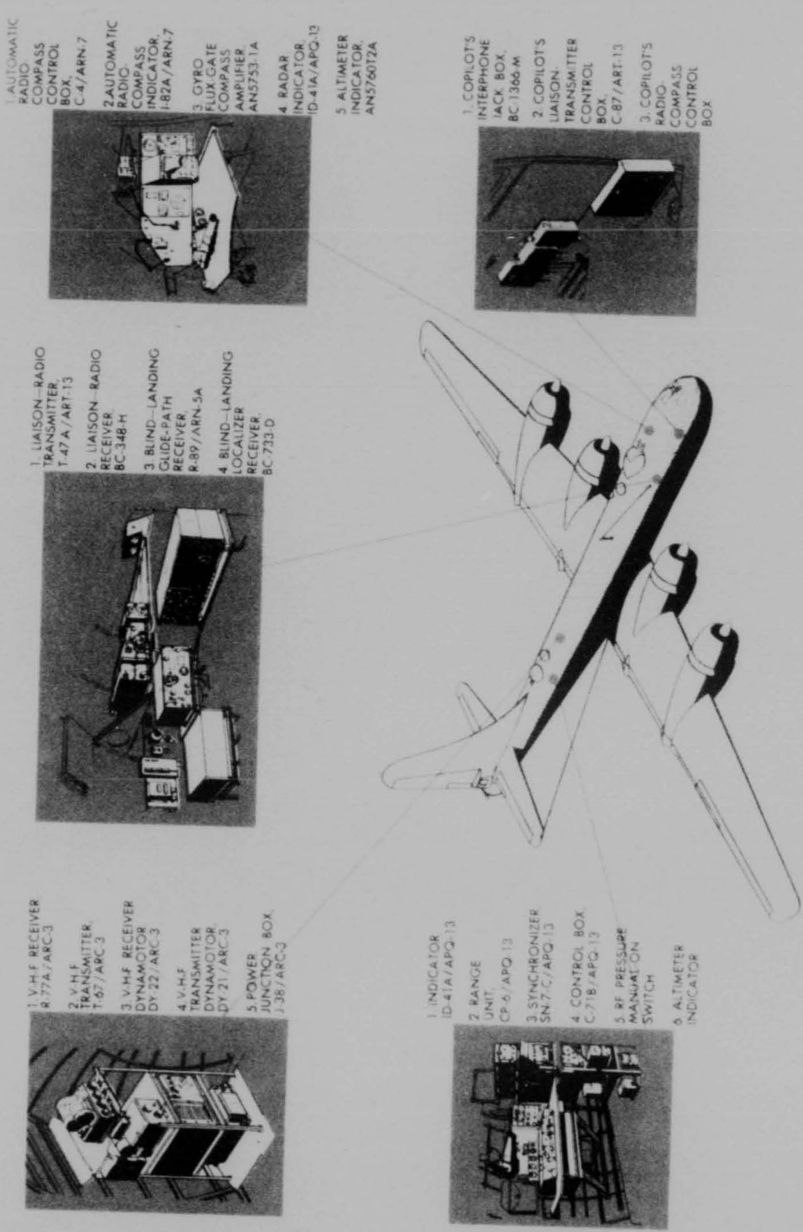
The designer is faced with the problem of minimizing the weight factor of the equipment, yet producing an item capable of standing the rough usage to which it will be subjected in flight. One method employed to reduce the weight in electronic equipment is to use primary voltages of frequencies of 400 cycles instead of the usual 60 cycles. This permits the use of transformers and reactors of a smaller size and weight for a given output.

Space is another factor which must be considered in the design of airborne radio equipment. The designer must know what space will be available for his equipment and design it to fit the alloted space. Normally, he will have to make the equipment in several parts and place these wherever there is a small amount of space available. This requirement is not so rigorous for bombardment types as it is for the fighter aircraft; nevertheless, it must not be neglected. Space is not always available near the position which the operator will occupy. Consequently, it is necessary that some method of remote control be provided. The problem of remote control is not extremely difficult except that it imposes additional weight to the equipment, and may accentuate maintenance problems as it creates more places for trouble to occur.

One problem in connection with design of airborne electronic equipment is that of high-voltage arcs when the equipment is being operated at high altitudes. The dielectric constant of air at high altitudes is less than it is at sea level. One method of solving this problem is to increase the size of the insulators and the amount of spacing between the parts of the equipment. This expedient should be avoided if possible, however, as it increases the space and weight requirements of the equipment. Another method often employed with radar equipment is that of pressurizing the high voltage portions of the set. This is effective in reducing the size of the equipment but it does not always reduce the weight, since a pressure-resisting case must be provided for the equipment. The third method which may be employed is that of reducing the voltage applied to communications equipment after a certain altitude is reached. A pressure switch is employed to activate this change-over at the predetermined altitude.

The design of antennas is becoming a problem of great importance with the rapid increase in the speed of aircraft. The addition of antennas on the surface of the aircraft increases drag proportional to the cube of the velocity. Therefore, it is desirable that the antenna system be so designed as to reduce the drag factor to an absolute minimum. Undoubtedly the antenna of the future will be fully contained in the fuselage of the aircraft—imposing new problems in design. The airborne antenna must be so designed that the fuselage will not shield it from the desired radiations. This may involve more than one antenna for a communication receiver and consequently increase the complexity of the system. At the present time, this problem is receiving considerable attention but a satisfactory solution has not been found.

Finally, mention should be made of the need for multichannel airborne radio equipment. If all aircraft transmitters were to be of the single channel type; that is, if the transmitter has to be retuned manually each time a new frequency is used, flexibility of communication would be lost. Older types of airborne equipment were of the single



Airborne Radio Communications Equipment

THIS PAGE IS DECLASSIFIED IAW EO 13526

channel variety. In aircraft which carried a radio operator, this was not a serious problem although retuning was time-consuming. In fighter aircraft, the alternative was to employ more than one transmitter in order to provide more than one channel.

Modern developments have brought about multichannel equipment. A high-frequency transmitter with ten pretuned channels is currently in use. The radio operator may change frequency merely by turning a selector switch. Very-high-frequency transmitters with eight pretuned channels are in use and newer equipment is being developed capable of providing many times more than this. To select a channel, the operator pushes a channel selector button. In a later phase of the study of United States Air Force communications, the need for this type of radio equipment will be discussed.

It may be seen readily that the factors involved in the design and construction of airborne electronic equipment are conflicting, and, at best, only a compromise solution to make the best possible compromise solution.

Essentially, the operation and employment of airborne radio communications is the same as for ground radio communications. The same regulations concerning call signs and security apply.

Representative Types of Airborne Radio Equipment

Figures 3-93 and 3-94 are illustrations of typical airborne radio equipment employed in the United States Air Force. A brief description of this equipment is included in Appendix V.

5. RADIO AIDS TO NAVIGATION

General

Many developments have occurred, to make flying easier and safer. Navigation under instrument conditions is greatly simplified by reference to the radio and radar aids which are available.

A comprehensive system of radio aids to navigation has been installed in the United States and on all the important airways throughout the world. These provide navigational facilities which are available for use under contact or instrument flight conditions. In all types of air operations, one of the prime factors in determining the success or failure of a mission is navigation. Bad weather conditions have been responsible for the loss of many aircraft. The losses have been caused largely by the lack of adequate radio aids to navigation or the inability of the pilot to use those provided. The inability to navigate and identify targets under all conditions of visibility has resulted in aborted missions, disaster to airborne operations, and the bombing of friendly troops.

All radio aids to navigation operated by agencies of the United States are listed in the Radio Facility Chart AN 08-15-1. Copies of these charts are carried in all aircraft and are revised frequently. Notice of changes which occur between revisions of the chart are brought to the attention of all concerned through radio or teletypewriter messages called Notices to Airmen (NOTAMS). A file of NOTAMS is maintained at every civilian and military air terminal.

Radio Ranges

Radio ranges are located adjacent to important airfields and are spaced at intervals along important airways, comprising an important aid to a pilot in navigating from one point to the next. Ranges located near an airfield perform another important function. One of these legs, or courses, is usually directed over the best runway of the field. In bad weather, the pilots approach the airport on the radio range and make a **procedure let-down** on the course that will bring them to the proper runway. This procedure has been standard practice for many years with the Civil Aeronautics Administration. Aircraft may be stacked on the various legs to await their turn in the event of bad weather. With the modern developments in landing systems the radio range procedure let-down is being used less frequently.

The radio range transmitter emits an aural signal by means of which the pilot may determine his direction in respect to the station to which he is listening and determine his position with respect to established airways. Generally, all range equipment transmits so that two or four beams or courses are ob-

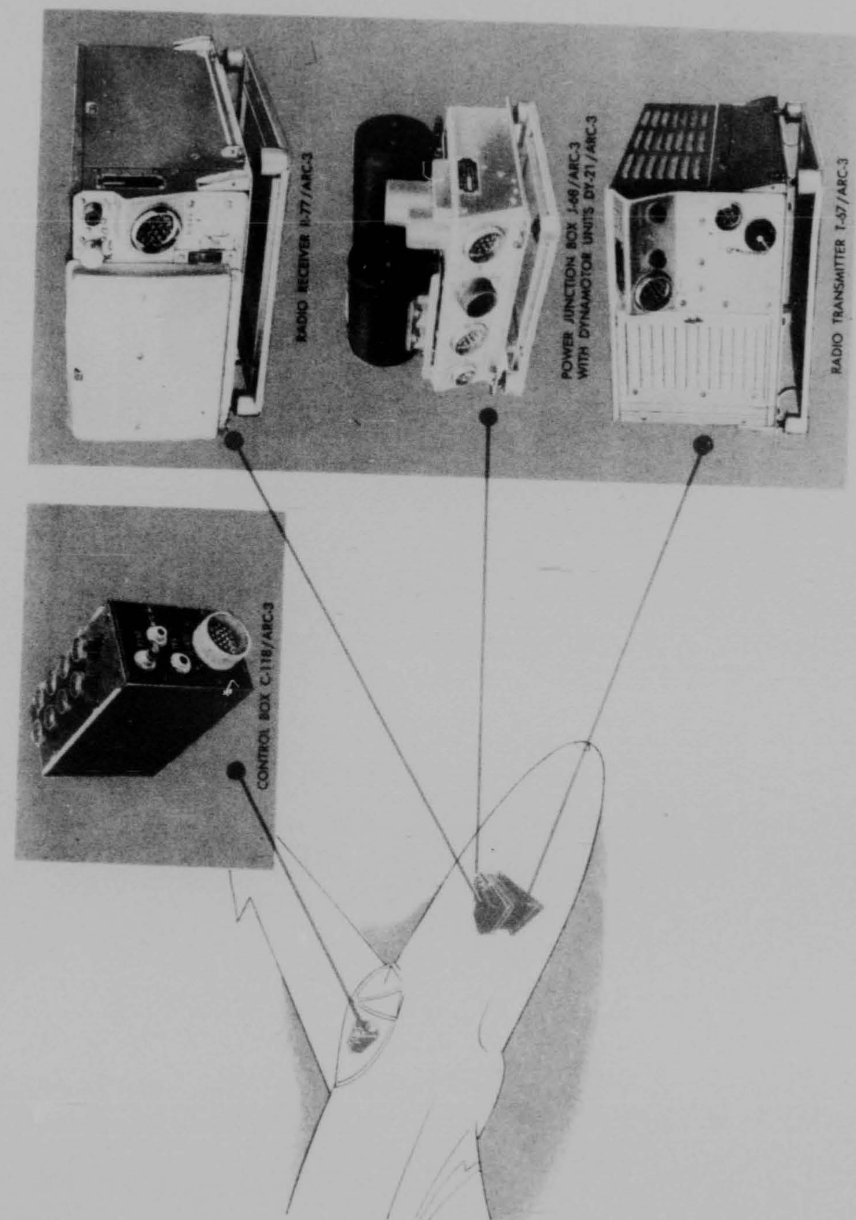


Figure 3-93 Radio Set, AN ARC-3

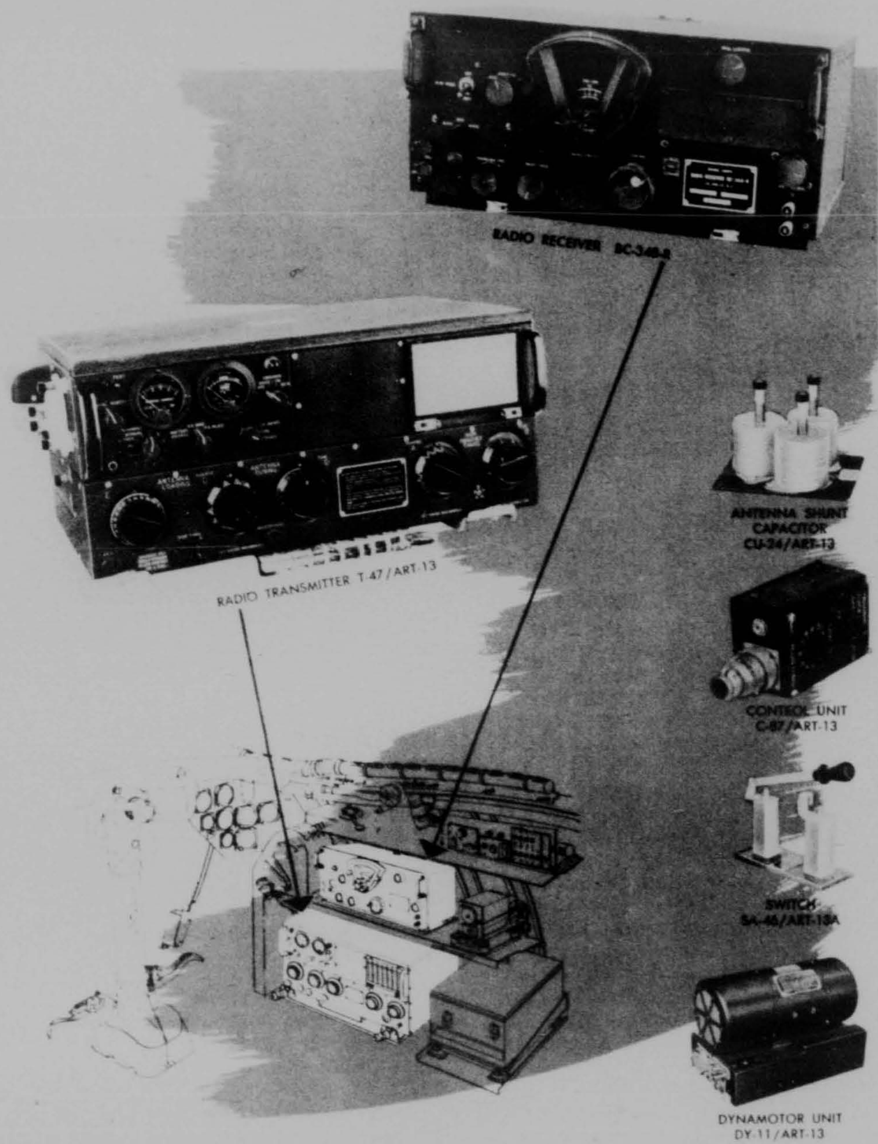

Figure 3-94 Radio Set, AN ARC-8

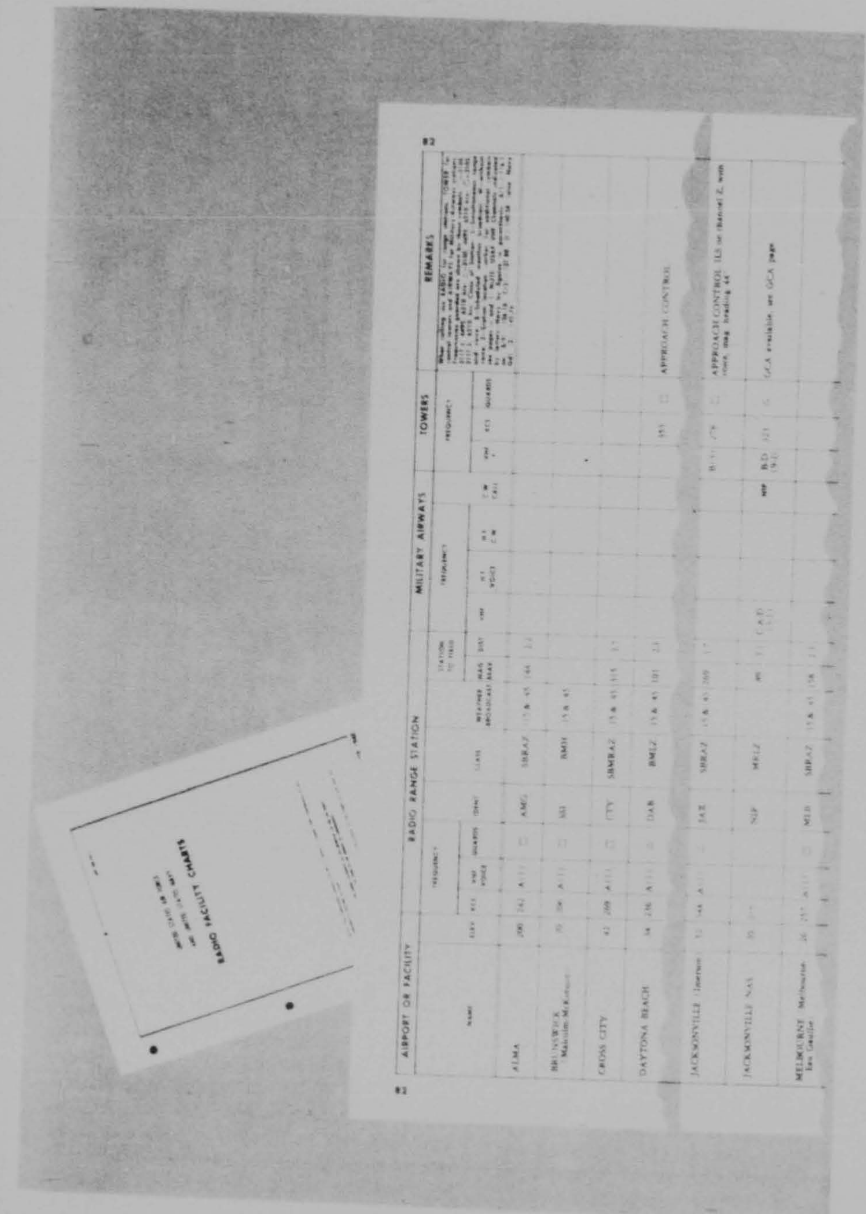
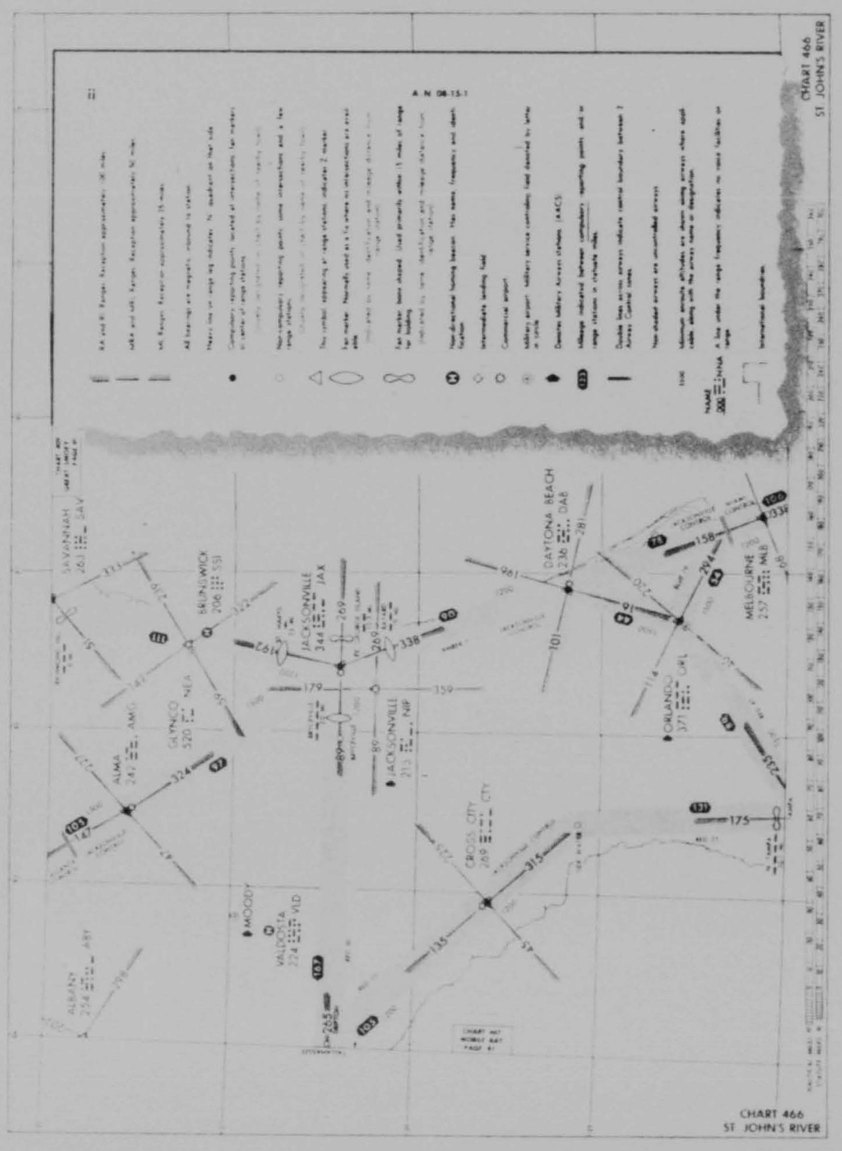


Radio Facilities Chart

THIS PAGE IS DECLASSIFIED IAW EO 13526



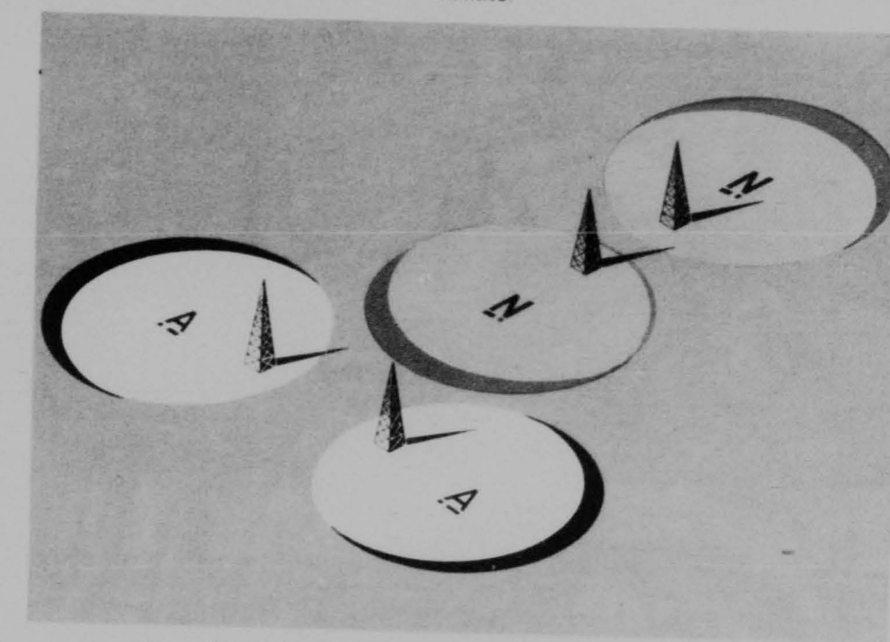


Figure 3-95 Directional Antenna Pattern in Unrelated Pairs

tained. The courses are normally placed parallel to established airways. A pilot can use the radio range as an aid to navigation, if his aircraft is equipped with a receiver capable of receiving the frequencies employed for transmission. No special equipment, such as a loop antenna, radio compass, or indicating equipment is required to fly the course of a radio range. All transmissions are modulated so that the receiver does not need a beat oscillator.

The following is the theory of operation of one particular type of four-course radio range. The field pattern of a single vertical antenna is theoretically circular. Two vertical antennas driven by a single transmitter will produce a field pattern similar to a figure eight. This is the basic field pattern employed in the four-course range under discussion. Figure 3-95 illustrates this type of pattern. If to this one set of antennas radiating a figure eight pattern, another pair of antennas is added so that the axis of the two pairs is perpendicular and the power is applied alternately to one pair then the other, a cloverleaf-shaped pattern will result. There are four zones, 90° apart, about the station where the field strength of one antenna is equal to the field strength of the adjacent antennas. These zones are called **equisignal zones.** If a means is used to detect these zones, they can be used as courses or beams leading directly to or from the station. The basis of operation of all radio ranges is the equisignal zone which is detected to indicate courses for the pilot to follow. (Figure 3-96)

The straight lines leading away from the radio range stations are the equisignal zones formed by the overlapping of the two radiated figure eight patterns. An ingenious method has been devised to detect the equisignal zones. **One pair of antennas transmits the letter N, while the other pair transmits the letter A.** An aircraft flying in the quadrant containing true north, or in the opposite quadrant, will hear the letter N (dah-dit).

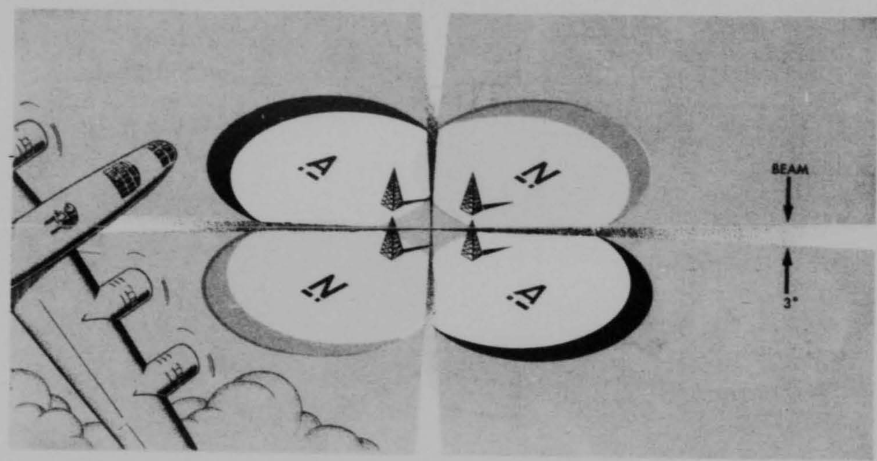

Figure 3-96 Radio Range Pattern

Aircraft flying in the remaining two quadrants will hear the letter A (dit-dah). The N and A are synchronized in such a manner that the dit of the A fits between the dah (—) and the dit (.) of the N, and the dah of the A fits between dah's of two N's. When both signals are received with equal intensity (at the equisignal zone), they blend to produce a continuous signal, indicating that the aircraft is on course. The equisignal zone, which is the course or "beam," is actually about three degrees wide. (Figure 3-97)

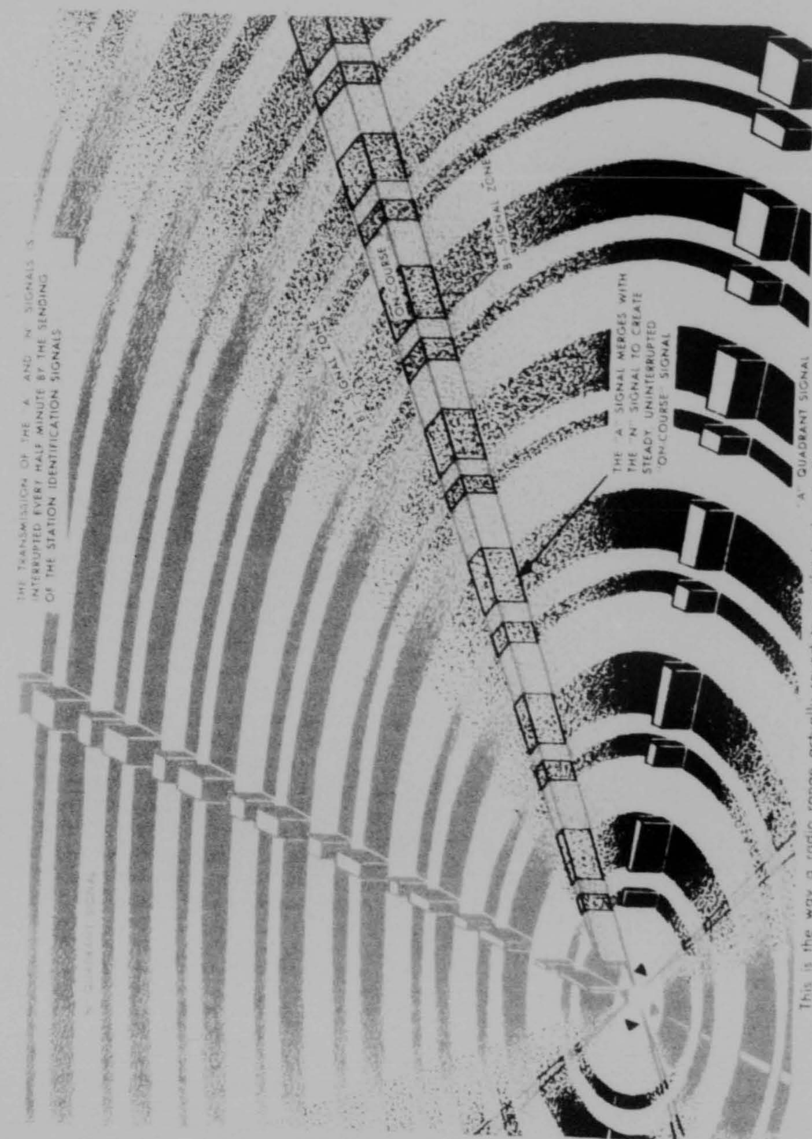
The quadrant containing the true bearing of 180 toward the station is the N quadrant for all ranges operated by the United States government. The opposite quadrant is also an N quadrant. When the north leg and true north line coincide, the N signal is transmitted in the northwest quadrant.

On either side of the course, there is an area where both the A and N signal may be heard. These signals are not heard with equal intensity, but depending on the location of the aircraft, the A is heard with greater intensity than the N or the N is heard with greater intensity than the A. The area on either side of the course where both the A and the N can be heard, but with different intensities, is known as the "twilight zone."

Directly above the radio range station, there is an area in which little or no signal is radiated. This area is known as the **cone of silence.** (Figure 3-98). When an aircraft is in this area, little or no signal is received, and it serves as a check point for the pilot indicating that he is directly over the station. The cone of silence is a great aid to the pilot, since it enables him to pin-point his location at that instant.

In the previous discussion, all the courses for the radio range station have been considered as being at right angles to each other. In actual practice, however, it is often desirable that the radio range courses parallel those of established airways and therefore all courses will not be at right angles. Within certain limits, however, these beams can be adjusted to furnish any desired course alignment. The courses are not independent of one another and consequently the readjustment of one course requires the readjustment of all the other courses. The courses are shifted by squeezing or rotated by bending.

"Squeezing the courses" means varying the angle between the courses, but maintaining the reciprocal course relationships. In other words, it is a rotation of one pair of courses electrically while opposite courses



This is the way a radio range actually sound to a pilot in the air. The tone gradation of each A or N signal indicates the relative intensity with which those signals are heard.

Figure 3-97 Radio Range Signal Pattern

THIS PAGE IS DECLASSIFIED IAW EO 13526

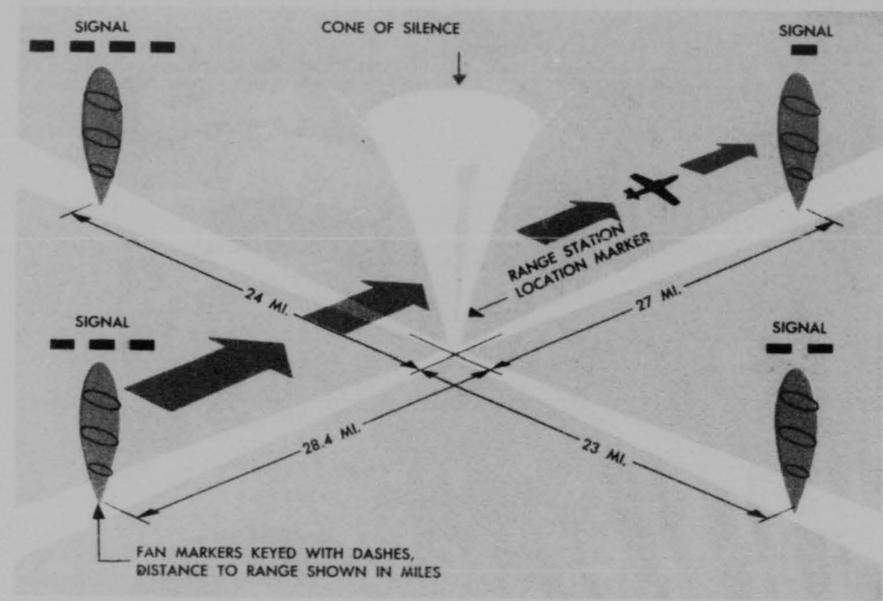


Figure 3-98 Cone of Silence and Fan Markers

still go straight through the station.

"Rotating the course" means moving all the courses an equal number of degrees in the same direction. If all the courses are to be moved, the same number of degrees in the same direction, the antenna could be rotated. In some types of equipment this is actually done; but the rotation of the courses can be accomplished effectively by electrical means without changing the physical position of the antennas.

"Bending of the courses" means varying the reciprocal relationships of the diagonal courses. This is done when it is necessary to bend a pair of opposite courses so they do not lie in a straight line. Each radio range is assigned an individual two- or three-letter identification sign or call sign. The cycle of A and N signals is interrupted every thirty seconds and the identification of the station is alternately transmitted over the antenna systems, first over the N antenna and then over the A antenna. In the twilight (bi-signal) zone, both identifications will be heard but with different intensities. It is extremely difficult for the human ear to distinguish between relative intensities of two signals interwoven with each other, as in the case of the A and N signals. Therefore, when flying in the twilight zone, the usual procedure is to listen to the station identification which is transmitted with distinct breaks, and by comparing the relative intensities of these two signals against the background of silence fly a reasonable accurate course in a twilight zone.

Adcock Radio Range. The Adcock radio range system receives its name from the type of antenna system employed. The Adcock antenna is a vertical antenna system emitting only vertically polarized waves with the major portion of the radiation confined to the lower part of the atmosphere. The Adcock range is normally a simultaneous-type range. The term simultaneous-type range derives its name from the fact that it can transmit radio range signals and voice communications at the same time. Both signals can be heard at the same frequency setting of the receiver.

Two radio transmitters are employed in this system. One is known as the "range transmitter;" the other is called the "carrier transmitter" and transmits the voice communication. The output of the range transmitter goes through a coupling unit where all squeezing, rotating, and bending are accomplished, and then to the antenna system. The two transmitters operate continuously and simultaneously. The range transmitter emits an unmodulated signal, and when employed alone, will not produce a tone in the receiver tuned to its frequency. The carrier transmitter may be voice modulated when voice transmissions are desired but is unmodulated at all other times.

The audio tone which is heard in the radio receiver is created by the beat note between the frequencies of the two transmitters. The carrier transmitter has a frequency which differs by 1,020 cycles from the frequency employed in the range of the transmitter. For example, when the transmitter is operating at 300 kcs, then the range transmitter will be operating at 301.020 kcs. Since these frequencies are so close together, both will enter the receiver and produce a 1,020 note. In effect, the carrier transmitter modulates the range transmitter approximately 30 per cent of the time, while the remaining 70 per cent is for the voice modulation. Most of the audible portions of the male speaking voice are in the lower portion of the voice band from 200 to 3,000 cycles. There is comparatively little voice energy at 1,020 cycles so the speech and tone do not interfere greatly with one another when both are received. A filter is contained in the receiver, however, which permits the operator to select any one of three positions and the desired mode of reception. He may choose to receive the voice communications alone, or the radio range signals alone, or receive both at the same time.

The radio range radiation takes place from the four antennas at the corner of the square as shown in Figure 3-96. The carrier transmitter transmits from a single vertical tower located in the center of the square and with equal intensity in all directions. Thus, the carrier transmitter may be employed, in addition to voice communication, by a radio compass at any direction from the station.

Adcock radio ranges are designated as full or medium power ranges in the Radio Facility Charts. Full power ranges are rated at 150 watts or more and have an effective range of about 100 miles. These carry the designation of RA. Medium power ranges are designated by MRA and have a power output from 50 to 150 watts and an effective range of about fifty miles. In both instances, the A indicates Adcock ranges. Maximum ranges of 600 miles over water are possible but the beam is too wide for navigational purposes; radio ranges normally employ frequencies between 200 and 400 kcs. The Adcock range is relatively free from night effect and all courses are stable and have a relatively constant useable range, day or night. They have a good cone of silence at all heights above the range station. On the other hand, the antenna equipment is bulky, and the installation is a major construction job. Skilled personnel and several weeks' time are required to install, calibrate, and align the range.

Loop-Type Radio Range. The principle involved in the loop-type radio range is the same for the Adcock radio range. However, the loop-type radio range employs only a single transmitter. This transmitter is modulated by a 1,020 cycle note in order to obtain the range information. If voice transmission is desired, it is necessary to shut down the range. This system is not a simultaneous range. Normally, the same transmission is employed for either range or voice transmission with a nondirectional antenna being used for the voice transmission. When a parasitic antenna is employed to produce course bending, this antenna may be used for the voice transmission.

Loop-type ranges have little if any advantage for long distance night operation, since the horizontal portion of the antenna causes a large horizontally polarized radiation which results in a strong night effect. A vertical antenna less than a quarter-wave high has a low angle of radiation, while a horizontal antenna less than a quarter-wave high has a high angle of radiation. This high-angle radiation component of the loop is refracted by the ionosphere and may be as strong as the vertical component when received at the aircraft. As a result, the equisignal zone of the loop-type range may swing erratically and sometimes fade altogether. Loop radio ranges have been responsible for many flying accidents. Reliable ranges at night are not over thirty miles, regardless of power. In addition to night effect, the loops are subject to swinging in high winds causing the radio beams to swing. Also, the cone of silence is not as well defined at higher altitudes as the cone of silence above the Adcock range stations.

Marker Beacons. In addition to the radio range equipment, there is usually a system of marker beacons used in connection with the radio range system. Definite fixes are not possible with the radio range equipment, except when passing directly through the cone of silence, and in some instances, particularly with loop-type radio ranges, the cone of silence is ill-defined, even indistinguishable, at higher altitudes. For this reason, marker beacons are used to aid the pilot in finding his exact position on the beam or over the station.

Fan marker beacons are very-high-frequency radio transmitters, installed at some distance from the radio range station, which transmit a fan-shaped pattern across the radio range beam. These fan marker beacons operate on a frequency of 75 mcs. and emit a signal which is received and presented visually in military aircraft. These signals are keyed to conform with the numbers assigned to the on-course signals across which they are located. Fan markers are keyed clockwise from true north to identify the course in which they are located. The first fan marker clockwise from true north is keyed with one dash, the second with two, the third with three, and the fourth with four dashes (Figure 3-98). Passing over a fan marker definitely establishes the position of the aircraft. At times, fan markers are installed at distances from two to four miles from the airfield on the leg of the course passing over the field, which facilitates instrument approaches. These fan markers are in addition to those installed at greater distances from the field. The signals emitted by the fan marker, their names, and the distances from the marker to the radio range stations are shown in the Radio Facility Charts.

Station markers, or Z markers, are installed at some radio range stations. These markers also operate on a frequency of 75 mcs. but are not keyed. They emit a steady signal vertically into the cone of silence and thus definitely establish the location of the cone of silence above any given radio range station. Z markers are employed in those cases where, due to the effects of terrain, the cone of silence is poorly defined or entirely lost. For air navigation, it is necessary to be able to pin-point the locations of the radio range stations so that the pilot knows exactly where he is in space.

VHF Radio Ranges. The same basic principles of operation apply to the VHF ranges as well as to the ranges previously discussed. However, the courses or beams of the VHF radio ranges projected along established airways are visual courses, while the courses projected across the airways are aural courses.

Ideally, radio range reception should be visual, not aural. The pilot needs his ears to receive airways communications, as well as traffic control instructions. In addition, he must listen to weather broadcasts, and keep alert for special messages which may be transmitted to all pilots over the CAA communications system on the same frequency as the radio range. Even when accompanied by a co-pilot, the pilot still does not have enough ears to hear simultaneously everything that he is supposed to hear. From the practical piloting point of view, it is essential to have course indication interpreted visually, not aurally.

Figure 3-99 illustrate the basic principle of a horizontally polarized two-course VHF radio range called the **visual-aural range** (VAR). The course identification signal, transmitted to the north or to the south (or to the west or to the east) is respectively either the D or the U signal in the Morse code, the equi-signal zone delineating the course, or a set of two audio frequencies suited for either aural or visual interpretation, similarly transmitted. Every thirty seconds, the range course identification sig-

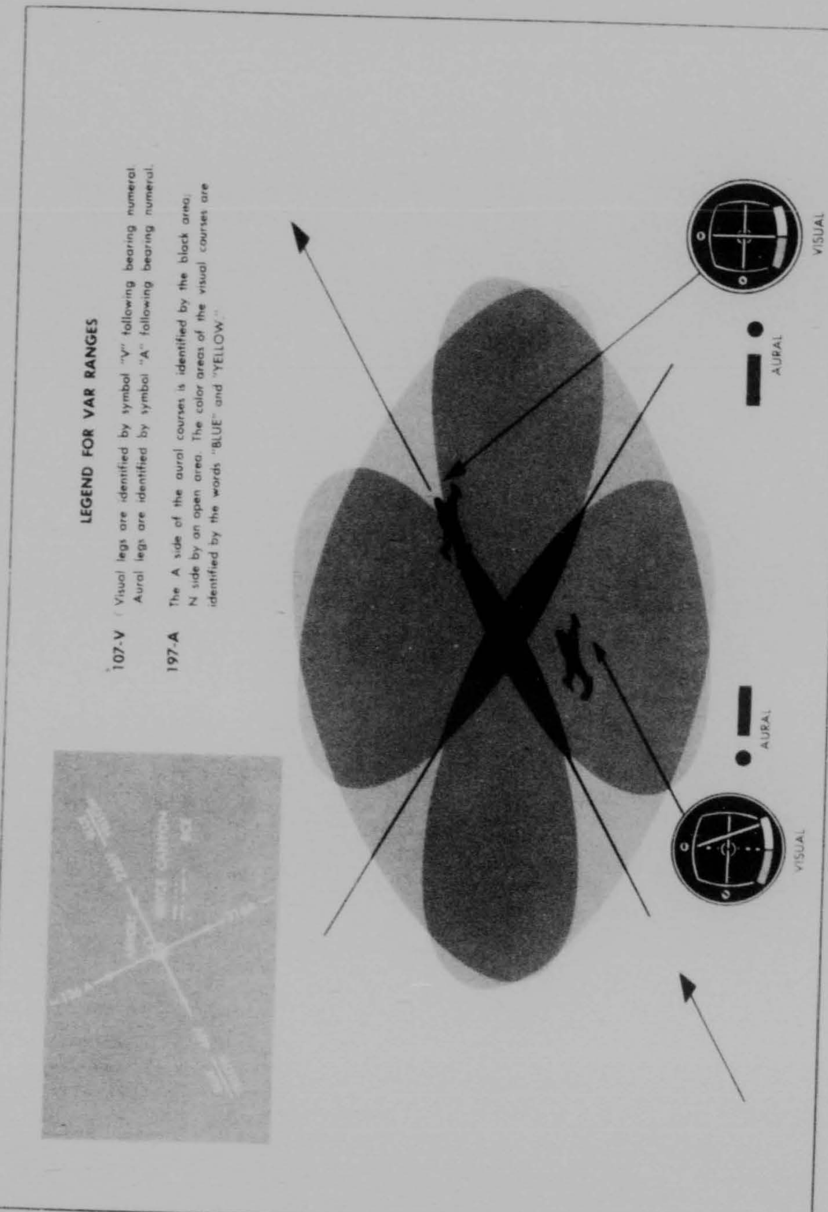

Figure 3-99 Two-Course Radio Range

THIS PAGE IS DECLASSIFIED IAW EO 13526

nals are interrupted, and a special antenna array (physically a counterpart of the course transmission array but at right angles to it) transmits the station identifying signal—first to the north or to the west, then to the south or to the east—followed by the letter N or S if the course lies primarily to the north or south, or the letters W and E if the course lies primarily to the west or east with respect to the transmitting station. Thus, in addition to the course identifying signals, and the station identifying signals, the radio range will also transmit directional information showing the pilot at once his direction with respect to the radio range station.

Since the ear cannot compare the intensity of the two signals employed for visual course, two filters are arranged in the receiver which will pass the 90- and 150-cycle frequencies' separately. Each of the modulation frequencies is then fed to a single meter whose needle normally rests at the center scale. When the 90 cycle frequency, which represents the A signal, is stronger than that corresponding to the N signal, the meter will deflect to one side. When the radio is reversed it will deflect in the other direction. Thus, a single meter indicates the quadrant signal and its amount, relieving the pilot of the necessity for the use of a headset.

The VHF Omnirange (VOR) is a radio aid to air navigation which furnishes definite track guidance between the range station and any point approximately fifty miles away when flying at a minmum instrument altitude in accordance with local terrain. The distance increases with altitude ranging at 150 miles for 14,000 feet.

Just as in the two-course visual-aural VHF range and the VHF runway localizer, the course is defined by the movement of a cross-pointer instrument in the aircraft. The distinctive feature of the omnirange is that the orientation of the course is under the control of the pilot without limitation as to azimuth.

Three basic instruments are used by the pilot to fly these ranges. The first is the aforementioned cross-pointer which indicates to the pilot his position relative to the desired course. The second is the azimuth selector, the dial face of which is similar in appearance to that of the automatic direction finder. The pointer of this instrument is rotated by means of a knob which serves as a manual course selection control. When the cross-pointer needle is centered, the position of the azimuth selector pointer indicates the magnetic bearing of the aircraft either to or from the station. The third instrument is a sense indicator described later.

In operation, the pilot selects a course by setting the pointer on the azimuth selector to the desired magnetic bearing and then flies that course by reference to the cross-pointer instrument. As in the navigational aids named above, this facility also has a reciprocal course. The sense indicator is similar in appearance to the ordinary panel meter but is mounted so that the pivot needle is at the left side of the case rather than at the bottom.

After a course has been selected and the sensing determined, the aircraft is always flown in the same direction as the deflection of the vertical cross-pointer indicator needle.

For example, if the aircraft is due south of the station, and it is desired to fly to the station, the azimuth selector is set so that the pointer reads zero degrees. For this condition, the sense indicator will point to the word "TO" indicating that the station is in front of the aircraft. (See Figure 3-100)

If a pilot wishes to determine his position in flight, he may tune his receiver to one station in his general area, rotate the azimuth selector until the vertical needle of the cross-pointer instrument is centered, and then note the azimuth selector bearing. By repeating the procedure with a second station, a fix can be taken. Each range is identified by a three-letter coded signal which is transmitted on the omnirange frequency.

VHF radio ranges have the same general characteristics of other VHF equipment: line-of-sight propagation and freedom from atmospheric noise. Any pilot can use the VHF radio range as an aid to navigation if the aircraft is equipped with the specialized receiving equipment used with the USAF instrument approach system. (IAS).

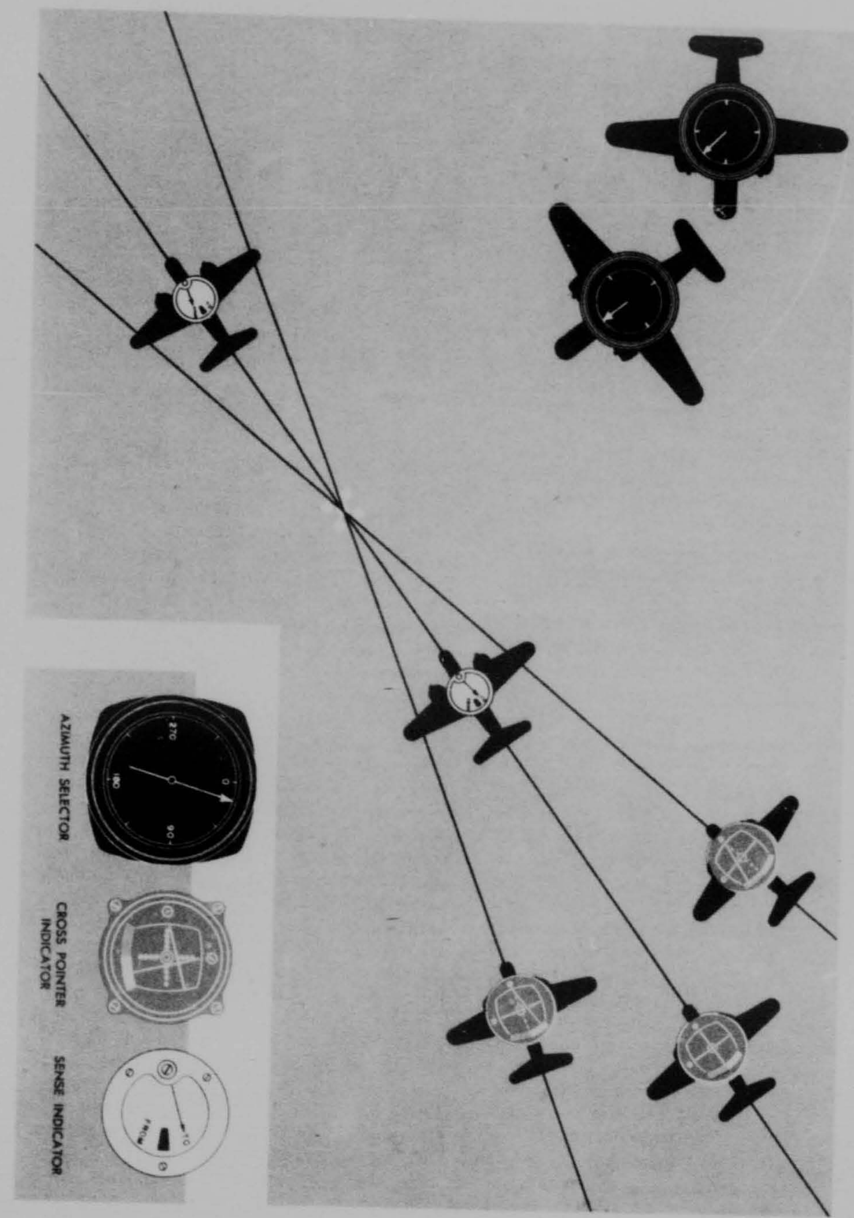

Figure 3-100 VHF Omnirange

Radio Compass

Valuable as the radio range is as an aid to navigation, it does not enable the pilot to determine his exact position, since it only furnishes a single direction and does not supply information concerning distance. In order to be able to establish his position, a pilot must have the direction and distance from a known object or the direction from two known objects. The radio compass is a device that may be employed in this manner.

Everyone is familiar with the fact that most ordinary portable radios will pick up radio broadcasts with a varying degree of volume, depending upon the position in which the set itself is placed. That is, reception will fade or build up in volume as the set is turned around. This characteristic is exhibited because most sets are equipped with a simple loop antenna built directly into the case. Loop antennas, even in this simple form, have definite directional characteristics. These characteristics are:

When the plane of the loop is parallel to the path of the radio wave, a maximum signal will be obtained.

When the plane of the loop is perpendicular to the path of the radio wave, a minimum signal will be obtained.

These directional characteristics of a loop antenna are utilized for navigation and other purposes in the modern, highly efficient loop antenna installed in USAF aircraft.

Like the antenna of a portable radio, an aircraft loop antenna picks up signals at maximum strength when the windings of the loop are parallel to a line drawn from the transmitting antenna to the loop (the edge of the loop is pointed toward the station). Minimum signal strength is picked up when the plane of the loop is perpendicular to this line. The position of minimum signal strength is known as a "null" position. A small change in the direction of the loop near a null position will cause a relatively large change in the received signal strength, while the same small change in loop direction near the maximum position will cause only a small change in the received signal strength.

In other words, the null position of the loop is sharply defined and the maximum position is broadly defined. Consequently, for direction finding, the null position is used in employing the direction of the transmitting station.

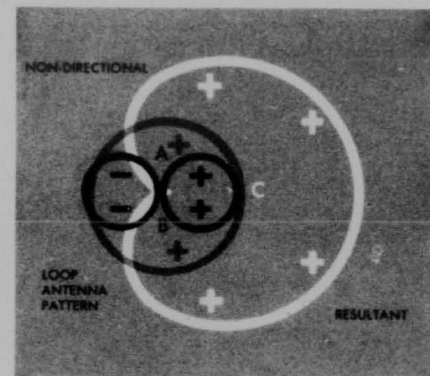

Figure 3-101 Sensitivity Pattern of Radio Compass

It will be observed that a single loop antenna is bidirectional, that is, the station may be in either one of two directions that are 180° apart. This is known as the 180° ambiguity of the loop antenna. It then becomes necessary for the pilot to solve the problem and determine the actual direction of the station.

However, the loop antenna system may be made unidirectional by the introduction of a sense antenna. With the aid of the sense antenna, the bidirectional loop becomes sensitive to the signals arriving from one direction only. The sense antenna is switched into the receiving antenna circuit, either by pressing the sense button (which automatically connects, in addition to the direction finding loop antenna output, the output of the nondirectional sense antenna), or by employing an automatic circuit which continuously gives unidirectional indication.

Figure 3-101 shows how the bidirectional properties of the simple aural-null loop antenna can be changed to a unidirectional sensitivity by the introduction into the antenna circuit of a nondirectional sense antenna. At A is shown the figure 8 pattern of a normally balanced loop antenna disposed vertically with respect to the ground. At B is shown the nondirectional sensitivity pat-

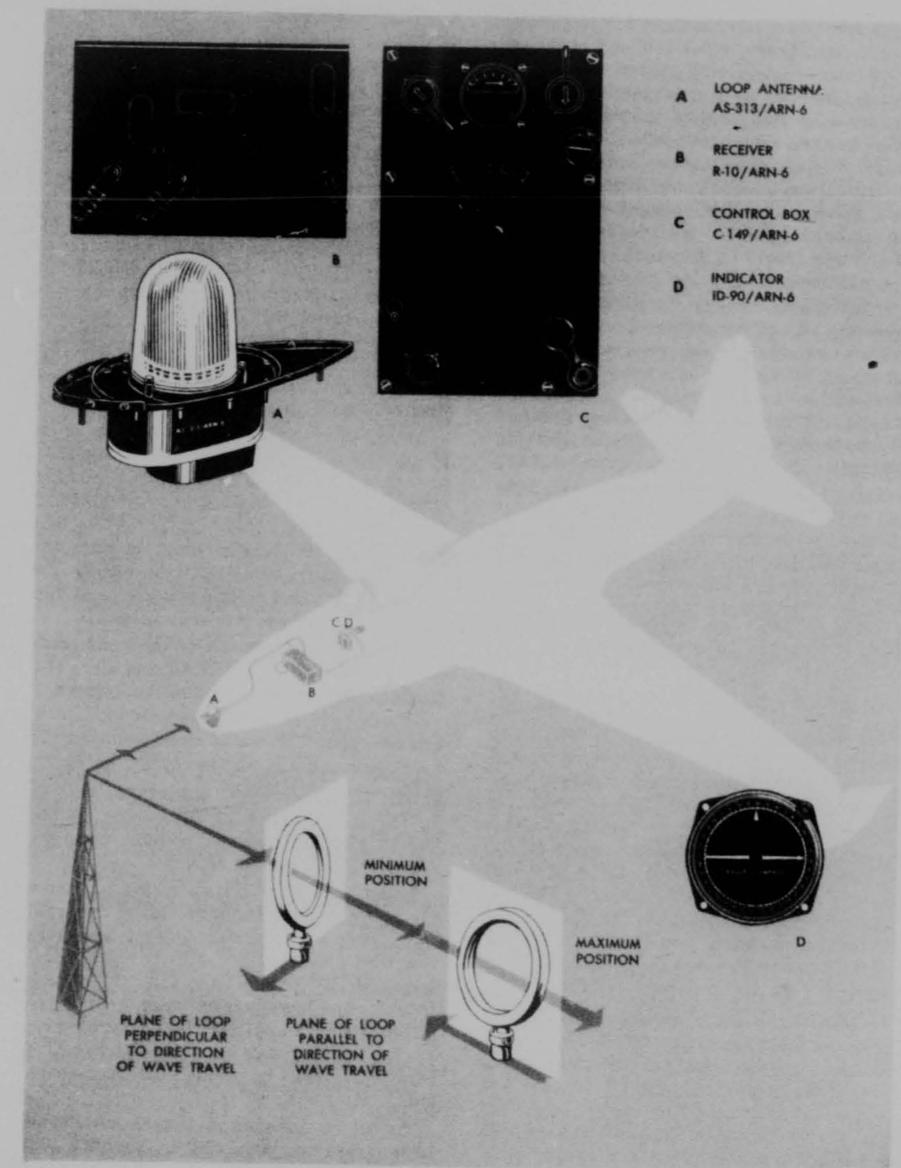

Figure 3-102 Radio Compass Installation and Operation

THIS PAGE IS DECLASSIFIED IAW EO 13526

tern of the sense antenna. When the signals from these two antennas are fed to the receiver simultaneously but 180° out of phase, the combined sensitivity pattern of both antennas assumes a heart-shaped (cardioid) pattern as shown at C in the figure. Thus, whenever the sense antenna's sensitivity is electrically added to the loop antenna's sensitivity, the combined sensitivity pattern of both antennas is aurally responsive only to signals arriving at right angles to the plane of the loop from one direction.

When installed in an aircraft together with a suitable receiver, fixed antenna, controll box and power supply, the directional qualities of the loop can be used for radio direction finding. The loop antenna receiver combination is called the radio compass, although the term "radio direction finding" also is used. There are three types of radio compass equipment employed by the USAF.

Fixed Loop with Left Right Indicator. The indicator employed with this equipment is centered when the loop is in the null position. The fixed-type loop radio compasses are still used in a small number of aircraft. However, the disadvantage of this type of radio compass is evident in that the aircraft must be headed toward the transmitting station in order to obtain a bearing.

Rotatable Loop with Left Right Indicator.

This is a later development of the fixed loop type in that the loop antenna may be manually rotated in order to position the loop on a null. An azimuth scale located near the loop rotating crank shows the longitudinal axis of the aircraft. The indications to the left right indicator are identical with those for the fixed loop type compass. When the left right indicator is centered, the loop is in the null position, and the needle of the azimuth indicator points to the relative bearing of the station from the aircraft.

Automatic Radio Compass. This type of radio compass equipment is the latest development, and currently the standard, in the USAF. When this equipment is used in the compass position, the loop automatically rotates to line up with the radio transmitter in the null position. A pointer turning upon an azimuth scale is synchronized electrically with the loop and indicates the position of the loop with respect to the aircraft, and thus the relative bearing of the radio station to which the radio compass is tuned.

The Aural Null. As stated previously, the null position of the loop antenna is indicated by the radio bearing indicator of the automatic compass, or by noting the reading on the azimuth scale when the left/right needle is centered in the case of the older equipment. Under some conditions, however, it is necessary to determine the null position without using visual indicators. The null position of the loop can be determined aurally by noting the minimum strength of the signals received in the headset, while the position of the loop is changed relative to the radio station. This minimum signal is termed the aural null. The terms "nose-null" and "wing-tip null" are defined as:

Nose Null. The hole in the antenna loop points toward the nose of the aircraft, and the aural null will be received if the radio station is directly ahead or directly behind the aircraft.

Wing-tip Null. The hole in the loop antenna points toward the wings of the aircraft, and a null will be received when the radio station is 90° to the right or left of the aircraft.

Figure 3-102 shows one of the radio compasses employed by the USAF and gives the technical data concerning that equipment.

Loran

Loran is the term for Long Range Navigation. It was developed during the war as an aid to navigation on over-water flights and to give the greatest possible accuracy consistent with maximum range.

Loran is a radio system which measures the time difference in the arrival of the radio waves from a pair of radio stations and from this time difference a line of position is determined. By obtaining a line of position from two or more station pairs, a fix is obtained giving accurately the actual location of the receiving station. Loran charts which carry these lines of position are used as an aid.

To better understand Loran, we should take an example as shown in Figure 3-103. Assume that two stations are 324 nautical miles apart which is 2,000 microseconds of

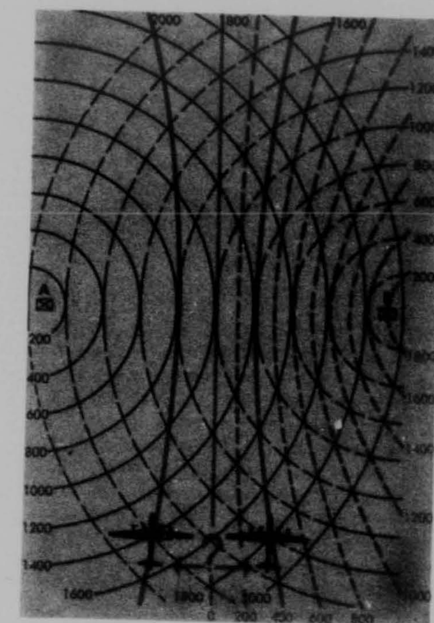

Figure 3-103 Simple Loran

radio time. First, let us assume that stations A and B are broadcasting at the same time. Dotted lines show points of equal time differences, and, as can be noticed, these time differences are the same on both sides of the zero (0) line. Thus, if an aircraft is on a time difference line of 400 microseconds, the pilot cannot know whether he is to the left or the right of the zero line.

This difficulty is removed in actual Loran practice by a method of pulse staggering which operates as follows: first, a "master" or A-type station transmits a pulse. After reception of this pulse, the "slave" or B-type station awaits a definite fixed amount of time plus another variable interval called the "code delay" before it transmits its pulse. As a result of this delay at all points within the area of coverage of the two stations used, the time interval between a master-station pulse and the next slave-station pulse is always greater than the interval between the slave-station pulse and the master-station pulse. This results in each time difference having a number of its own. (See Figure 3-104.)

Thus, if an aircraft were at the line of position marked with the cross shown in Figure 3-104, it would indicate that the Loran operator would have a reading of 2,600 microseconds time interval. In order to get a fix, the operator would need to obtain a similar reading from another station pair, and where the two lines of position cross, he would have his fix point.

Time measurement is made possible by the use of the cathode-ray tube measuring device that has been employed extensively in radar. The receiver operates in the medium frequency band and feeds a video signal to the indicator unit. The signal from the master station arrives at the aircraft first and is shown on the cathode-ray tube, then the signal from the slave station arrives and is shown on the same tube.

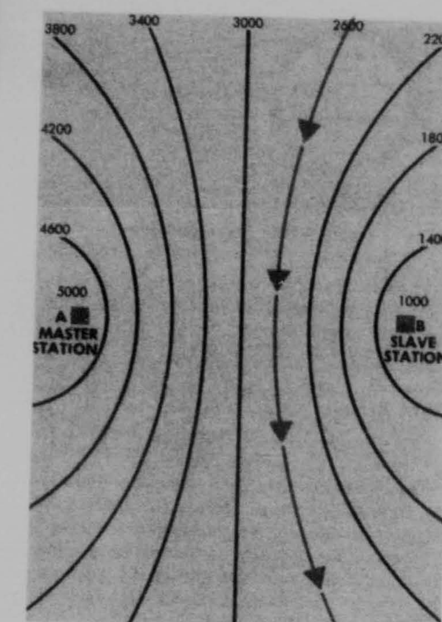

Figure 3-104 Actual Loran Practice

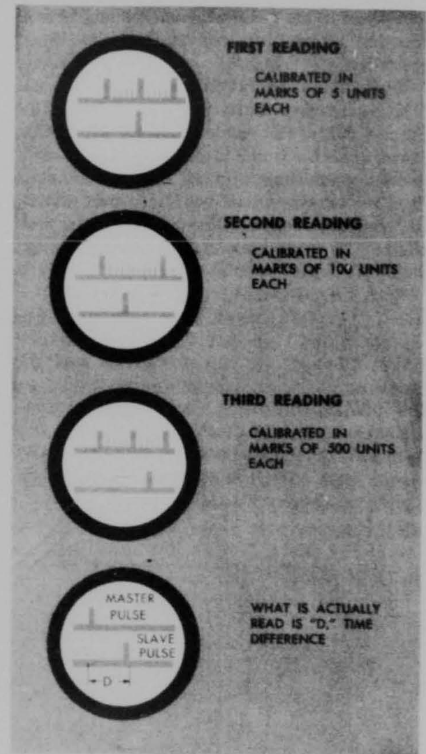

Figure 3-105 Loran Readings

Various readings are taken to give accuracy. A typical group of readings taken from the CRT might be:

First Reading	24
Second Reading	300
Third Reading	3,500
	3,824 microseconds

The operator can then measure directly the time difference in the arrival of the two signals. In addition to measuring this time difference, the operator is able to determine the identification of the station by reading the setting of certain dials on the face of the equipment. With this information, he is then able to refer to his Loran chart and determine the line of position upon which he is located. By repeating the process upon a second pair of stations, he is able to determine a second line of position and from this information to determine a fix.

The accuracy with which positions may be obtained by Loran varies with the location of the aircraft relative to the ground stations, and with atmospheric receiving conditions. In general, it is comparable to positions obtained by celestial observations. Errors of less than a half-mile may be expected in favorable locations and under good conditions; in unfavorable locations under poor conditions errors occasionally may exceed five or ten miles.

The effective range of Loran over sea water is about 600 to 700 nautical miles in the daytime and 1,200 to 1,400 nautical miles at night. This great range is achieved by the use of relatively low radio frequencies, just above the standard broadcast band, which can be propagated over the curvature of the earth.

The navigator can think of Loran as merely another method of determining line-of-position. These Loran lines may be crossed with other Loran lines, with sun lines, star lines, radar-range circles, or bearings to provide fixes. Loran lines are fixed with respect to the earth's surface; accuracy is not dependent upon the aircraft compass or chronometer, and it is not necessary to break radio silence to use Loran. Subject to the variation in range with time of day, Loran readings are possible at all times and in all weather conditions except during severe electrical disturbances, and they are almost as easy to make in rough air as in smooth air. A set of readings may be made and the position of the aircraft may be determined in three to five minutes under favorable conditions.

Loran is subject to enemy action and may be jammed. Such action can be detected and identified as intentional jamming by a well trained operator. The traffic handling capacity of the Loran system is unlimited. The system is entirely automatic and functions continuously. Therefore, any number of aircraft may use the system simultaneously without interference.

Special charts have been printed for use

in Loran navigation. They are on the Mercator projection and contain superimposed lines-of-position for the stations most likely to be received in the area covered by the chart. Each station's lines-of-position are in different colors and are marked with the microsecond reading if the aircraft is on that line-of-position. On most charts, the lines are separated by intervals of 20 microseconds. For any reading between these lines the navigator must interpolate by eye and draw his line-of-position.

High-frequency Direction-finding

High-frequency direction-finding (HF D/F) is another system provided to assist in navigating over long distances. This type of navigational aid is primarily for use with multiengine aircraft which carry a radio operator. These stations are, in general, used for providing fixes and courses to steer. The D/F nets consist of three or more stations placed in a line or semicircle that usually stretches some 600 miles in length and are located along the air routes. When in range of such a net, the pilot or radio operator may call in for a fix. The D/F operator then alerts the net and the aircraft is requested to send a series of dashes and call letters on which the D/F stations can take bearings. These bearings are then forwarded to an evaluation center for the purpose of plotting the bearings and determining the fix. At the evaluation center, the triangulation method is employed to determine the exact location of the aircraft. Three or more bearings are drawn on a map of the area covered by the net. Since these stations normally monitor aircraft frequencies, it often happens that they hear the request for a fix before the net is alerted and thus are able to send in the bearings before they are asked to do so.

The D/F service does not stop with the giving of a single fix or bearing. Often, the net tracks aircraft for hours, particularly when it is known that they are low on fuel or are disabled. In this way, the location of the aircraft is known at all times, and if the aircraft is forced down, rescue operations can be initiated immediately. Constant practice of all personnel involved in this operation is required in order to increase the efficiency of this system.

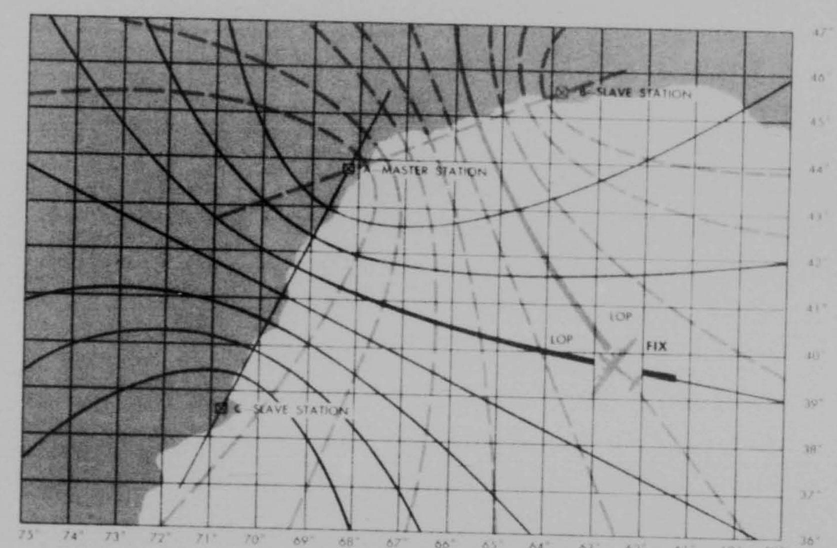

Figure 3-106 Loran Navigation Chart

The principle of operation of any direction-finding ground-based equipment is predicated on the use of a sensitive directional antenna, usually the Adcock type. The ground station manually, or electrically, turns the antenna until a null is obtained and the direction of the aircraft is determined. The same principles underlying the airborne radio compass are applied here.

A fair degree of accuracy may be expected from this system, roughly a ten-mile error at distances of 500 miles. The ranges of such a direction-finding system varies, depending on the time of day and the atmospherics conditions at any time. The range of an efficient system is approximately 1,000 to 2,000 miles. However, the system has inherent limitations. The fact that most of the transmissions must be Morse code makes it rather slow. The system is easily saturated since only one aircraft may use the system at one time. Also, it is vulnerable to enemy countermeasures such as jamming.

VHF Direction-finding

The VHF D F system operates on the same principles as the HF system. The paramount difference is in the use of the two systems. The VHF system is limited by the line-of-sight conditions under which it operates. Its primary use is with fighter aviation, since voice communication is employed between the pilot and the direction-finding station and because of the range limitation of the equipment employed.

Instrument Approach System

Facilities for the guidance of aircraft from point to point under adverse weather conditions have existed for a long time. Such facilities will guide the aircraft to the vicinity of the airfield but are not sufficiently accurate to bring the pilot close enough to the runway to land without visual reference to the ground. The USAF instrument approach system (Figure 3-108) consists of the radio transmitting and receiving equipment that furnishes the pilot with lateral and vertical guidance to the runway, and indication of distance away from the runway.

The system is used by multiengine-type aircraft provided with specialized airborne receiving equipment. All the indications to the pilot pertaining to his course glide path and distance to go are by visual means. Course and glide path information is presented on a two-pointer indicator; a vertical needle indicates the glide path. Present indication of distance is shown by an aircraft marker beacon light mounted on the instrument panel. This method provides the pilot with a series (usually three) of check points along the line of flight. Approaches to within fifty feet of the ground and at the rate of one aircraft every three minutes is considered possible for undamaged aircraft flown by experienced pilots and when a suitable means of controlling the aircraft to the point of entry on the glide path exists. No facilities are included for handling and stacking procedures.

The localizer transmitter, located at the far end of the runway, provides the signal that when received by the localizer unit located in the aircraft, give the pilot a **"fly right"** or **"fly left"** indication to keep his aircraft lined up laterally with the runway. The range of this signal is approximately forty miles at an altitude of 5,000 feet. The range of different installations of the localizing equipment may vary, depending upon the type of terrain over which the signal is transmitted, the condition of the transmitter, and the installation and condition of the receiving equipment.

The glide-path transmitter, located approximately 750 feet from the approach end of the runway and approximately 400 feet from the center line of the runway, provides (in conjunction with the aircraft receiving equipment) a "fly up" or a "fly down" signal to guide the pilot along a safe descent path to the ground. The range of the glide-path transmitter may vary under the same conditions as for the localizer transmitter.

Three marker beacon transmitting apparatus, one located near the approach end of the runway, one located approximately one mile from the approach end, and one located approximately four and one-half miles from the end of the runway provides the pilot with indication of his distance from the landing area. The marker beacon transmitters have a vertical range of approximately 3,000 feet.

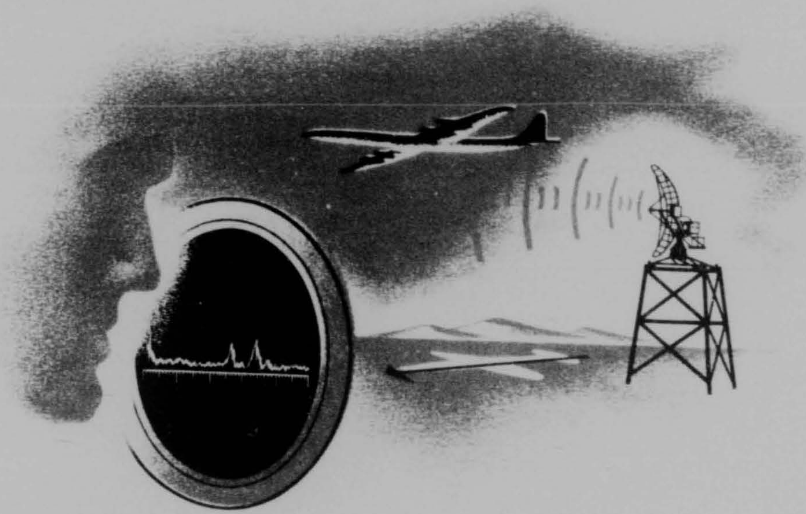
CHAPTER 4 - RADAR



SECTION 1 - HISTORY OF RADAR

1. GENERAL

Radar is a radiation device which may be used for detection and ranging of targets independent of time and weather conditions. It is properly studied under communications since it extends one of the senses of the commander—that of sight. It furnishes him with intelligence by permitting him to see some object that is not visible. The word "radar" is derived from the phrase RAdio Detection And Ranging.

2. HISTORICAL DEVELOPMENT

Undoubtedly, radar was one of the greatest scientific developments which emerged from World War II. Its development, like that of most other great inventions, was mothered by necessity—in this case, the necessity for offsetting an offensive weapon which made its first appearance in World War I, the military airplane. The basic principles upon which its functionings depend are simple and easily understood. Therefore, the seemingly complicated series of electrical events encountered in radar may be resolved into a logical series of functions.

Although the complete history of the origin and growth of modern radar is long and complicated, it is of sufficient interest to sketch here its main points.

Successful pulse-radar systems were developed independently in America, England, France, and Germany during the latter part of the 1930's. Behind the development lay more than fifty years of radio development for communication purposes, and a few early suggestions that, since radio waves are known to be reflected by objects whose size is in the order of a wavelength, they might be used to detect objects in fog or darkness.

THIS PAGE IS DECLASSIFIED IAW EO 13526

The fact that radio waves have optical properties identical with those of light was established by Heinrich Hertz in 1886 in the famous series of experiments in which he first discovered radio waves. Hertz showed, among other things, that radio waves were reflected by solid objects. In 1904, a German engineer, Hulsmeyer, was granted a patent in several countries on a proposed way of using this property in an obstacle detector and navigational aid for ships. In 1922, Marconi strongly urged the use of short waves for radio detection.

One of the first observations of radio echoes was made in the United States in 1922 by Dr. Albert H. Taylor of the Naval Research Laboratory. Taylor observed that a ship passing between a radio transmitter and receiver reflected some of the waves back toward the transmitter. By 1930 further tests proved the military value of this principle for the detection of surface vessels which were hidden by smoke or darkness. Further developments were conducted with carefully guarded secrecy. During this same period, Dr. Breit and Dr. Tuve of the Carnegie Institute at Washington published a report concerning their investigations of the ionosphere in which they first employed the principle of pulse ranging for measuring the height of the ionosphere. It is this principle which characterizes modern radar. After the successful experiments of Breit and Tuve, the radio-pulse echo technique became the established method for ionospheric investigation in all countries. In retrospect, the step from this technique to the idea of employing it for the detection of aircraft and ships is not a great one. The application was evolved by various individuals, acting independently and almost simultaneously in America, England, France, and Germany about ten years after the original work by Breit and Tuve.

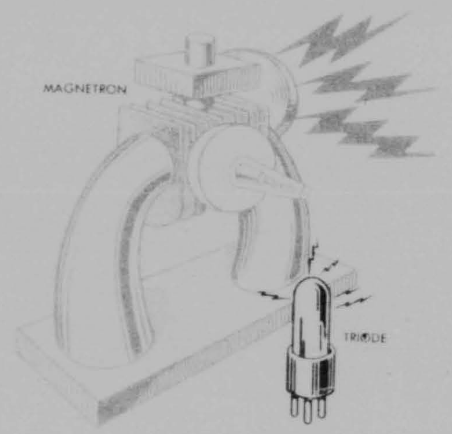
The United States military research agencies have a long history of early experiment, total failure, and qualified success in the field of radio detection. In early 1939, a radar set designed and built by the Naval Research Laboratory was given exhaustive tests at sea during battle maneuvers. Earlier, in November 1938, a radar position-finding equipment intended for the control of antiaircraft guns and searchlights, was designed and built by the Signal Corps Laboratories. This set underwent extensive tests and then went into production and became known as the SCR-268. The Air Force requested the Signal Corps to design and construct a long-range radar for the detection of aircraft. This set was successfully demonstrated in November 1939, with actual large-scale production getting underway in August 1940. This radio equipment became known as the SCR-270.

British radar was developed at about the same time but its application proceeded at a somewhat faster rate because of the pressure of war. The first experimental radar system of the type suggested by Sir Robert Watson-Watt was set up in the spring of 1935 on a small island off the coast of England. Development work during the summer led to the blocking out of the main features of the British early-warning stations by fall. Work began in 1936 toward setting up five stations about twenty-five miles apart to protect the Thames estuary. By March 1938, all these stations, the nucleus of the final chain, were complete and in operation.

British radar development then turned its maximum efforts to airborne equipment. Two types were first envisioned: a set for the detection of surface vessels by patrol aircraft, to be known as "ASV equipment," and an equipment for enabling night fighters to home on enemy aircraft, to be known as "AI" (Aircraft Interception). The first work was done on the ASV equipment and a successful demonstration made during fleet maneuvers in September 1938. Working models of the AI equipment were completed by June 1939 and successful demonstrations were made to the RAF Fighter Command in August. Four of these sets were installed and operating when the war broke out in September.

Emphasis on airborne radar brought out clearly that if sharp radar beams were to be produced by antennas small enough to be carried on aircraft, wavelengths shorter than the $1\frac{1}{2}$ meters used in the early British airborne equipment would have to be em-

ployed. This naturally led to the effort of developing a generator of microwaves which could give pulse power adequate for radar use. By early 1940, a British version of the multicavity magnetron had been developed to the point where it was an entirely practicable source of pulsed microwave energy.



In the fall of 1940, an early model of this magnetron operating on ten centimeters was brought to the United States for examination. The first American test of its power capabilities was made in October at the Bell Telephone Laboratories. This test confirmed British information and demonstrated that a generator now existed which was capable of supplying several times the power of the conventional triodes then in use and at a frequency four times greater. This point marks the beginning of modern radar.

The rapid progress of radar has been effected by free interchanges of information between the Americans and the British during the war. Under the pressure of war, the development of radar in seven years may be compared with the development of aircraft over a period of forty years.

Multicavity magnetron oscillators which will be discussed later, are now available for use in pulsed and continuous-wave generators at wavelengths from .5 to 50 centimeters. The upper limits of peak power now available are approximately 100 kilowatts at 1 centimeter, and 3 megawatts at 10 centimeters. The amount of peak power available for use decreases as the wavelength is decreased but improvements in magnetron design have been steadily pushing the amount of peak power available to higher values. Magnetrons may have operating voltages from about 1 kilovolt to 40 kilovolts. The magnetic field essential to operation ranges from 600 to 15,000 gausses. Tunable magnetrons are now available for many portions of the microwave band.

The effectiveness of radar as both an offensive and defensive weapon is already generally known, but some of the most salient features may bear repeating.

The British early-warning chain of radar stations is credited with having saved that country during the German blitz warfare in late 1940. Its tactical employment permitted a small RAF fighter force to be used at its greatest efficiency. The radar system allowed the aircraft to remain on the ground until approaching enemy aircraft were detected, then the fighters could be sent into the air to meet the enemy. The employment of an aircraft warning system of this type enabled the RAF to withstand the assaults of a numerically greater air force. If the method of maintaining aircraft on constant air patrol had been employed, it would have required many more pilots and aircraft than the British had available for the task. The use of radar permitted the planes to be serviced and the pilots to rest during periods of inactivity.

At first, radar was envisioned as a defensive weapon, but as the war progressed it came to be used for offensive purposes. By the end of May, 1941, radar had been employed to track aircraft automatically in azimuth and elevation and later to track the target automatically in range. This was the prototype of the antiaircraft position finder. The equipment for this purpose later became known as the SCR-584 and the SCR-545.

Further advancement in the field of air-

THIS PAGE IS DECLASSIFIED IAW EO 13526

borne radar permitted the development of sets that could be employed for long range navigation through overcast skies and the carrying out of strategic bombing missions in all kinds of weather. The technique of radar bombing was developed which permitted the bombardier to hit his target even though it was not visible to him. These developments gave the Air Force the ability to perform its job on an around-the-clock basis in all kinds of weather—an essential feature in successful military operations.

Gunfire-control radar developed as rapidly as the other types of radar. The Navy had success in destroying enemy shipping and naval forces with radar-controlled guns. However, the development of fire-control radar was not confined to surface equipment. The same principles were employed in making airborne gun-laying equipment.

Radar, both airborne and ground, has made a lasting impression on military tactics and will find an important place in the defense scheme of the nation and in any future military operations. Its employment in civilian aviation is still uncertain since the equipment is expensive and requires experienced personnel for operation and maintenance. In 1946, Signal Corps research workers received echoes from the moon with an SCR-271 radar.

Radar is being employed extensively in marine navigation, particularly in large, crowded harbors, such as those of New York and San Francisco.

SECTION 2 - PRINCIPLES OF RADAR

1. DEFINITION

Radar is the application of radio principles for detection of objects in space. In order to understand radar, it may be pertinent to use a familiar analogy.

2. GENERAL PRINCIPLES

Radar operates on a principle that is very similar to the reflection of sound waves. If a person shouts towards a cliff or some other sound-reflecting surface, he will hear the shout return from the direction of the cliff. What actually happens is that the energy in the sound wave travels through the air until it strikes the cliff where some of the energy is absorbed and the remainder is reflected back in the direction from which it came. Since some time elapses between the shout and the returned echo, it is possible to measure the distance of the object. Sound travels through air at approximately 1,100 feet per second. If a person shouts and it takes four

seconds from the instant he shouts until he hears the echo, he will be able to calculate that he is 2,200 feet from the object. The sound takes one half of the elapsed time to travel the distance to the cliff and the other half to return. Therefore, one half of the total time multiplied by the velocity of sound will give the distance to the object.

The distance to the object, however, is not the only consideration; to be able to determine the location of the object in space, it is necessary to know the bearing and altitude of the target as well as the distance from the observer. If a directional device is built to transmit and receive the sound waves, it then becomes possible to determine the direction and height of the object as well as the distance. A source of pulsating sound, at the focus of a parabolic reflector, is so arranged that it transmits a parallel beam of sound waves. The receiver is a highly directional microphone located inside a reflector to increase its directional effect. The microphone may be connected to an amplifier and a loudspeaker. It is assumed that the distance between the transmitter and the receiver is negligible when compared to the distance to the cliff.

To determine the distance and direction, the transmitting and receiving apparatus is placed so that the line of travel of the transmitted sound wave and the received echo coincide. The apparatus is then rotated until the maximum volume of the echo is received. The distance to the cliff can then be determined by multiplying one-half of the elapsed time in seconds by the velocity of sound. This will be the distance along the line RA. If the receiver apparatus is equipped with a circular scale marked in degrees and has been properly oriented with respect to north, the bearing or direction of the cliff may be determined. Thus, if the bearing is 45°, the cliff lies northeast of the receiving position.

To determine altitude (Figure 4-2), the transmitter and receiver are elevated from the horizontal position while aimed in the same direction. At first, the echo is still heard but the elapsed time is increased slightly. As the angle of elevation is increased further, a point is found where the echo disappears. This is the angle at which the sound wave is passing over the top of the cliff and therefore is not being reflected to the receiver. The point at which the echo disappears is that where the angle of elevation is such that the apparatus is pointed at B. If the receiving apparatus is equipped with an elevation scale, the angle of elevation may be determined as well as the distance RB. With this information, it is possible to determine the distance RA and the altitude AB. However, the altitude AB is the altitude above the transmitting station.

3. OPERATING PRINCIPLE

All radar equipment operates on a principle very much like that just described for sound waves. In radar equipment, a radio wave of extremely high frequency is used instead of a sound wave.

The energy transmitted by the radar equipment is similar to that transmitted by an ordinary radio transmitter. The radar has one outstanding difference in that it detects its own signals. It transmits a short pulse of radio energy and then rests for a short period of time waiting for a signal to return. This cycle of transmitting and waiting is repeated from 60 to 4,000 times per second depending upon the design range of the equipment. If there is no object in space for the outgoing energy to strike, it simply travels on out and is lost.

If, however, the wave strikes an object such as an aircraft, a ship, a building, a hill, or a cloud, some of the energy will be returned as a reflected wave or an echo. When the object in space is a good conductor of electricity and is large, as compared with a quarter-wavelength of the transmitted radio energy, a strong echo is returned by the object. However, if the object is a poor conductor of electricity or is small when compared with a quarter-wavelength of the transmitted radio energy, the returned echo will be weak. When radio energy strikes an object possessing the proper characteristics, some of the energy will be reradiated. In effect, the object becomes a source of radio energy or a parasitic transmitter. The atmosphere itself may cause reflection under conditions similar to those discussed in con-

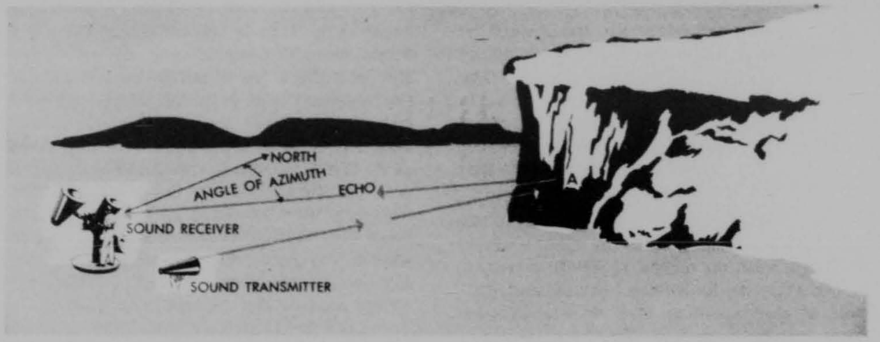


Figure 4-1 Determination of Direction

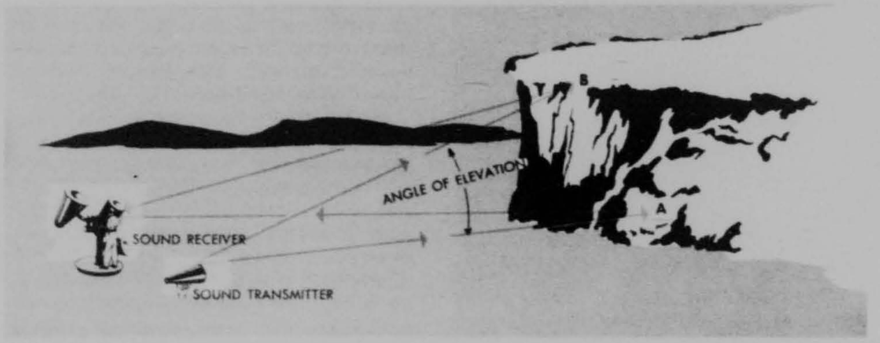

Figure 4-2 Determination of Height

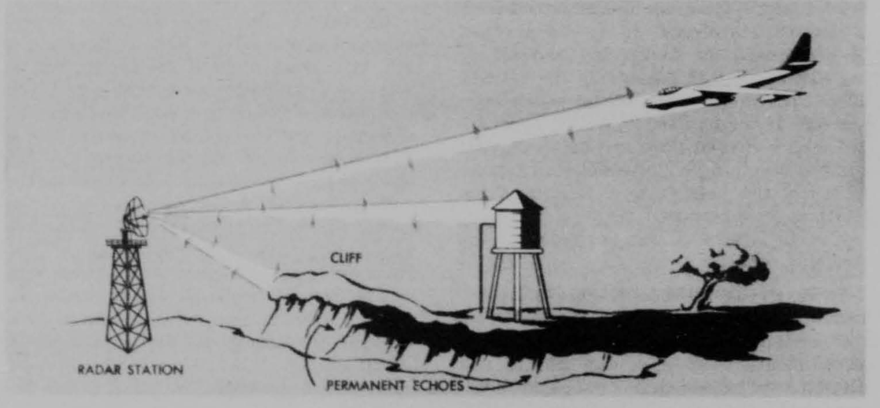

Figure 4-3 Transmission and Reflection of Radar Pulses

Restricted

junction with ionospheric and tropospheric propogation.

Radio waves of extremely high frequency travel in a straight line and with the speed of light. Accordingly, there will be an extremely short time interval between the transmission of the pulse and the reception of the echo. Therefore, it must be possible to measure this very small time interval if the range of the object is to be determined. The cathode-ray tube makes it possible to measure this small time interval with a high degree of accuracy, even to one ten-millionth of a second. (The functioning of the cathode-ray tube will be discussed in detail elsewhere in this chapter).

Radar employs a highly directional antenna to transmit and receive the radio energy in a more or less sharply defined beam. The beam is similar to that of the anti-aircraft searchlight. Therefore, when a signal is picked up, the antenna can be rotated until the received signal is maximum, and the direction of the object may be determined by the antenna position.

4. RADAR METHODS

Continuous-wave

One of the methods for detecting aircraft employs a continuous-wave type of transmission and makes use of the Doppler effect to detect the presence of an object in the space that is being scanned. When radio-frequency energy, which is being transmitted continuously, strikes an object which is moving toward or away from the transmitter, energy is reflected but its frequency is changed slightly. The change in frequency is known as the Doppler effect. A similar effect at audible frequencies is readily recognized when the pitch of a train whistle changes as it approaches and recedes from the listener. The radar application of this effect measures the difference in the frequency between the transmitted and reflected energy to determine the presence and speed of a moving target. This method works well with fast moving objects, but not with slow moving objects since there is very little change in the frequency in the latter case. CW systems are, therefore, limited to the detection of fast moving objects. The rate at which the wavelength will change may be readily computed from the following formula:

$$\Delta\lambda = \lambda \frac{\mu}{v}$$

$\Delta\lambda$ = change in wavelength
λ = wavelength of the transmitted wave
μ = velocity of the object radially from the transmitter.
v = velocity of radio waves.

If the object is moving away from the source of radio energy, the wavelength will be longer, and, therefore, the reflected signal frequency will be lower than the frequency at the transmitter. When the object is moving toward the source of radio energy, the reflected frequency will be higher than that of the transmitter.

Frequency Modulation

A second method that has been employed for radar work is the frequency modulation method. If the frequency of the transmitted energy is varied continuously and periodically over a specified band, the frequency of the energy of the transmitter being radiated at any instant will be different from that being received by the object in space. This difference occurs because of the time required for the energy to reach the object and return. The frequency difference depends on the distance traveled and can be used as a measure of range. Moving objects produce a frequency shift in the returned signal because of the Doppler effect and influence the accuracy of range measurement.

Pulse Modulation

The method most widely employed in modern radar is the pulse-modulation method. Radio-frequency energy can be transmitted in short pulses of a time duration varying from one to fifty microseconds. If the transmitter is turned off before the reflected signal returns from the object in space, the receiver can distinguish between the transmitted and received signals. After all the reflections of interest have returned, the transmitter is again turned on and the cycle is repeated. The receiver collects the returned signal, applying it to an indicator which is capable of measuring the time interval between the transmitted signal and the returned signal.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Since the velocity of radio energy is constant, the time measurement becomes a measure of the distance traveled and normally is calibrated directly in miles. This method does not depend on the relative frequency of the returned signal or on the motion of the target; thus, the difficulties experienced in the C-W and FM methods are not present.

Determination of Range. The velocity of radio frequency is the same as that of light, approximately 186,296 miles per second, or approximately 328 yards per microsecond.

The constant velocity of radio-frequency energy is applied in pulse-modulated systems to determine range by measuring the time required to travel to the object and return. For example, assume that a pulse, one microsecond long, is transmitted toward an object which is 32,800 yards distant. Figure 4-4 shows the conditions at the instant the pulse is radiated. When the pulse reaches the object, it has traveled a distance of 32,800 yards at 328 yards per microsecond, and therefore, 100 microseconds have elapsed. Figure 4-5 shows the radar pulse just as it arrives at the target. A portion of the pulse is then reflected, and the energy is returned over the same path. Since the return trip is also is 32,800 yards, the time required is again 100 microseconds. Figure 4-6 shows the pulse returned to the radar station. The total elapsed time is now 200 microseconds, since the distance traveled is twice the actual range of the object. For radar ranging, therefore, the velocity is considered to be one half of the true value, or, 164 yards per microsecond. In the example, range = time in microseconds times 164 = 32,800 yards.

In order to employ the time-range relationship, the radar system must have a time-measuring device. In addition, since there may be more than one object in the region under search, some means of separating and identifying pulses must be included. The cathode-ray tube is well suited to such a task since it retains the information on its screen for a short time and also forms a time scale. The time scale is provided by using a linear sweep to produce a known rate of motion of the electron beam across the screen of the cathode-ray tube.

The measurement of time is illustrated in the following example. Assume that a cathode-ray tube is used with a horizontal linear sweep which produces a beam with a velocity of 1 inch per 100 microseconds across the screen. The signals received from an object at a range of 32,800 yards are applied to the cathode-ray tube as a vertical deflection. Following the same sequence of operations as in the previous illustration, Figure 4-7 shows the radio-frequency pulse leaving the radar antenna and the sweep just starting across the screen. In 1 microsecond the leading edge of the pulse has moved 328 yards from the antenna and the sweep trace has moved 0.01 inch across the screen. The pulse is shown on the screen as a vertical deflection since the receiver detects the pulse which is supplied to the transmitting antenna. After 100 microseconds elapsed time, the pulse reaches the object 32,800 yards away, and the sweep trace has moved 1 inch. (Figure 4-8). Since the radio-frequency pulse energy is out at the object, there is no vertical deflection of the trace. The reflected pulse returns to the radar antenna at the end of 200 microseconds, during which time the sweep trace has moved a total distance of two inches. For the length of the received pulse (1 microsecond), the sweep is deflected vertically (Figure 4-9) giving a total elapsed time of 201 microseconds. Thus, with a constant sweep-trace velocity of one inch per 100 microseconds, a time scale is produced which is equivalent to 100 microseconds times 164 yards per microsecond or 16,400 yards per inch of trace. If another object returned the transmitted pulse in 300 microseconds, the returned signal would be indicated 3 inches from the start of the sweep, and the range of the object would be 300 x 164 = 49,200 yards.

The single trace will not persist on the screen of the cathode-ray tube for sufficient time to be useful. Therefore, it is necessary to repeat the pulse transmission and the sweep trace periodically. If the two operations are made to start in the same time relation to each other, signals returned from a given object will be superimposed on each by successive sweeps. The signals from all objects will be shown on the cathode-ray tube in their proper range positions.

5. PULSES AND DUTY CYCLE

Pulse Repetition Frequency (PRF)

Sufficient time must be allowed between the transmitted pulses for an echo to return from any target located within the maximum workable range of the system. Otherwise, the reception of echoes from more distant targets will be obscured by succeeding transmitted pulses. This necessary time interval fixes the highest frequency which can be used for pulse repetition.

When the antenna is rotated at a constant speed, the beam of energy strikes a target for a relatively short time. During this time, a sufficient number of pulses of energy must be transmitted in order to return a signal which will produce a lasting indication on the face of the cathode-ray tube. The persistence of the screen and the rotational speed of the antenna therefore determine the lowest repetition rate that may be employed.

In a system in which the entire interval between transmitted pulses is used in the indicator, the repetition frequency must be very stable if accurate range measurements are to be made. Since the persistence of the cathode-ray tube will normally be fairly long, successive traces should appear in exactly the same position to avoid blurring.

High-repetition frequencies are employed in radars that are designed for short ranges. Low-repetition frequencies are used in long range radars.

Pulse Length

The minimum range at which a target can be detected is determined largely by the length of the transmitted pulse. If a target is so near the transmitter that the echo is returned to the receiver before the transmitter is turned off, the reception of the echo obviously will be masked by the transmitted pulse.

Normally, it is said that a radar set measures the distance to the target. Actually it measures the time required for a radar pulse to reach the target and be reflected back to the station. Thus, the range scale on a radar indicator is a scale of elapsed time repeated in synchronization with the transmitted pulses. It may be regarded as a distance scale since there is a fixed relationship between a particular distance and the time required for a radar pulse to traverse it in both directions. The minimum range difference at which two targets can be resolved varies directly with the pulse length. With a 1 microsecond pulse, aircraft inseparable in azimuth can be resolved if they differ in range by more than 164 yards plus a small distance which depends on the characteristics of the receiver and indicator. With a 5 microsecond pulse, this limit becomes 820 yards plus the additive constant. In other words, targets may be resolved in range if they are separated by a distance equal to one-half of the pulse length. Since a reflecting object of the smallest possible depth in range will just return the entire pulse, it is apparent that the return from a thin sheet of metal at right angles to the radar beam will have an indicated depth equal to one-half of the pulse length. In a like manner, the indication from objects having considerable depth will be increased by an amount equal to one-half of the pulse length. Obviously, it is desirable that pulse length be as short as possible in order that the best range resolution be obtained.

It is customary to calibrate radar equipment so that range is measured to the beginning of the pulse representing the nearest edge of the target. This removes the range error, caused by the pulse length, on the side of the target nearest the radar but adds the entire error to the far side. Thus, the range accuracy to the near side is unimpaired but, depending upon the shape of the target, identifying characteristics such as size may be obscured. Also, since this is an error in range only, two targets less than one-half pulse length apart will appear on the indicator as a single target.

The major portion of the range error is due to the pulse length, however, a small part of this error is the result of the recovery time of the receiver. The receiver requires a small amount of time to recover from the transmitted pulse before it is in condition to receive a returned pulse.

THIS PAGE IS DECLASSIFIED IAW EO 13526

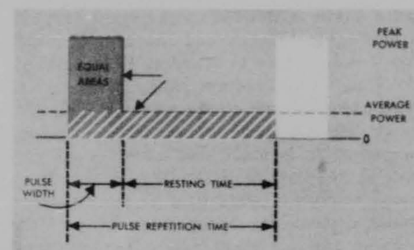

Figure 4-11 Relationship of Peak and Average Power

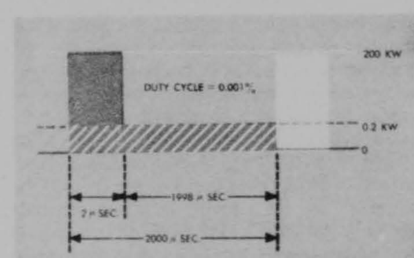

Figure 4-12 Duty Cycle

Average and Peak Power

A radar transmitter generates radio frequency energy in the form of extremely short pulses and then is turned off between pulses for comparatively long intervals. The useful power of the transmitter is that contained in the radiated pulses and is termed the "peak power" of the system.

Power is normally measured as an average value over a relatively long period of time. Since the radar transmitter is resting for a time which is long compared to its operating time, the average power delivered is low when compared with the peak power available during the pulse.

A definite relationship exists between the average power dissipated over the period of one cycle and the peak power developed during the pulse. The time of one cycle of operation is the reciprocal of the repetition frequency, $T = 1/f$. Other factors remaining constant, the longer the pulse length the higher the average power; and the lower the pulse repetition frequency the lower the average power. Thus:

$$\frac{\text{Average power}}{\text{Peak power}} = \frac{\text{pulse length}}{1/f}$$

These general relationships are shown in Figure 4-11.

The operating cycle of the radar transmitter may be described in terms of the fraction of the total time that the RF energy is radiated. This time relationship is called the "duty cycle" and may be presented as:

$$\frac{\text{Pulse Length}}{1/f} = \text{duty cycle}$$

For example, a radar with a pulse length of 2 microseconds and a pulse-repetition frequency of 500 cycles per second will have a duty cycle of 0.001. The time for 1 cycle is 1/500 seconds or 2,000 microseconds and the duty cycle equals 2/2,000 or 0.001.

Likewise, the ratio between the average power and the peak power may be expressed in terms of the duty cycle:

$$\frac{\text{Average power}}{\text{Peak power}} = \text{duty cycle}$$

In the above example, it is assumed that the peak power is 200 kilowatts. For 2 microseconds, then, 200 kilowatts of power are available, while for the remaining 1,998 microseconds, zero power is available. Then: average power $= 200 \times 0.001$ or .2 kilowatts.

High peak power is desirable to produce a strong echo over the maximum range of the equipment. Low average power enables the transmitter tubes and circuit components to be made smaller and more compact. Thus, it is advantageous to have a low-duty cycle. The peak power which can be developed is dependent upon the interrelation between peak power and average power, pulse length, and pulse-repetition frequency.

SECTION 3 - FUNCTIONAL COMPONENTS OF THE RADAR SYSTEM

1. GENERAL

Radar systems, although very much alike in theory, vary greatly in detail. They may be very simple in design and detail or they may be very complicated if the information desired is very extensive. However, a single basic radar system can be visualized in which the functional parts hold equally well for all specific equipment. The varying details are the result of manufacturers' designs and patents, and the degree of refinement of the circuits increases with an increase in frequency.

2. FUNCTIONAL BLOCK DIAGRAM

The functional breakdown of a pulse-modulated radar system resolves itself into six essential components. Figure 4-13 illustrates the block diagram of a pulse-modulated radar system. The functions of the parts may be summarized briefly as follows:

Timer

The timer (also known as the "synchronizer," "keyer," or "control central") supplies the synchronizing signals which times the transmitted pulses and the indicator,

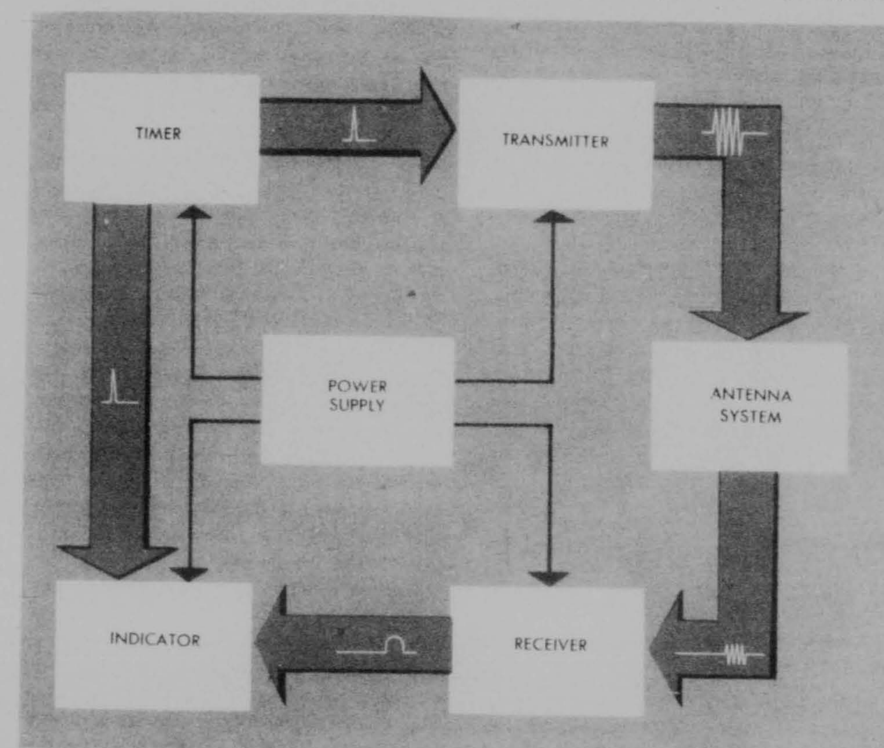

Figure 4-13 Functional Block Diagram of a Fundamental Radar System

and coordinates the functions of other associated circuits. It functions to insure that all circuits connected within the radar equipment operate in a definite relationship with each other and that the interval between pulses is of the proper length. There are two practical methods of supplying the timing requirements.

The first of these methods is the timing by a separate unit. The pulse-repetition frequency, that is, the number of pulses per second, can be determined by an oscillator of any stable type such as a sine-wave oscillator, a multivibrator, or a blocking oscillator. The output is then applied to the necessary pulse-shaping circuits to produce the required timing pulse. Figure 4-14 shows several typical combinations that may be employed for this purpose. The timing of associated components can be accomplished with the output of the timer or by obtaining a timing signal from the transmitter as it is turned on.

Timing also may be accomplished within the transmitter. The transmitter with its associated circuits may establish its own pulse length and pulse-repetition frequency and provide the synchronizing pulse for other components of the system. This action may be accomplished by a self-pulsing or blocking radio-frequency oscillator with properly chosen circuit constants. This method of timing eliminates a number of special timing circuits, but the pulse length and pulse-repetition frequency may be less rigidly controlled than may be desired for some applications.

Transmitter

The transmitter generates the radio-frequency energy in the form of extremely high-powered pulses of very short time duration.

In the self-pulsing radar transmitter, the functions of transmitting and timing are carried out by the same component, as shown in Figure 4-15. This type of transmitter in effect oscillates at two frequencies; the carrier frequency, as determined by the LC constants of the tank circuit, and the pulsing frequency as determined by the RC constants of the grid circuit. The grid capacitor largely controls the pulse length in that its size determines the number of positive RF swings required to charge it sufficiently to block the transmitting tube. The grid leak resistor controls the pulse repetition frequency to the extent that it determines the time required for a sufficient charge to leak off the grid capacitor to unblock the transmitting tube. The timing pulse for other components is developed across a resistor in the cathode circuit of the blocking oscillator.

In the externally pulsed type of radar transmitter, the function of the radio frequency is relatively simple. It generates powerful impulses of radio frequency energy at regular intervals. As the resting time is very long compared with operation time, the oscillator may be greatly overloaded and thus the peak power output may be increased. In this type of operation, the transmitter requires power in the form of high-amplitude square-topped waves that are properly timed. In most cases, the oscillator cannot perform its function directly and therefore it is necessary to use a driver and modulator (Figure 4-16). A driver in any circuit, when triggered, drives the modulator with a rectangular pulse of accurately timed length. A modulator is a circuit which supplies power to the radio-frequency oscillator in the form of a timed, high-amplitude, rectangular pulse. The driver, when triggered, shapes a rectangular pulse of proper time length which in turn operates the modulator. The modulator then furnishes the high-plate voltage to the radio-frequency oscillator for the predetermined pulsing time. Thus the transmitting function may be carried out by the combined performance of a driver, modulator, and the radio-frequency oscillator. The modulator acts as a power amplifier for the driver and as a switch for the radio-frequency oscillator.

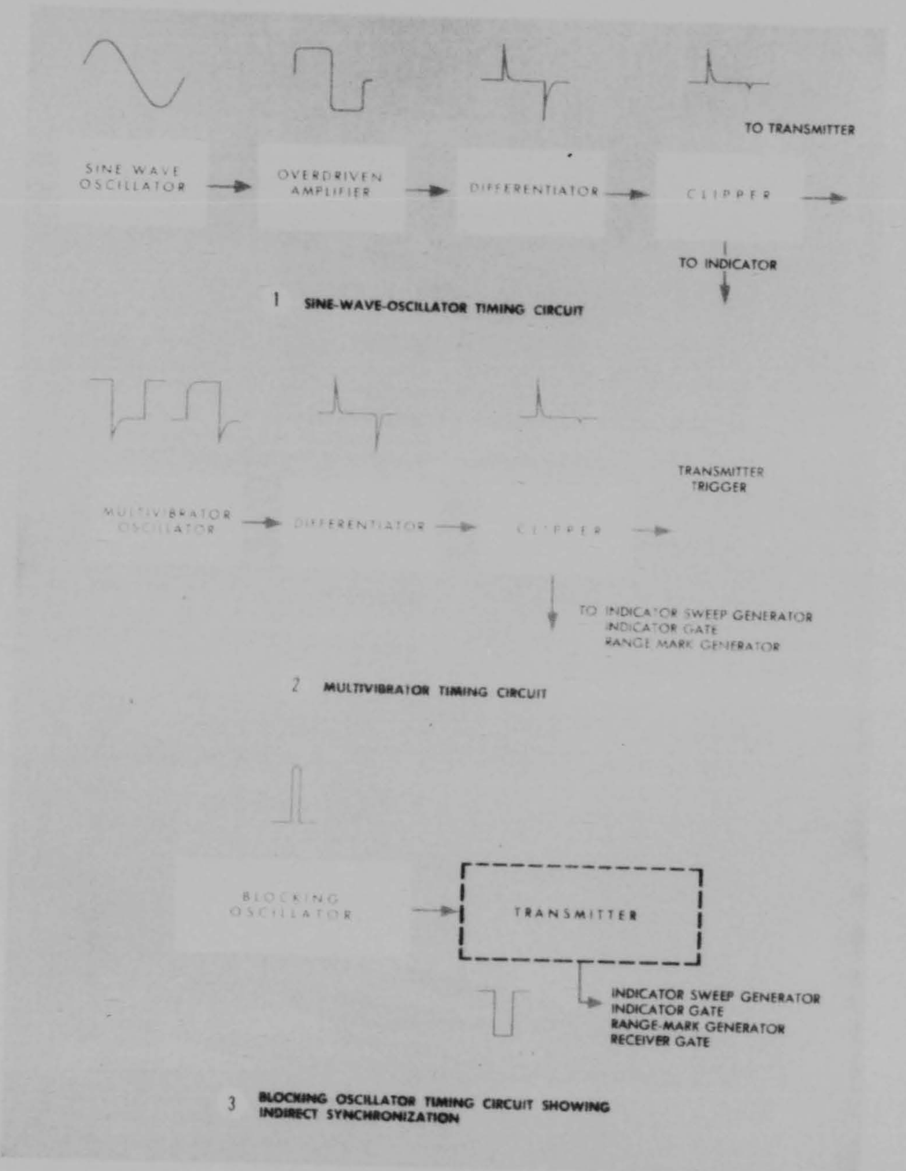

Figure 4-14 Representative Methods of Timing Radar Systems

THIS PAGE IS DECLASSIFIED IAW EO 13526

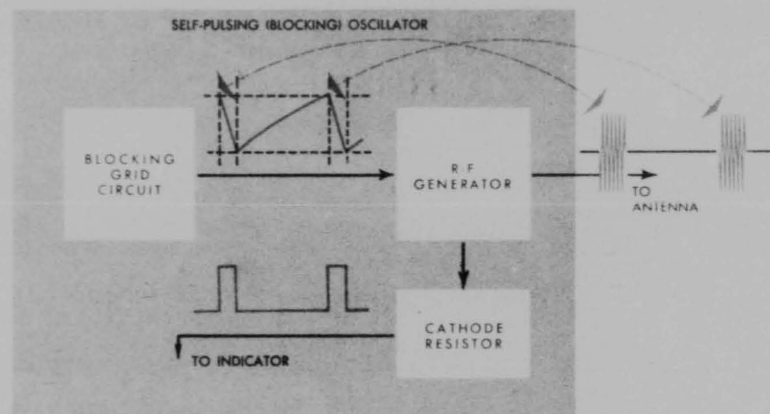

Figure 4-15 Self-Pulsing Oscillator Functioning as Transmitter and Timer

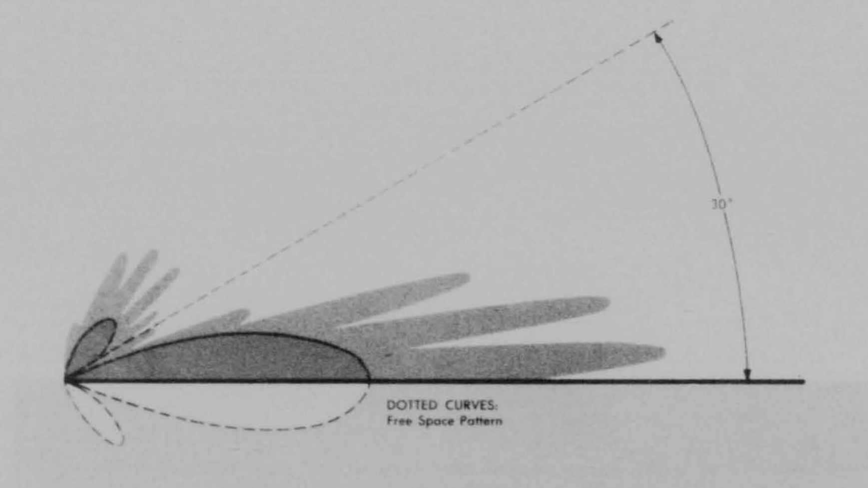
Antennas

The function of the antenna system is to take the energy from the transmitter, carry it to a radiating element, reflect it into a narrow directional beam, recover a portion of the returned energy and pass it to the receiver with a minimum of loss. The antenna system consists of the radio-frequency transmission lines from the transmitter to the radiating antenna array, the antenna array itself, and the transmission line from the antenna array to the receiver. Any antenna switching device or receiver protecting device is considered part of the antenna system.



Simple Antenna Pattern Showing Ground Reflection

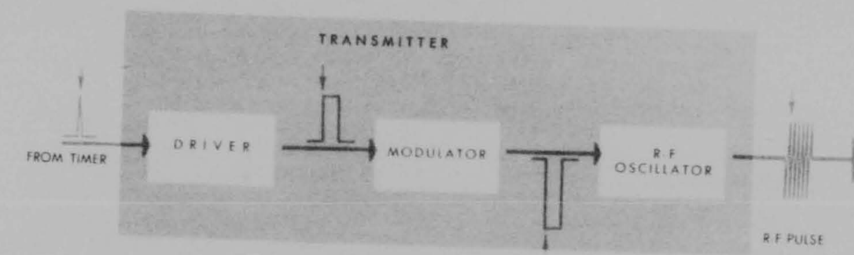


Figure 4-16 Externally-Pulsed Transmitter

Whenever a receiver is operated in close proximity to a transmitter, a certain amount of energy inevitably finds its way into the receiver directly from the transmitter by means of stray capacitance of the input circuit leads. In certain instances, such signals resulting from the main transmitted pulse must be eliminated entirely from the output of the receiver. Therefore, the receiver input circuit must be gated, or turned off during the time of transmission so that it will be completely insensitive to any transmitted signal.

Sometimes, it is desirable to couple a small amount of the transmitted radio-frequency energy to the receiver for timing purposes. However, the signal directly available from the transmission line is so large that the receiver input circuit may be burned out. Because of the high sensitivity of the receiver, the strong signal also will cause blocking of the receiver tubes which employ RC grid circuits. This blocking occurs because the tubes are overdriven, causing the grids to pass current and charge the capacitors in the grid circuit. After the signal has passed, the charge remains as a grid bias which is much greater than cutoff. Both of these conditions

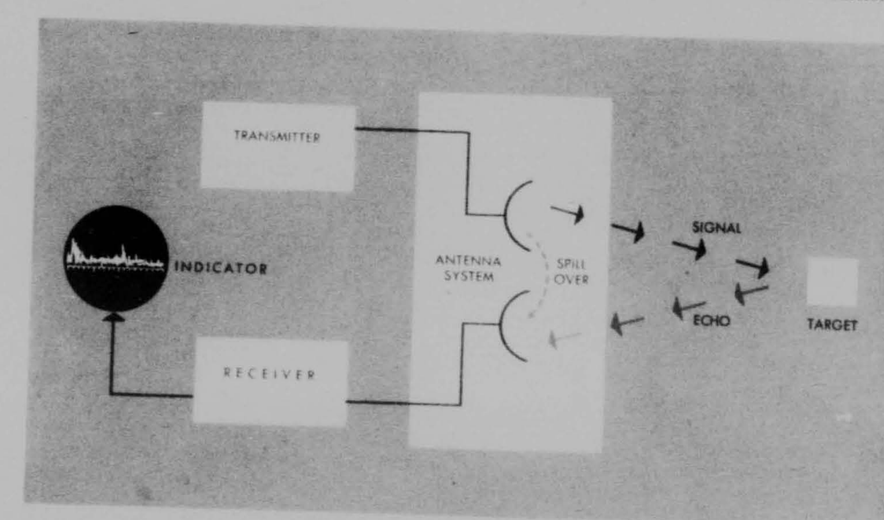

Figure 4-17 Simple Antenna System for Transmitting and Receiving

THIS PAGE IS DECLASSIFIED IAW EO 13526

place a limit on the amount of transmitted pulse which can be allowed to reach the receiver. These are the reasons for employing receiver protective devices. It has been previously mentioned that radar is capable of measuring a minimum range equal to one-half the pulse length plus a small distance which is dependent upon the characteristics of the receiver and the indicator. The time required by the receiver to recover from the transmitter is a portion of the additional distance. The amount of time required for the receiver to recover is partly dependent upon the efficiency of the receiver protective device.

The simplest antenna system contains two antenna arrays; one for transmitting and one for receiving (Figure 4-17). In this arrangement, the receiving antenna must be shielded from the powerful pulses of energy that are transmitted. Usually, the directivity of the antenna system is sufficiently great to permit the location of the receiving antenna in a region of minimum radiation. In an aircraft, the fuselage may be used for a shield.

A more practical method of solving the problem is the use of a single antenna and a switch capable of connecting the antenna to the transmitter or the receiver at the proper instant. The switch protects the receiver during the time the pulse is being transmitted and isolates the transmitter from the receiving circuit during the time of reception. Otherwise, the weak signals returned would be lost or partially lost in following the transmission line back to the transmitter. It is nearly impossible to devise a mechanical switch capable of performing the job efficiently. Most of the switches for this task are of the electronic type, and are called "T-R" (transmit-receive) boxes.

The system for using a single antenna must be as efficient as possible. All of the energy generated by the transmitter should be radiated from the antenna. All the returned energy should reach the receiver. This efficiency is most easily obtained by matching the impedance of the antenna to the characteristic impedance of the transmission line. During the transmission of the pulse, the transmitter must be matched to the transmission line and the receiver must present an open circuit of high impedance to the transmission line. During the reception time the conditions must be reversed. Figure 4-18 illustrates the employment of a mechanical switch.

The problem of switching is simplified because most transmitters have a different impedance when they are operating than when they are inoperative. If properly matched during the pulse transmission time, the transmitter will be mismatched during the receiver time and the transmission line will become resonant. A typical antenna system in which the receiver and the transmitter are connected by branch line to the antenna is illustrated in Figure 4-19. The junction of the three lines is known as a T-junction.

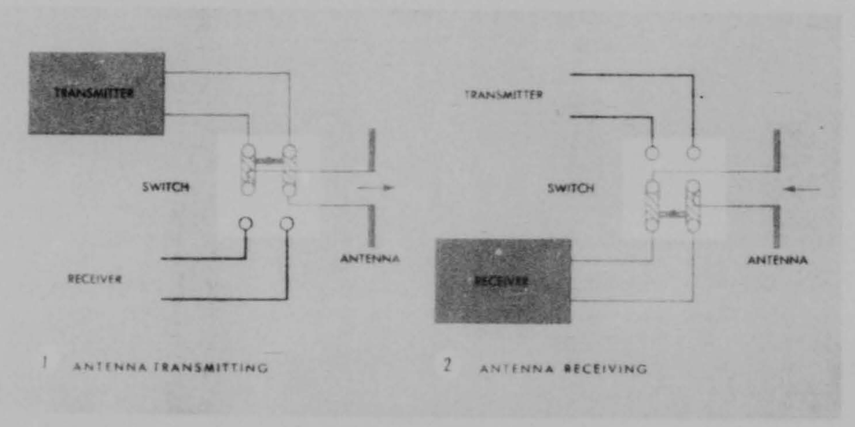

Figure 4-18 Mechanical Antenna Switch

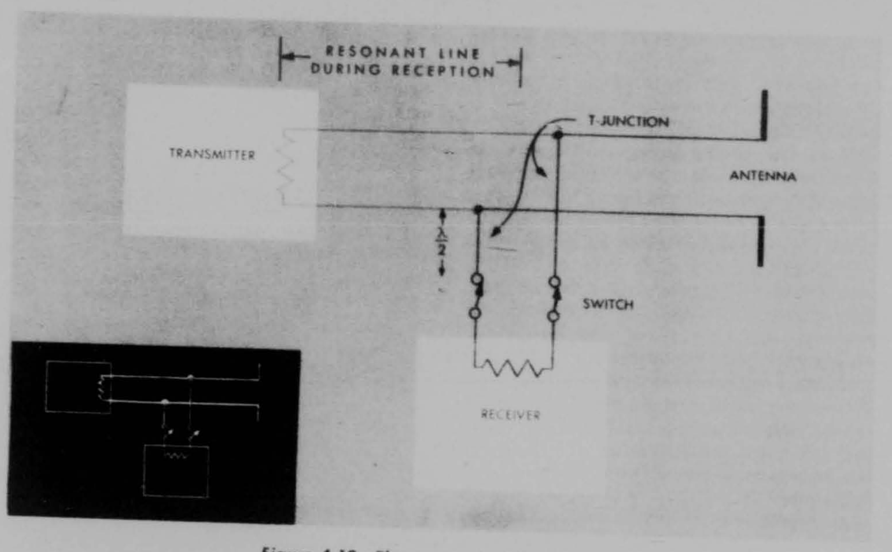

Figure 4-19 Elementary Switching System

Figure 4-20 illustrates one of the types of electronic transmit-receive switches. The spark gap used in a given T-R system may vary from a simple one formed by two electrodes placed across the transmission line to one enclosed in an evacuated glass tube with special features to improve operation. The requirements of the spark gap are that its resistance be very high until the arc is formed, and then very low during conduction through the arc. At the end of the transmitted pulse, the arc should be extinguished as rapidly as possible to remove the loss caused by the arc, and to permit signals from nearby targets to reach the receiver.

The simple gap formed in air has a resistance of from thirty to fifty ohms. This is usually too high for use with any but an open-wire transmission line. The time required for the air surrounding the gap to be completely deionized after the pulse voltage has been removed is about ten microseconds. During this time the gap acts as an increasing resistance across the transmission line to which it is connected. However,

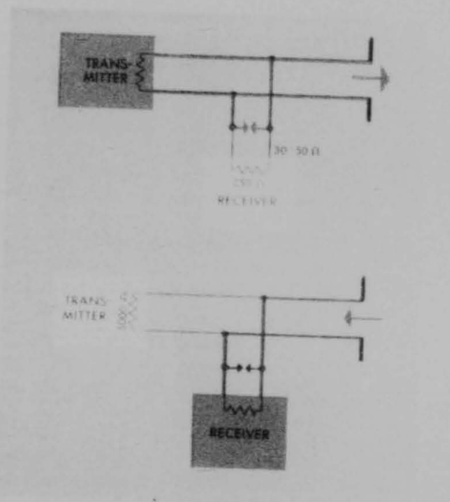

Figure 4-20 Electronic T-R Switch

in a T-R system using an air gap the received signals reaching the receiver through the gap have half their proper magnitude after three microseconds. This is known as recovery time.

The value of the voltage to break down a gap, and the running voltage during the arc may be lowered by reducing the pressure of the gas surrounding the electrodes. T-R tubes are therefore used in which the spark gap is inclosed in a glass envelope and the tube is partially evacuated. The arc is formed by conduction through an ionized gas or vapor so that the tube cannot be entirely evacuated; thus there is an optimum pressure which will give the best T-R operation. The recovery time or deionization of the gap can be reduced by introducing water vapor into the tube rather than air. A T-R tube containing water vapor at a pressure of 1 millimeter of mercury will recover in .5 microsecond.

The principal types of **radiators** employed in radar systems are: the stacked dipole array with untuned reflector, the dipole with tuned reflector and directors, the dipole with parabolic reflector, and various arrangements of dielectric radiators used in conjunction with wave guides.

The type of antenna which is widely used in radar equipment is the dipole with a parabolic reflector. Since microwaves have characteristics very similar to those of light waves, the parabolic reflector is very efficient at microwave frequencies. If the dipole is placed at the focal point of the reflector, the energy will be concentrated into a beam in much the same manner as a search-light reflector controls a light beam. The parabola converts the spherical waves as radiated by the dipole into a plane wave after reflection. The parabolic reflector may take many forms. Figure 4-21 illustrates the principle of the parabolic antenna.

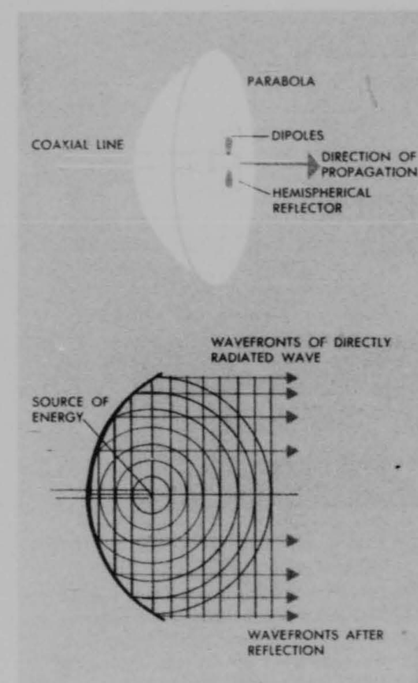

Figure 4-21 Parabolic Antenna

Receivers

The function of the receiver is to amplify the weak signal that is returned by the target to the antenna system, and feed the pulses to the indicator. Since the radar frequencies are high, it is difficult to obtain sufficient amplification. The radar receiver is usually of the superheterodyne type with good stability and extreme sensitivity. The stability is maintained in the microwave region by careful design and the over-all sensitivity is greatly increased by the use of many stages of the intermediate frequency amplification with each stage having a rather low amplification factor. Special types of tubes having low interelectrode capacitance have been developed for use in the radio frequency and intermediate frequency stages.

Figure 4-22 illustrates the block diagram of a typical radar receiver. The radio frequency amplifier may not be present in the higher frequency ranges and thus the received signal may be fed directly to the mixer stage. In this case, it is desirable to use as short a receiver input transmission line as design requirements permit. The mixer and local oscillator may be close to the T-junction of the transmission line in

order that the received radio frequency may be converted to the lower intermediate frequency before being relayed to the remaining stages of the receiver. One or two stages of intermediate frequency amplification are frequently located immediately after the mixer stage and function as a preamplifier to offset the considerable attenuation encountered in coupling the weak signals to the components of the receiver which may be located at some distance from the antenna system. The radio frequency components of the receiver are normally located near the antenna in order to reduce the problem of transmitting this radio frequency any distance since there is a considerable engineering problem in transmitting radio frequency over transmission lines.

Indicators

For many years, the study of high-frequency phenomena was impeded by the lack of an oscillograph which would respond to very rapid changes in current and voltage. Mechanical oscillographs are incapable of following changes occurring at rates faster than a few thousand cycles per second.

The electron is nearly instantaneous in its response to the influence of electric and magnetic fields. The development of the vacuum tube suggested its use as an electronic device in the study of high-frequency phenomena.

In order to determine the range, azimuth, and height of a target, the indicator uses the received signal to produce a visual indication of the desired information. The cathode-ray tube, which is a type of vacuum tube, is an ideal instrument for the presentation of radar data since it not only shows a variation of a single quantity, such as a voltage, but gives an indication of the relative values of two or more synchronized variations. The usual indicator is basically the same in function as the low-frequency test oscilloscope that is employed so extensively in the laboratory. The focusing, intensity, and positioning controls are similar. The sweep frequency of the radar indicator is determined by the pulse repetition frequency of the radar system and the sweep duration is established by the setting of the range-selector switch.

The Cathode-ray Tube. The simpler systems of data presentation generally employ electrostatic deflection of the cathode-ray tube. The electron beam is made to follow some pattern by means of controlled differences in potential between pairs of deflecting plates.

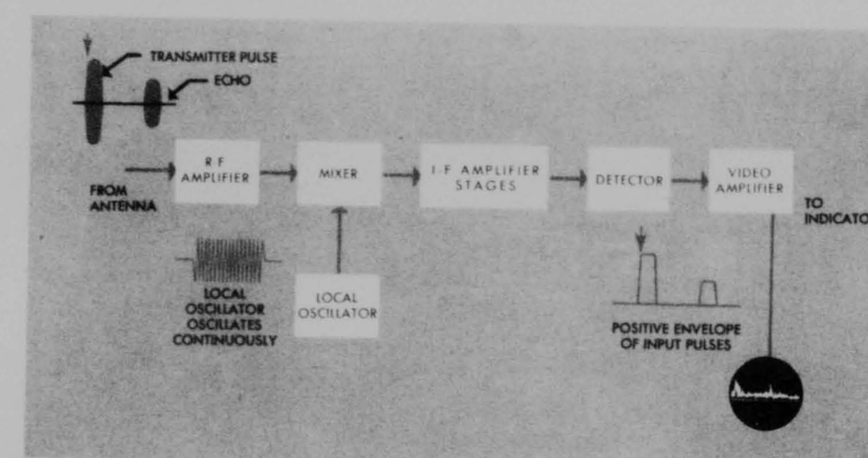

Figure 4-22 Components of Radar Receiver

THIS PAGE IS DECLASSIFIED IAW EO 13526

The more highly refined systems of data presentation generally utilize the electromagnetic deflection of the cathode-ray tube with a long persistence screen. The position of the electron beam at any instant is determined by causing it to pass through a magnetic field produced by control currents passing through deflecting coils mounted outside the cathode-ray tube. If intensity modulation is used, the bias is such that the tube is held just beyond cutoff and the video output of the receiver is applied to either the grid or the cathode with such polarity as to release the beam of electrons and allow the trace to appear on the screen. Thus, the bright spots on the screen represent returning echoes detected by the radar system.

The basic cathode-ray tube in its present form consists of six principal parts contained within an evacuated tube.

A hot cathode for producing the electrons to form the beam. The cathode is heated by a filament.

A grid is employed to control the number of electrons escaping from the cathode and to control the intensity of the electron beam.

A first anode to draw the electrons from the cathode into the beam.

A second anode is employed to accelerate the electrons and to focus them into the beam so that they will strike the screen in a pinpoint spot.

Electrodes or coils to deflect the electron beam by means of the voltage or current to be observed.

A fluorescent screen which is excited by the electron beam to produce a visual indication of the path followed by the electron beam.

The first four parts of the cathode-ray tube constitute what is commonly known as the "electron gun," since they serve to generate and direct the stream of electrons into a beam which constitutes the moving element of the cathode-ray tube.

Electrostatic Deflection. The elements of a typical cathode-ray tube employing electrostatic deflection are shown in Figure 4-23. The electrons emitted by the cathode are focused and acelerated by the action of the grid and anodes. By virtue of the aperture in the various tube elements and the form of the electric field around the two anodes, the electron beam is constricted into a narrow beam which passes between each of the two sets of deflecting plates before reaching the screen. In this tube, the beam is focused and deflected by electrostatic action. If a voltage is applied to the horizontal deflecting plates and made to vary in some predetermined manner, the electron beam passing between these plates can be made to vary its position in such a manner that it will sweep from one side of the tube to the other. Now, if a voltage is introduced to the vertical deflection plates, the electron beam will be deflected by that voltage also. The position of the electron beam is the result of two voltages applied to the two sets of deflecting plates. If the voltage applied to the vertical deflection plates is taken from the radar receiver, the signal returned by the target in space will cause the electron beam to be deflected upward and produce visual indication of the target.

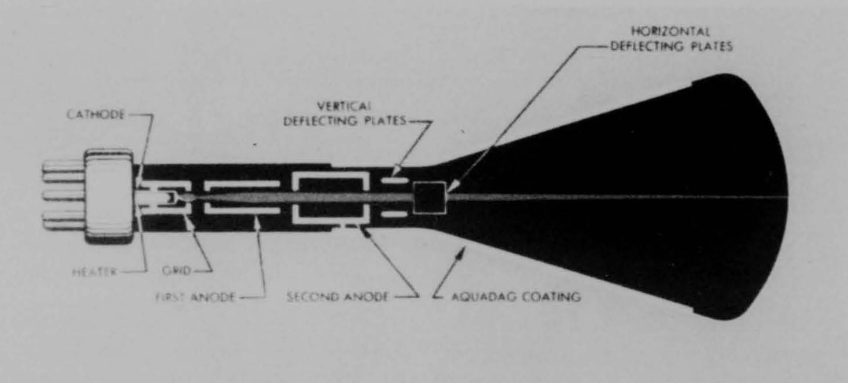

Figure 4-23 Electrostatic Cathode-Ray Tube

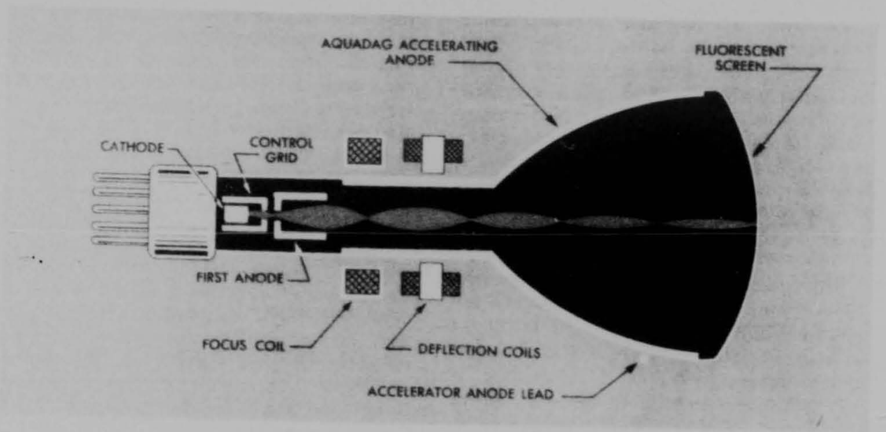

Figure 4-24 Electromagnetic Cathode-Ray Tube

Electromagnetic Deflection. The electromagnetic type of cathode-ray tube has come into common use because of the greater definition possible with magnetic focusing. Also, electromagnetic deflection has a number of advantages over electrostatic deflection, particularly when a rotating radial sweep is required to give polar indications.

The production of the electron beam in the electromagnetic cathode-ray tube is essentially the same as in the electrostatic cathode-ray tube. The grid structure is similar and the use of the grid to control the number of electrons in the beam is identical. The elements of a typical cathode-ray tube employing electromagnetic focusing and deflection are shown in Figure 4-24.

The focusing coil of an electromagnetic tube is wound on an iron core. This core is generally constructed with a small airgap for concentrating the magnetic field. The coil may be moved along the neck of the tube to a limited extent in focusing the beam, but the normal method, after the coil is in the proper position, is to vary the amount of current flowing through the coil.

There may be only one pair of coils employed to produce the desired effect, and in some cases they will be arranged so that they can rotate around the axis of the tube. In other types of usage, two pairs of coils are employed to produce the same results. These will, in general, be fixed or relative to the tube and will be at right angles to each other. Two anodes are used for accelerating the electrons from the cathode to the screen of the tube (Figure 4-24). The second anode is the graphite coating on the inside of the glass envelope. The envelope is shaped differently from that of the electrostatic tube, since it is necessary to have enough space along the neck for both the focusing and the deflection coils. These coils must be mounted as close to the electron beam as is physically possible.

Cathode-ray tubes in which the focus is electrostatic and the deflection is electromagnetic are employed in certain applications. Other special types are those in which the focusing or deflection may be accomplished by electromagnetic action. Such special types of cathode-ray tube are not widely used.

THIS PAGE IS DECLASSIFIED IAW EO 13526

The relative advantages of electrostatic and electromagnetic control are as follows:

The electromagnetic tubes have a greater structural simplicity (the electromagnetic tube has no deflecting plates or focusing anode that must be carefully aligned); greater ruggedness, which makes for greater reliability in mobile equipment; and shorter tube lengths which reduces the over-all size of the equipment in which electromagnetic cathode-ray tubes are used.

Electrostatic - cathode-ray tubes require little voltage or current to produce the required deflections. Therefore, the auxiliary circuits are simpler and difficulties from deflecting coil inductance are avoided.

Practically all cathode-ray tubes are coated on the inside of the envelope with a graphite coating (Aquadag coating) whose primary function is to attract secondary emissions of the fluorescent screen. If electrons were allowed to pile up on the screen, it would soon require a very large negative voltage to operate the tube. This would interfere with normal operation. When the electron beam strikes the screen, some of the energy of the electrons is given up in dislodging electrons in the fluorescent coating employed in the screen. These dislodged electrons are known as "secondary emissions." If the number of secondary electrons emitted equals the number that originally strike the screen, there will be no change in the fluorescent screen voltage and the tube will continue to function properly. The graphite coating is also used to provide shielding for the electron beam. In some cathode-ray tubes there is no metallic accelerating anode and the graphite coating is connected so as to perform this function as well.

In some types of electrostatic tubes, an extra anode, called an "intensifying ring," is used to increase the brilliancy of the spot on the screen. This ring is made of metal and is cemented to the inside of the glass. It accelerates the electron beam after deflection has taken place and gives the electron beam greater kinetic energy, thus causing the spot to be more brilliant.

Fluorescent Screens. To convert the energy of the electron beam into visible light, the area where the beam strikes is coated with a phosphor chemical which has the property of emitting light when bombarded with electrons. This property is known as "fluorescence." Continued emission of light for a short time after bombardment is called "phosphorescence."

All fluorescent materials are associated with a characteristics relationship between the intensity of the emitted light and the colors contained in that light. Willemite, which emits a green light, has been used generally for coating cathode-ray tube screens. Recently, however, other materials have been developed which emit different colors, and have varying abilities to hold the image on the screen when the electron beam has passed on. Typical phosphors or fluorescent materials used are as follows:

Willemite (zinc othosilicate), for predominantly green light.

Zinc oxide, for predominantly blue light.

Zinc beryllium silicate, for predominantly yellow light.

Zinc sulphide and cadmium zinc sulphide mixture, or zinc beryllium silicate for nearly white light.

All fluorescent materials have some afterglow, or phosophorescence, but the duration of the afterglow varies with the material, as well as with the amount of energy in the beam causing the emission of light. For oscilloscopes that are used for observing nonrepeating phenomena or periodic phenomena which ocur at a low repetition rate, a screen material on which the image will linger is desirable. The screen of such a tube is described as having "long persistence," since the light emitted by phosphorescence fades out slowly. In applications where the image changes rapidly, afterglow is a disadvantage, since it may cause confusion on the screen. Manufacturers generally designate the persistence and color of the screen of cathode-ray tubes.

The intensity of the spot on the screen of a cathode-ray tube is dependent on two factors: first, the speed of the electrons striking the screen; second, within limits, the number of electrons that strike the screen at one point within a certain length of time. The amount of light which the phosphor is capable of emitting is limited and

once the maximum has been reached, further increase in the electron bombardment has no effect on the light intensity. There are obviously two ways of controlling the intensity of the spot in an oscilloscope. One way is to increase the speed of the electrons when it is desired to make the spot brighter, and to decrease this speed to make the spot less intense. Since changing the speed requires that other adjustments be made in the tube, this method is not generally used. The second way of controlling the spot intensity is to control the number of electrons in the electron beams by applying suitable control voltages to the control grid.

The images on the screen of a PPI are produced by fluctuations in the intensity of a moving beam of electrons which sweep across the face of the cathode-ray tube. Since the coating on the inside of the tube has a finite thickness, the final image as it appears on the face of the tube is diffused or spread in all directions. For the cathode-ray tubes now in general use, this diffusion is in the order of 0.01 inch. That is, the minimum distance on the screen between the centers of two spots which just touch each other is approximately 0.02 inch. If nothing else limited the resolution of the PPI, the indicated size of the object would be increased by a fringe equal to 0.01 inch.

It should be understood that this figure is variable within rather wide limits, depending on the position of the target on the screen, the receiver gain and focusing adjustments of the indicator, and the reflecting qualities of the target. It should probably be considered a minimum figure rather than an average figure.

Since the distance from the center of the PPI to the edge of the tube will represent different ranges for different setting of the range selector-switch, the distance represented by the diffusion will also vary. For example, if the PPI is used on the 20-mile scale, the diffusion amounts to 486 feet, while on the 100-mile scale it amounts to 2,430 feet.

Power

In the functional diagram of the radar system, the power supply is represented as a single block. However, it is unlikely that any one power supply would meet the complete requirements of a radar system. Normally, each component requires voltage of several different values in order to make it operative. In addition, some primary source of power must be supplied. Figure 4-25 illustrates a diagram of power supply used in connection with some radar equipment, however, it is not complete.

3. TYPES OF OSCILLOSCOPE PRESENTATION

Figures 4-43 through 4-50 are illustrations of the most common types of radar-scopes in current use. It is not an all-inclusive representation since special adaptations of these basic types may be made for special applications. General information is given in connection with each figure.

SECTION 4 - THE APPLICATION OF RADAR PRINCIPLES

1. GENERAL

Radar is still in a state of development, but it is possible to rely upon the information that radar equipment is able to furnish so that the greatest possible benefits may be obtained through its use. In considering this subject, one must not think in terms of the present but in terms of radar requirements of the future. A radar system may be the only practicable warning device in the event of another war.

2. THE IDEAL RADAR

In this discussion, the radar of the future is referred to as the "ideal radar" and is endowed with six functions which it must have in order to fulfill its mission. The six items of information which radar must furnish are: range; azimuth or bearing; eleva-

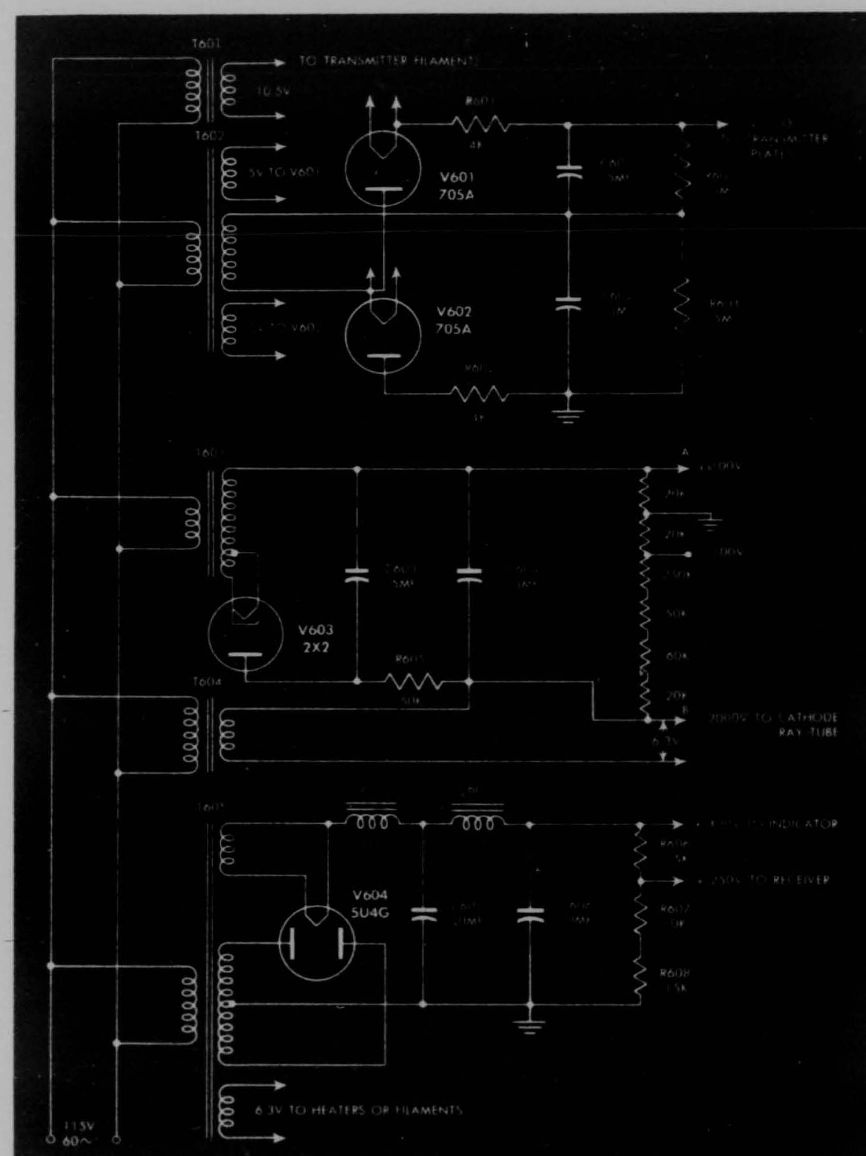

Figure 4-25 Schematic Diagram of Power Supply Circuits

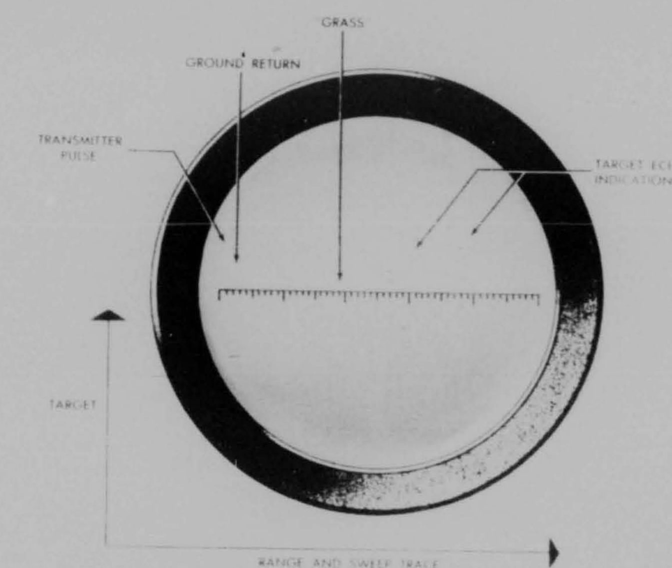

Figure 4-26 A-Type Radar-scope Display

A-Type

Description:	An indicator with a horizontal sweep trace giving range only. Signals appear as vertical deflections above or below the time scale.
Data presented:	Range is read horizontally from left to right. Azimuth is read from a dial on the antenna or from a counter operated by the rotation of the antenna. Elevation data not presented.
Target indication:	Appears as a deflection of the trace at target range. Deflection may be up or down.
Type deflection:	Electrostatic.
Application:	Determining range, test scope, IFF display.

THIS PAGE IS DECLASSIFIED IAW EO 13526

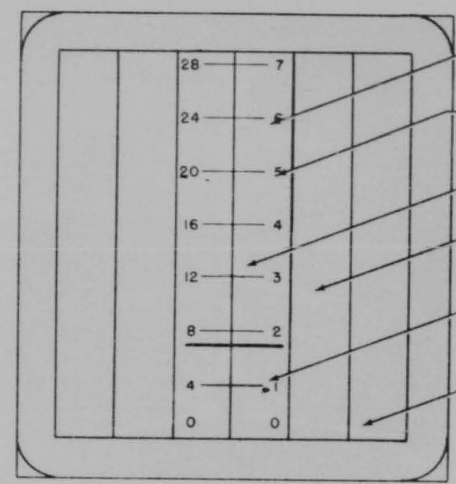

Figure 4-27 Modified A or L-Type Radar-scope Display

Modified A- or L-Type

Description: A modification of A-type for aiming a double lobe system in azimuth. A vertical time base indicates range. The signal from the left lobe appears as a horizontal deflection to the left; the signal from the right lobe appears as a horizontal deflection to the right. The ratio of the signal amplitudes is indicative of the error in homing.

Data presented: Range is presented bottom to top. Azimuth obtained by matching pips and homing on the target. Elevation is not presented.

Target indication: Deflection left from left antenna or lobe, and right from right antenna, or lobe.

Type deflection: Electrostatic.

Application: Determining range and relative bearing.

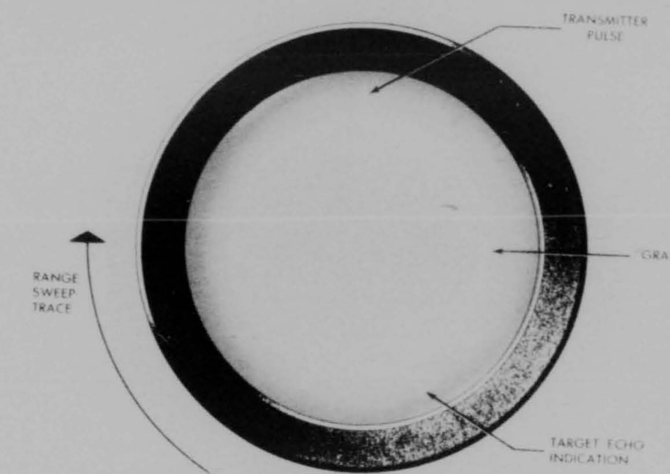

Figure 4-28 J-Type Radar-Scope Display

J-Type

Description: A modification of A-type in which the sweep produces a circular range scale near the circumference of the CRT face. The signal appears as a radial deflection of the time trace.

Data presented: Range is presented on the circumference in a clockwise direction. Azimuth is read from a dial on antenna or geared to antenna at maximum echo as antenna rotates. Height not presented.

Target indication: Deflection from circle.

Type deflection: Electromagnetic.

Application: Gunlaying, radio altimeter, Shoran.

THIS PAGE IS DECLASSIFIED IAW EO 13526

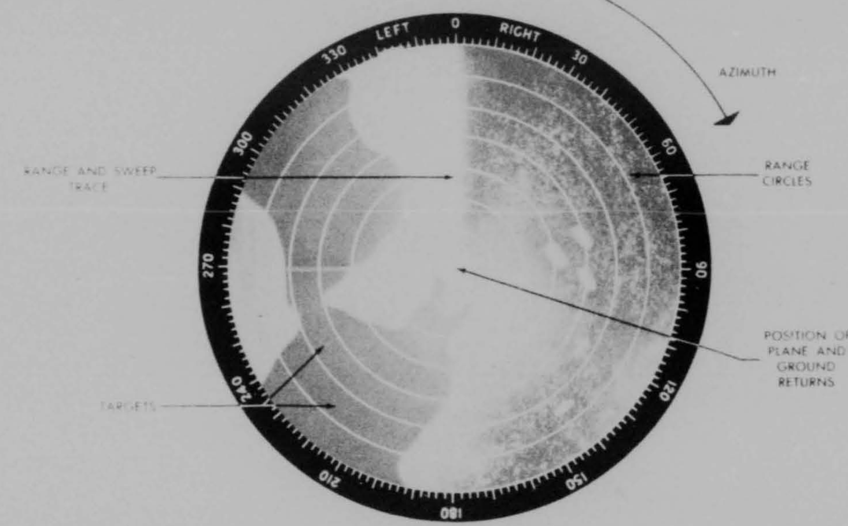

Figure 4-29 PPI-Type Radar-Scope Display

Plan Position Indicator (PPI)

Description: The sweep is a radius of the tube face (from center to edge) and moves through 360°. It gives azimuth by direction of the radial line and range by the distance of the signal from the center of the screen.

Data presented: Range is read radialy from the center of the tube. Electronic range markers may be added. Azimuth is read around the circumference of the tube. Trace rotates with the antenna. No height provision.

Target indication: Target appears as a bright spot on face of tube at correct range and azimuth.

Type deflection: Electromagnetic.

Application: Low-altitude blind bombing, high-altitude blind bombing, surface search, air search, tactical control of aircraft.

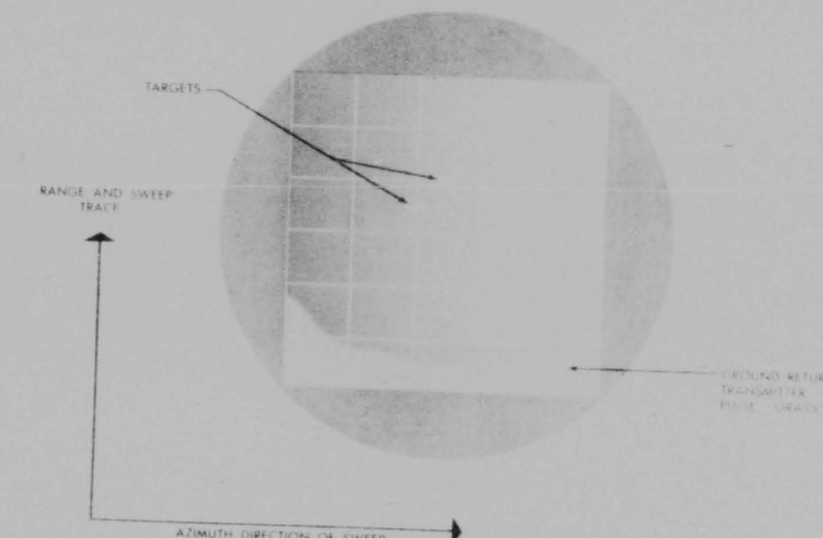

Figure 4-30 B-Type Radar-Scope Display

B-Type

Description: In B-type presentation, the signal appears as a bright spot with azimuth angle as the horizontal coordinate and range as the vertical coordinate.

Data presented: Range is presented vertically bottom to top. Azimuth presented left to right using a fixed number of degrees (sector scan). No height given. Electronic range and azimuth.

Target indication: Bright spot at correct range and azimuth.

Type deflection: Electromagnetic.

Application: Aircraft interception (airborne), air search.

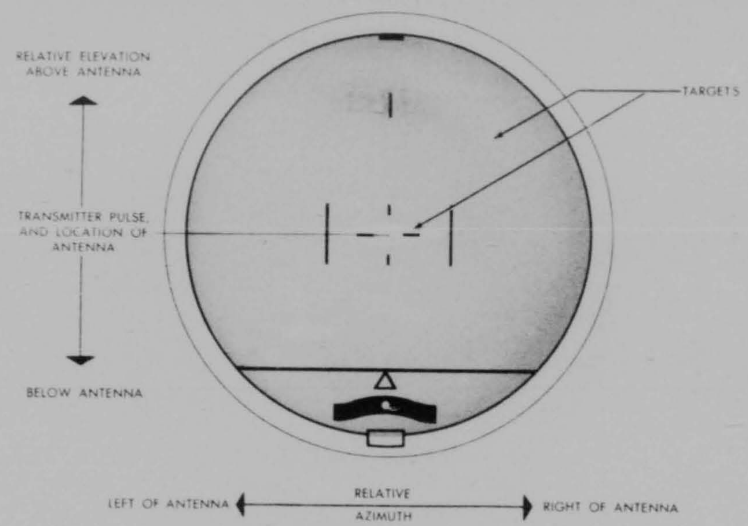

Figure 4-31 C-Type Radar-Scope Display

C-Type

Description: The signal appears as a bright spot at relative azimuth angle and elevation angle. Azimuth angle is the horizontal coordinate and elevation the vertical coordinate.

Data presented: No range presented. Range is read from another type scope. Rate of closing on target may be estimated by wings that grow on target echo as range decreases. Relative azimuth to right or left is read in degrees (sector scan). Relative elevation up or below antenna is read in degrees (sector scan).

Target indication: Bright spot at relative azimuth and elevation.

Type deflection: Electromagnetic.

Application: Aircraft interception. Usually used with a B-type scope (airborne).

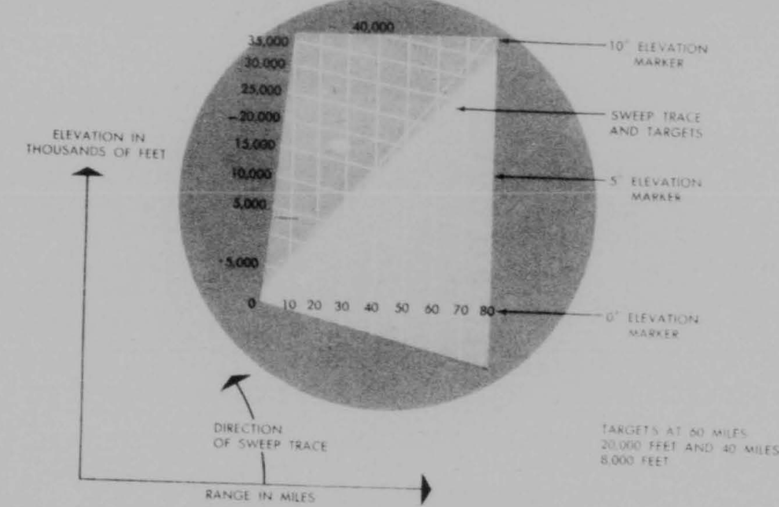

Figure 4-32 RHI-Type Radar-Scope Display

Range Height Indicator (RHI)

Description: The target appears at slant range. This slant range is resolved into range and height. Range is the horizontal coordinate and height above the antenna is the vertical coordinate. A family of calibrated curves on a cursor reads in 1,000's of feet.

Data presented: Range is read horizontally left to right. Azimuth is read from a PPI tube as target appears during the rotation of the antenna. Elevation is read vertically from bottom to top. Trace pivots at origin.

Target indication: Bright spot appears at correct range and elevation.

Type deflection: Electromagnetic.

Application: Height-fading.

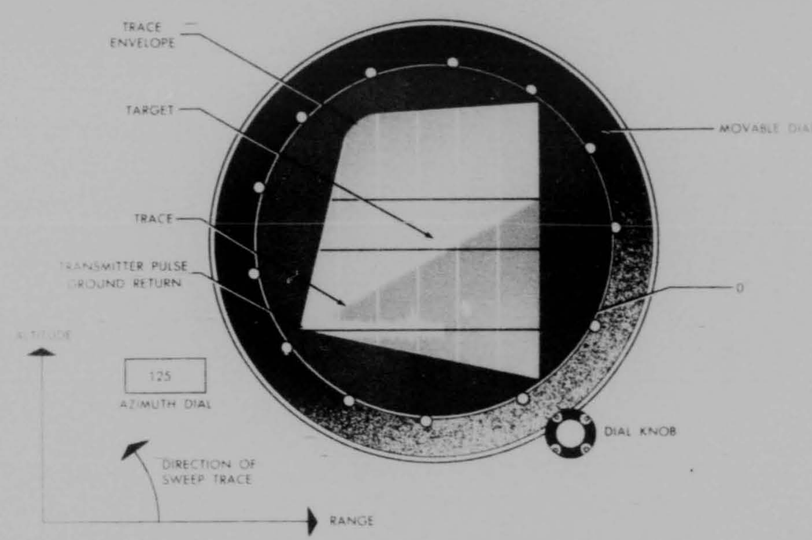

Figure 4-33 Lightweight RHI-Type Radar-Scope Display

Light-weight Range-Height Indicator (RHI)

Description:	The target appears at slant range. The slant range is resolved into range and height above the antenna. Range is read along the horizontal coordinate and height is presented along the vertical coordinate. Height is read from a movable dial on circumference of tube. A movable cursor is placed over target indication. Moving cursor up or down moves dial to correct altitude reading.
Data presented:	Range is presented horizontally from left to right. Azimuth is read from a dial connected to antenna. Elevation is read from dial on circumference of tube.
Target indication:	Bright spot appears at correct range and elevation.
Type deflection:	Electromagnetic.
Application:	Height-finding.

tion; speed and sense; number and type of aircraft; and recognition.

Range

The range of the radar system must be unlimited so that objects may be detected at distances that are nearly half way around the world. These great distances are made necessary by the advent of aircraft and guided missiles of the future which may have speeds in the order of 5,000 knots. It readily can be seen that ranges considered adequate for the relatively slow-flying aircraft of World War II will become entirely inadequate with the advent of aircraft capable of flying faster than the speed of sound. It therefore becomes necessary that radar of the future have ranges much greater than can be obtained at present.

The Joint Communications Board has agreed upon the following five definitions for classifying ground radar equipment by slant range.

VLR (Very Long Range). Equipment whose maximum on a reflecting target of one square meter normal to the signal path exceeds 800 miles, provided line-of-sight exists between the target and the radar.

LR (Long Range). Equipment whose maximum range on a reflecting target of one square meter normal to the signal path exceeds 300 miles but is less than 800 miles, providing line-of-sight exists between the target and the radar.

MR (Medium Range). Equipment whose maximum range on a reflecting target of one square meter normal to the signal path exceeds 50 miles but is less than 300 miles, provided line-of-sight exists between the target and the radar.

SR (Short Range). Equipment whose maximum range on a reflecting target of one square meter normal to the signal path exceeds 50 miles but is less than 150 miles, provided line-of-sight exists between the target and the radar.

VSR (Very Short Range). Equipment whose maximum range on a reflecting target of one square meter normal to the signal path is less than 50 miles, provided line-of-sight exists between the target and the radar.

Azimuth or Bearing

A radar system must be able to determine the azimuth of any target that it is able to detect. The present day radar systems are able to satisfy this requirement to a reasonably high degree.

Elevation

In order to control aircraft from the ground so that the positioning of that aircraft in airspace may be exact, it is necessary that the altitude of the aircraft be determined. The radar should be able to determine the altitude of any target at any detectable range.

Speed and Sense

Information concerning the speed with which the detected object is traveling must be made instantaneously available, along with the sense or direction of travel of the target.

Number and Type

Before effective countermeasures may be taken against any type of action that an enemy may be contemplating, it is necessary that the number of aircraft or guided missiles in the formation be determined as well as the type of aircraft.

Recognition

The radar must be capable of recognizing a target. This information must be automatic and available as soon as the target has been detected by the radar. It is extremely important that the operators on the ground know whether the target is friendly or hostile.

These, then, are the desirable characteristics of the ideal radar. However, present day radar falls far short of this. At present, most of the radar employed for detection or search fall in the medium-range classifications. It is satisfactory in the azimuth determination. Most radar of today does not furnish elevation information as a part of its, regular information. This data is obtained in most cases by the employment of an additional height-finding radar designed for this specific purpose. In addition the range of today's radar equipment is not satisfactory. None of the present radar devices

THIS PAGE IS DECLASSIFIED IAW EO 13526

is capable of giving immediate information concerning the speed and sense of the aircraft; this is available only after the aircraft has been observed by the radar for a short period of time. This time delay must be eliminated in the future since there will not be sufficient time to employ it with faster-moving aircraft. The operators may make an educated guess concerning the numbers of aircraft in flight but it requires an extremely skilled operator before any degree of accuracy is obtainable by this means.

3. GROUND RADAR EQUIPMENT

Lightweight Radar

The selection of radar equipment for a given purpose is determined not only by the capabilities of the equipment, but also by size and weight factors. For example, warning of the approach of hostile aircraft must be provided for front-line troops. To satisfy this requirement, a light-weight, search-type radar is required. This radar must be light enough to be truck-transportable, and yet rugged enough to withstand rough treatment. A number of radar sets have been constructed with these requirements in mind.

The most successful of these sets are the AN/TPS-1B, for search or surveillance purposes, and the AN/TPS-10 for height finding.

The radar set AN/TPC-1B is a light-weight, medium range (in excess of 50 miles, but less than 300 miles), portable, ground-radar set designed for general search and tracking in range and azimuth, but it will not indicate height or angular elevation. All of the components break down into small packages, no package weighing more than 180 pounds. This provision makes possible movement of the components for short distances by manpower alone. A trained crew of six is able to assemble the equipment from carrying cases to operating position in about thirty minutes. The indicator of this radar may be connected by long cables in order that it may be used at a distance from the other components—from the relative security of a foxhole, for example. Both PPI and A-scan presentation is used. An operating crew of two is required.

Radar set AN/TPS-10 is a lightweight, short range, ground radar designed especially for height-finding of aircraft. It is very useful in regions where ground-clutter or permanent echoes limit the use of other types of radar. This advantage is obtained through the use of a rocking, vertically-narrow beam. The equipment is intended to operate in conjunction with light-weight, search-type radars such as the AN/TPS-1B. Such a combination of equipment makes possible ground control of aircraft. The AN/TPS-10 may be broken down into components, the heaviest of which weighs 170 pounds. It can be installed by a trained crew of six from carrying case to operating position in about thirty minutes. The indicator employs both RHI and A-scan presentations .An operating crew of two is required.

Fixed-Type Radar

The problem of designing and building a radar which will operate for long periods, which will be able to supply information on large amounts of air traffic, and which will be accurate to a high degree has been solved to a certain extent. Three examples of fixed-type radar, that is, not designed with mobility as one of the primary considerations, are discussed below.

The first large capacity radar to be constructed was the AN/CPS-1 or Microwave Early Warning. It is designated "air-transportable" since the components could be carried by a cargo-type aircraft. It is a search radar employing microwaves capable of low and high altitude coverage. It provides highly accurate range and azimuth information. The problem of site selection is largely overcome by the frequency employed. Time of assembly from crates to operating position requires a minimum of three days for a trained crew of ninety men.

The information derived from this radar is presented in two ways. Search information is presented by B-scan indicators. Information for the use of personnel charged with controlling aircraft is presented on PPI-scopes. As many as five B-scan indicators with adjustable azimuth coverage from 40 to 100 degrees and 30-, 80-, and 100-mile sweeps in any sector from 0 to 200 miles may be employed with each MEW. The B-scan indicators are normally set so that each covers 90° or less. In this way, B-scan No. 1

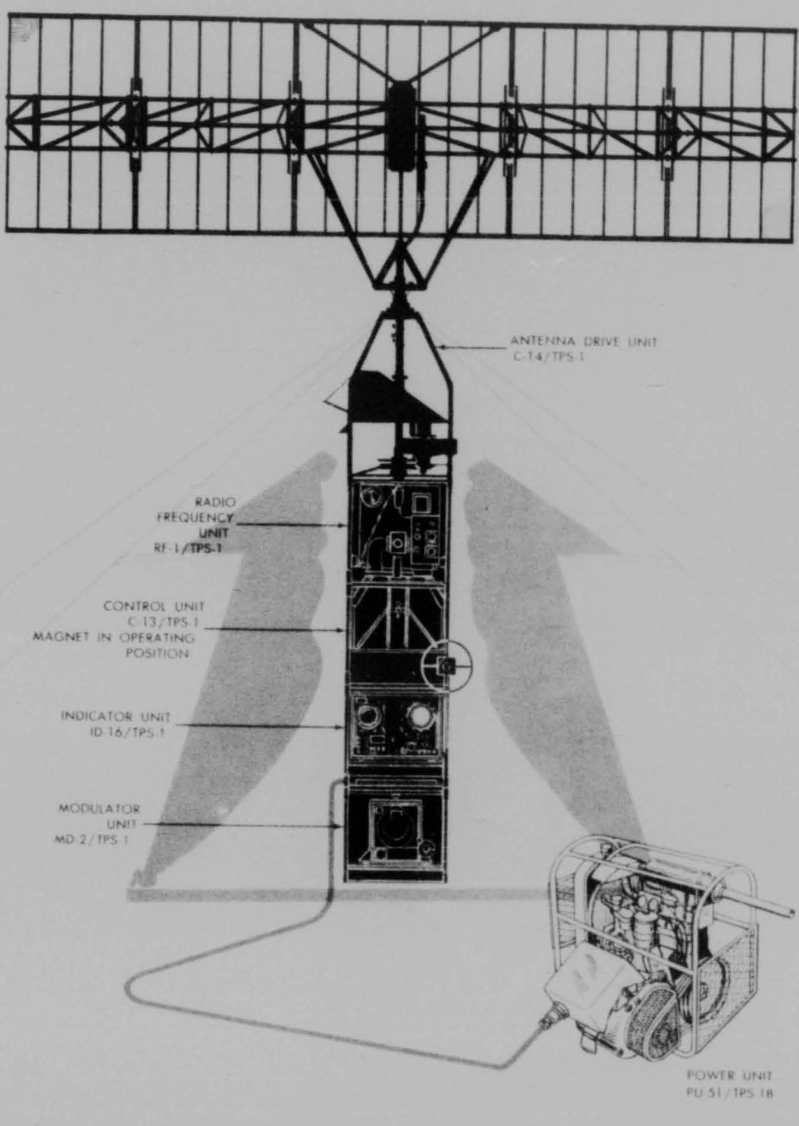

Figure 4-34 Radar Set, AN/TPS-1B

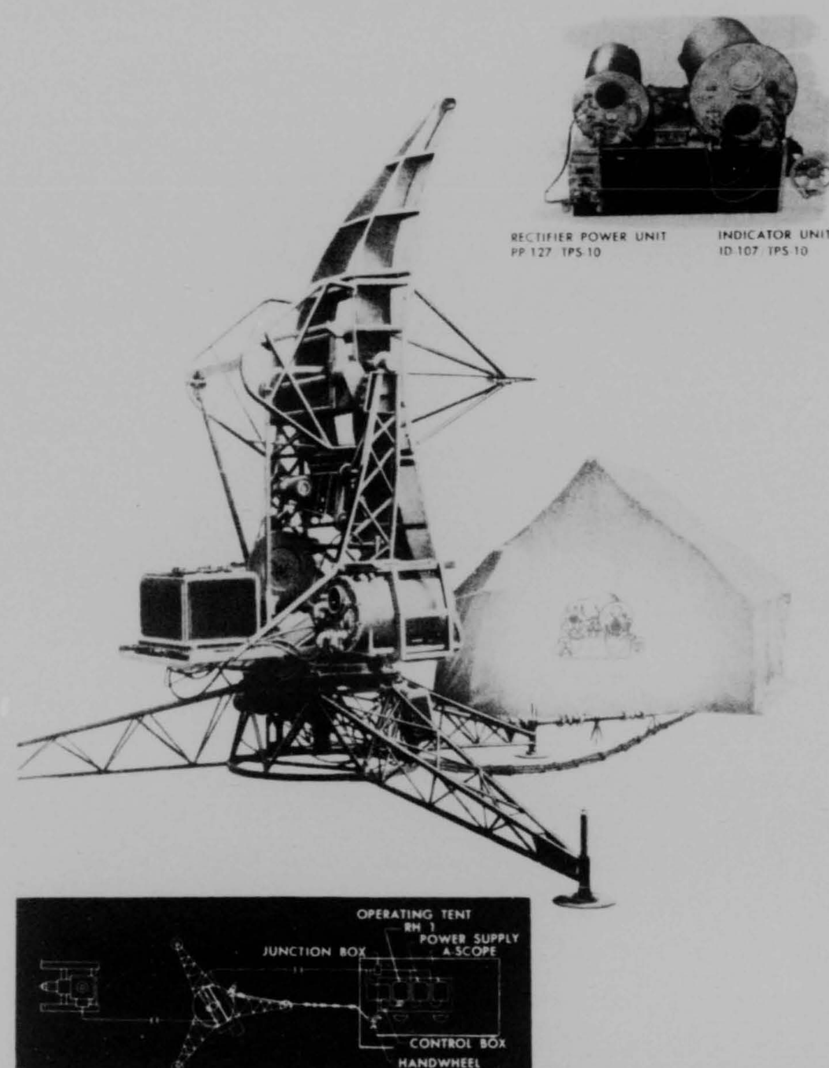

Figure 4-35 Height Finder Radar Set AN/TPS-10

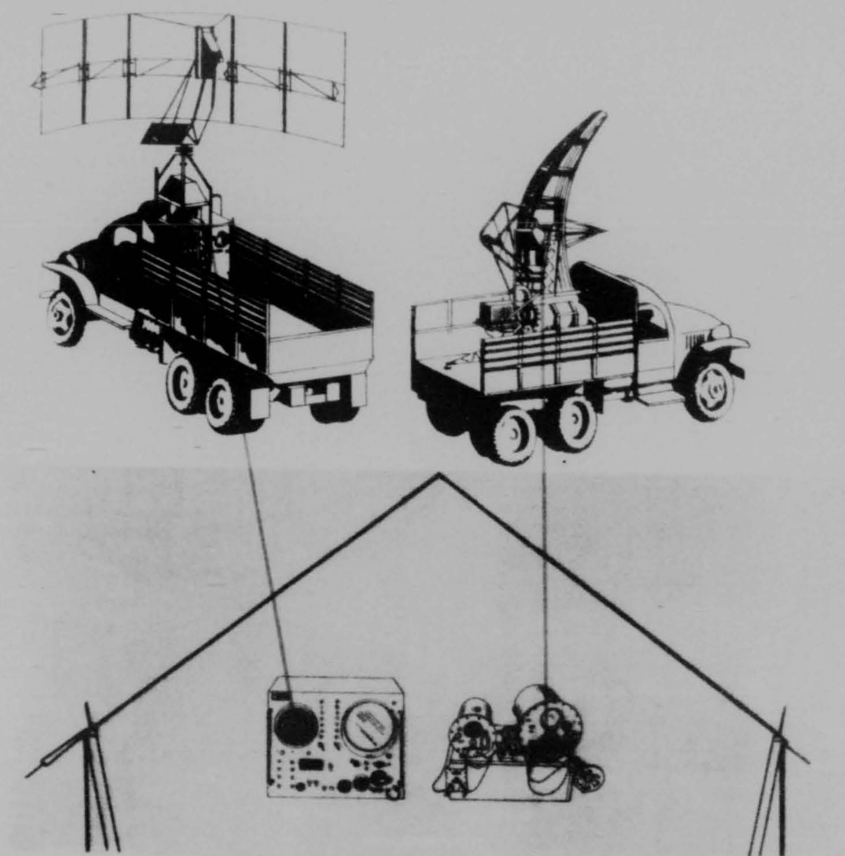

searches from 0°-90°, B-scan No. 2 searches 90°-180° and so on. B-scan No. 5 may search 360° for the purposes of a supervising operator, or may be employed as are the other indicators. This method of operation reduces the amount of airspace actually searched by each operator. Because of this, each operator is subject to less eyestrain and is able to watch more closely for target indications in his own sector.

It is not within the scope of this text to describe radar station operation. Let it suffice to say that the PPI-scope is more efficient from the control-of-aircraft point of view, and that the radarscopes as employed with an AN/CPS-1 are grouped separately from the B-scan indicators.

Inasmuch as the MEW is incapable of determining the height of targets, the development of a suitable height-finding radar was essential. While the AN/TPS-10 could be employed with the MEW, it was not designed for sustained operation.

The radar set AN/CPS-4 answers the need for a companion set for the MEW. It is an air transportable, short-range, ground-radar set designed to find heights of aircraft. Like the AN/TPS-10, the beam of the AN/CPS-4 is

THIS PAGE IS DECLASSIFIED IAW EO 13526

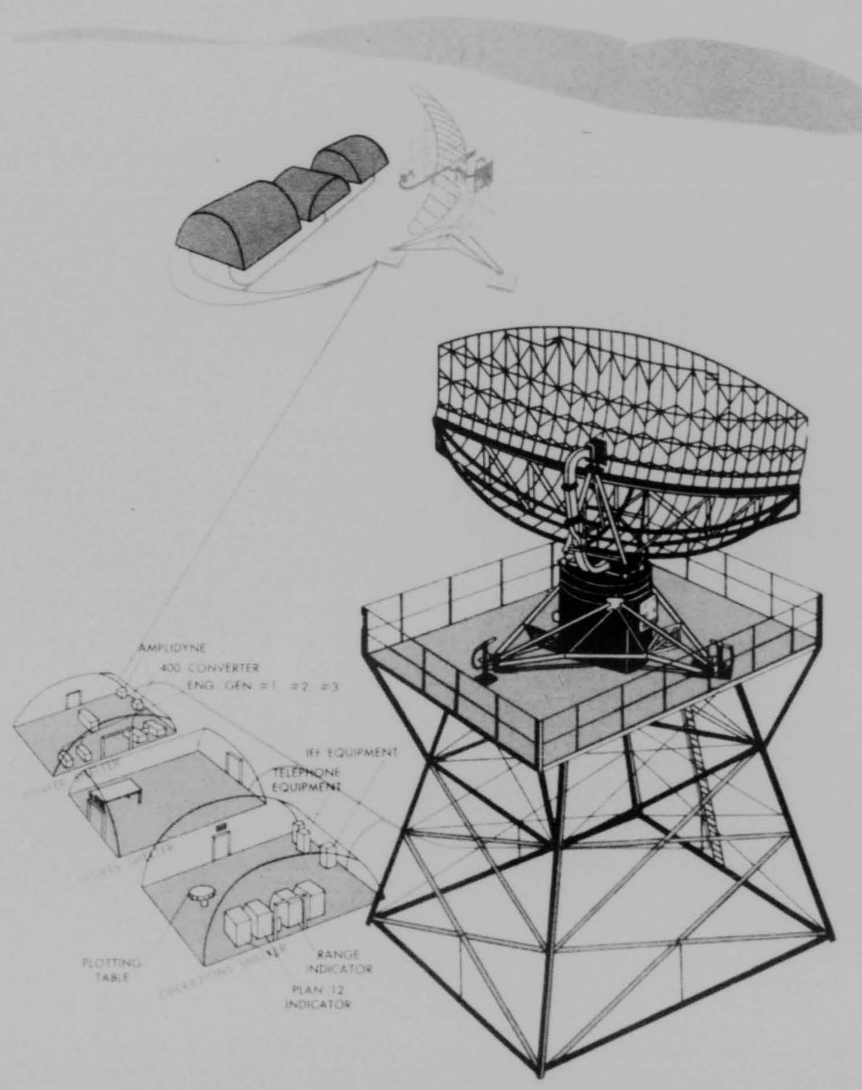

Figure 4-36 Radar Set, AN CPS-5

vertically narrow. This equipment is electrically tied in with the search set enabling three-dimensional data to be available for the control of aircraft. A trained crew of thirty men can assemble the AN CPS-4 in one day. The set employes one RHI, two PPI's and two A-scopes for monitor and test purposes. Three operators are required for this equipment.

The AN CPS-5 incorporates the features of heavy, early warning sets with the portability of the lighter weight sets. Designed for early-warning operations, the AN CPS-5 can be installed in one day with a crew of thirty men, comparable to the normal operating strength of a lightweight early warning unit. The set operates at a lower frequency than the AN CPS-1 (1,300 megacycles) but has almost the same maximum range. When properly sited, a range of 200 miles can be expected. While it does not afford height-finding facilities in itself, when incorporated with the regular height finders adequate control facilities can be given. The entire unit weighs nineteen tons as compared with the sixty-six tons for the AN CPS-1.

The ultimate in search-control radars of today is the V-Beam, the AN CPS-6. This is a microwave, ground radar designed for search, control, general air traffic control functions. It is able to find heights of aircraft by the use of a V-shaped radiation pattern. Hence, its nickname, "V-Beam." This radar is characterized by its high traffic-handling capacity, relative freedom from sitting difficulties, long-distance coverage at a low angle, and high resolution with moderate accuracy. Time of assembly from crates to operating positions is approximately one week with a trained crew of ninety men. A large number of indicators may be employed with this equipment. Normally furnished with each set are eight PPI, four RHI and seven B-scopes. As with the AN CPS-1, the large number of radar-scopes employed adds to the accuracy of interpretation of information displayed.

Identification and Recognition

It is necessary, for tactical reasons, to be able to determine the identity of a target. Just as a sentry must challenge everyone approaching his post, so must the radar operator challenge all targets detected by his radar equipment. Early recognition is imperative to avoid alerting personnel and equipment unnecessarily.

The problem of identification is to convey intelligence, by means of an electronic device, from the detected object to the detecting device for the purpose of ascertaining the identity of the target. In other words, the problem involves providing each ship, aircraft, guided missile, armored vehicle, and ground unit with some electronic means of showing its identity. It is also necessary, to provide these same units with means for obtaining the desired information.

In addition to the usual problems involved in identification, the identification of aircraft presents some peculiar problems of its own.

First, the difference between two similar terms must be established:

Identification is the indication by an act or means of one's own friendly character or individuality.

Recognition is the determination by any means of the friendly or enemy character, or the individuality, of another unit or individual. Recognition includes determining the type of target (aircraft, ship, tank, etc.) and its nationality.

Identification and Recognition System. At the present time, no system of identification and recognition is 100 per cent satisfactory. The problem is to convey intelligence by means of an automatic electronic device.

To accomplish this identification, a system of three components has been developed. One component of the system is used for transmitting the challenge. The second is used for receiving the challenge and returning the proper coded reply or identification. The third component is used to receive and display the coded reply. The challenging transmitter or interrogator, at one location, sends out a signal which is received at the distant station. This signal causes the distant station to return a characteristic reply. This reply is received at the initial location and is presented to the operator in such a manner that he is enabled to recognize the target—actually, the distant station.

As radar, at present, is the means of detecting a target at long ranges, the iden-

THIS PAGE IS DECLASSIFIED IAW EO 13526

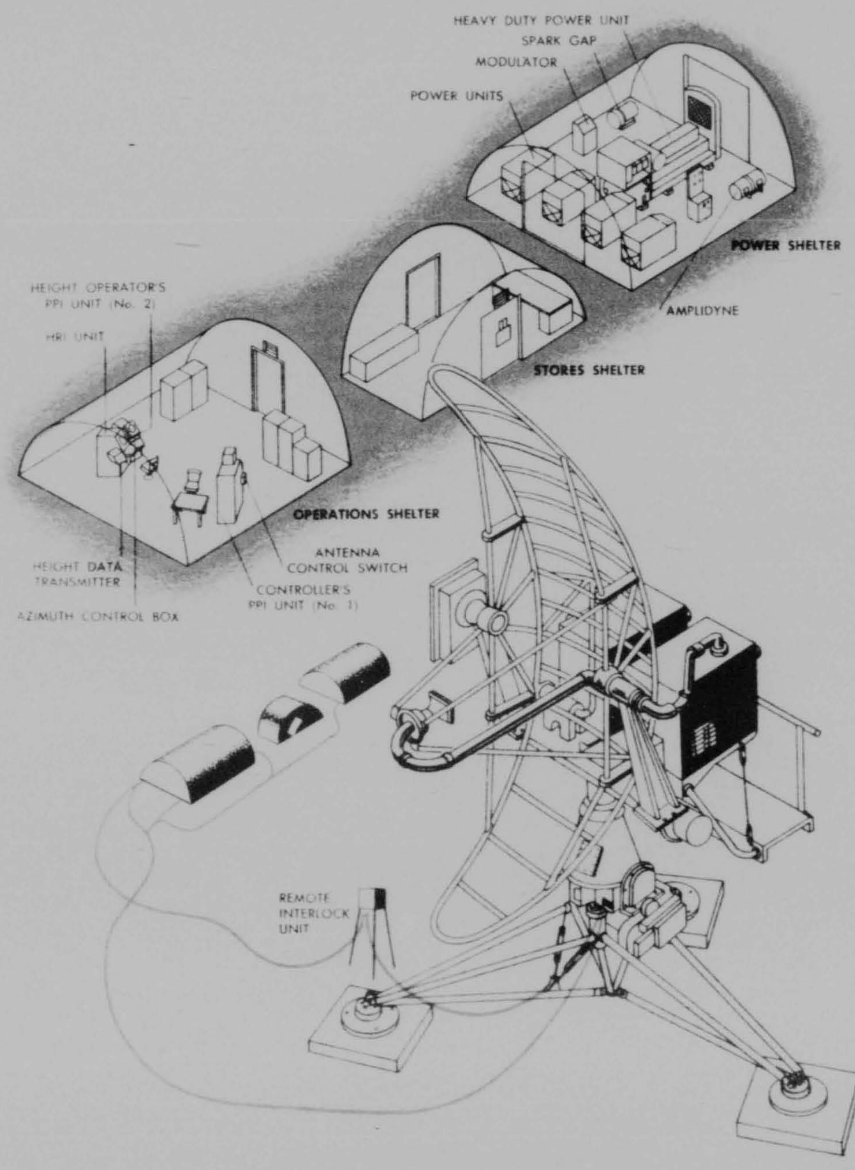

Figure 4-37 Radar Set, AN/CPS-4

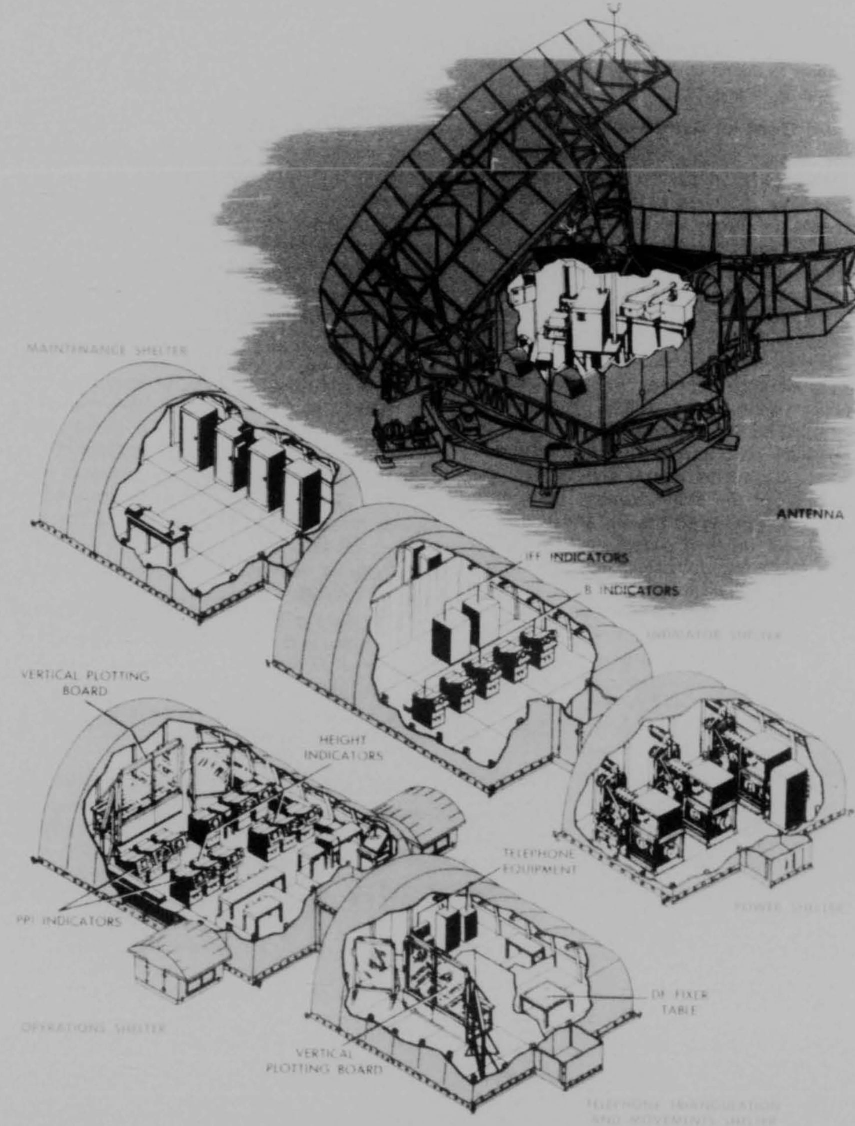

Figure 4-38 Radar Set, AN/CPS-6 (V Beam)

tification and recognition system is usually interconnected with the search radar. The display may be an integral part of the search radar set or may be separate. When separate, the display is independent of the radar equipment, but is located nearby.

Ground Control Approach (GCA)

A third type of ground radar for use by the Air Force has been developed. This is the GCA system which provides facilities for directing the movement of aircraft in the vicinity of an airdrome and over a predetermined glide path for a safe approach to the proper runway, under conditions of adverse visibility. Accurate and continuous information regarding the location of incoming aircraft with respect to the predetermined glide path is presented to the ground operators in the form of range, azimuth, and elevation data by the radar components of the system. This information is interpreted by the operators as lateral and vertical deviations from the predetermined glide path for the type of aircraft making tne approach. Instructions are then passed on to the pilot by a radio communications system in the form of corrections for him to make in order to keep on the proper glide path. With the aid of these instructions, the pilot is able to bring his aircraft to a point in line with the runway and below the ceiling, and prepared to make a visual landing.

In addition to providing the desired information concerning the approach, the system under favorable terrain conditions is capable, when well sited, of furnishing range and azimuth information to a pilot within 30 miles and up to an altitude of 4,000 feet. This information is utilized in controlling aircraft and positioning them for the final approach.

The GCA system differs from previous systems in that all the specialized equipment for effecting the approach is located on the ground. The only equipment required in the aircraft is a two-way radio communications set operating in either the HF or VHF band.

4. AIRBORNE RADAR EQUIPMENT

General

With the rapid development of air power during World War II, it soon became evident that to carry on the air war under all weather conditions both day and night, it would be necessary to devise some method to make such operations increasingly effective. Broadly speaking, the problem faced by the Air Force was to find equipment that would permit all-weather operations, and that would provide each aircraft with the special equipment which would permit it to function at its maximum range and its maximum effectiveness.

The need for twenty-four hour operations poses special problems such as flight safety, navigation, bombing, and landing aids, which must be solved before this type of operation may be successfully undertaken on any large scale.

In addition to the daylight-darkness factor, the additional problem of weather must be taken into consideration. To approach maximum effectiveness, the Air Force must be able to mount its attack regardless of the weather in the target area, the weather conditions along the route, and at the home bases. Some of the Air Force special requirements are these:

Precision Navigation. There must be a device (or devices) permitting precision navigation during instrument flight conditions, when neither ground observations (pilotage) nor celestial observations can be obtained.

Accurate Bombing. There must be a device to permit accurate bombing of targets when the target is obscured by clouds, smoke, haze, or dust.

Safe Landing. There must be a device or system to aid the aircraft in landing at the home bases when the visibility and ceiling are below the safe visual conditions. The Instrument Landing System and the Ground Control Approach, although not perfect, are currently the best available for the purpose.

In addition to the advantages to be obtained by devices that permit all-weather and around-the-clock operations, there are other advantages which may be obtained through the employment of effective electronic aids.

Among these are:

Fewer aircraft will be lost in operational accidents.

Each aircraft will waste less fuel if it can

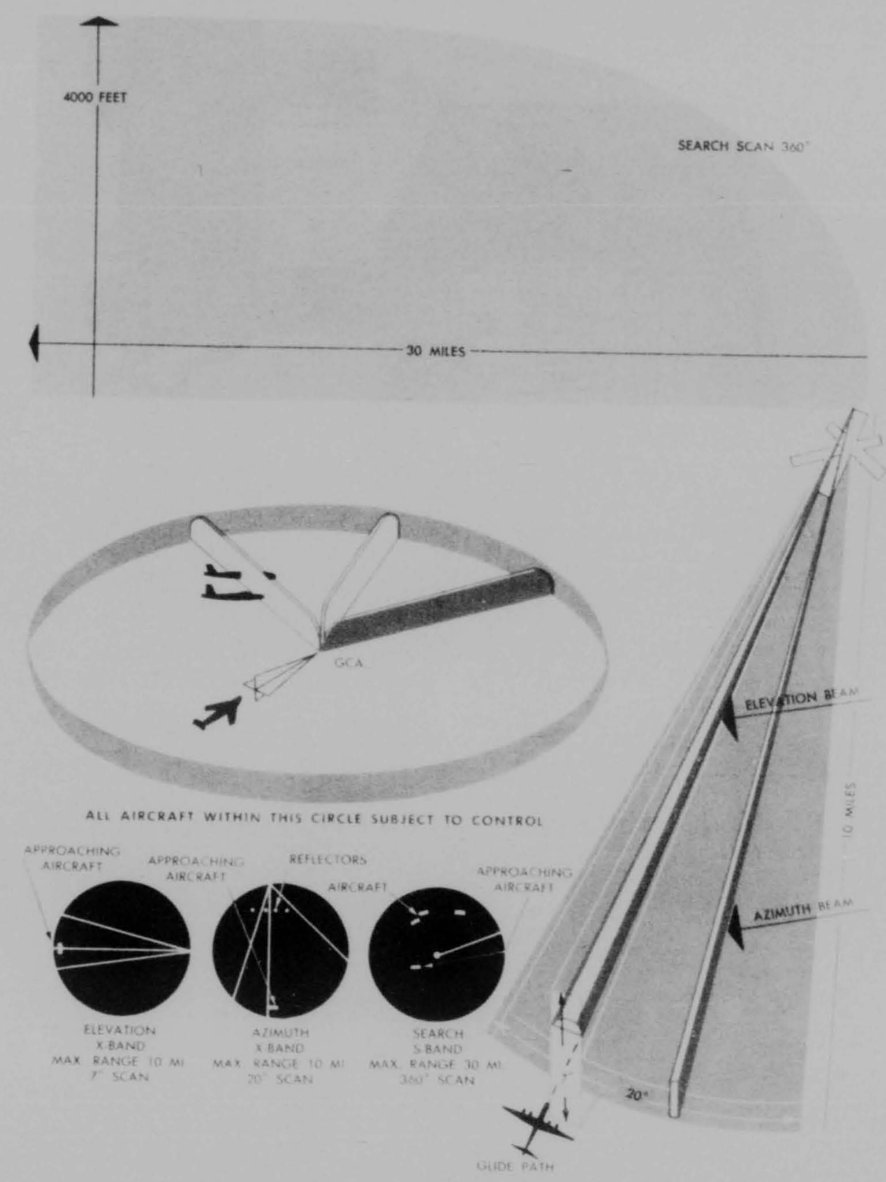

Figure 4-39 GCA

THIS PAGE IS DECLASSIFIED IAW EO 13526

tification and recognition system is usually interconnected with the search radar. The display may be an integral part of the search radar set or may be separate. When separate, the display is independent of the radar equipment, but is located nearby.

Ground Control Approach (GCA)

A third type of ground radar for use by the Air Force has been developed. This is the GCA system which provides facilities for directing the movement of aircraft in the vicinity of an airdrome and over a predetermined glide path for a safe approach to the proper runway, under conditions of adverse visibility. Accurate and continuous information regarding the location of incoming aircraft with respect to the predetermined glide path is presented to the ground operators in the form of range, azimuth, and elevation data by the radar components of the system. This information is interpreted by the operators as lateral and vertical deviations from the predetermined glide path for the type of aircraft making tne approach. Instructions are then passed on to the pilot by a radio communications system in the form of corrections for him to make in order to keep on the proper glide path. With the aid of these instructions, the pilot is able to bring his aircraft to a point in line with the runway and below the ceiling, and prepared to make a visual landing.

In addition to providing the desired information concerning the approach, the system under favorable terrain conditions is capable, when well sited, of furnishing range and azimuth information to a pilot within 30 miles and up to an altitude of 4,000 feet. This information is utilized in controlling aircraft and positioning them for the final approach.

The GCA system differs from previous systems in that all the specialized equipment for effecting the approach is located on the ground. The only equipment required in the aircraft is a two-way radio communications set operating in either the HF or VHF band.

4. AIRBORNE RADAR EQUIPMENT

General

With the rapid development of air power during World War II, it soon became evident that to carry on the air war under all weather conditions both day and night, it would be necessary to devise some method to make such operations increasingly effective. Broadly speaking, the problem faced by the Air Force was to find equipment that would permit all-weather operations, and that would provide each aircraft with the special equipment which would permit it to function at its maximum range and its maximum effectiveness.

The need for twenty-four hour operations poses special problems such as flight safety, navigation, bombing, and landing aids, which must be solved before this type of operation may be successfully undertaken on any large scale.

In addition to the daylight-darkness factor, the additional problem of weather must be taken into consideration. To approach maximum effectiveness, the Air Force must be able to mount its attack regardless of the weather in the target area, the weather conditions along the route, and at the home bases. Some of the Air Force special requirements are these:

Precision Navigation. There must be a device (or devices) permitting precision navigation during instrument flight conditions, when neither ground observations (pilotage) nor celestial observations can be obtained.

Accurate Bombing. There must be a device to permit accurate bombing of targets when the target is obscured by clouds, smoke, haze, or dust.

Safe Landing. There must be a device or system to aid the aircraft in landing at the home bases when the visibility and ceiling are below the safe visual conditions. The Instrument Landing System and the Ground Control Approach, although not perfect, are currently the best available for the purpose.

In addition to the advantages to be obtained by devices that permit all-weather and around-the-clock operations, there are other advantages which may be obtained through the employment of effective electronic aids.

Among these are:

Fewer aircraft will be lost in operational accidents.

Each aircraft will waste less fuel if it can

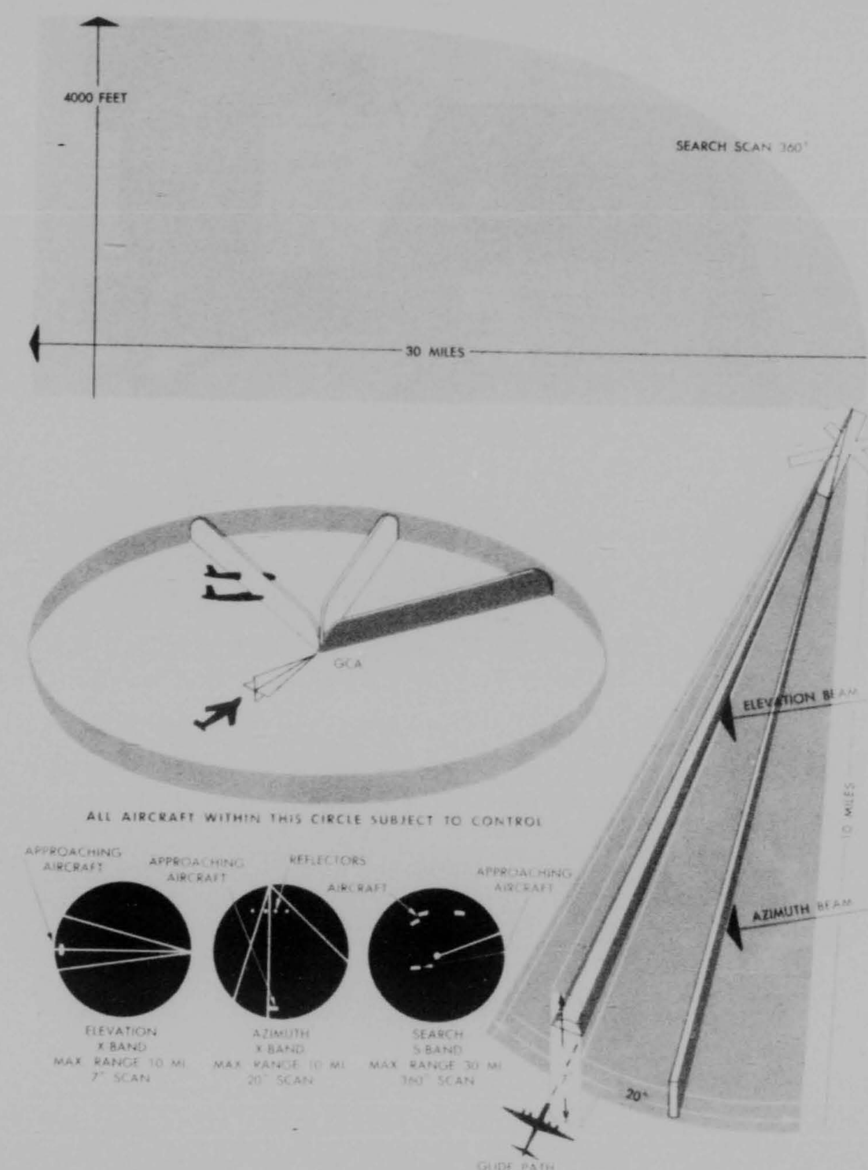

Figure 4-39 GCA

THIS PAGE IS DECLASSIFIED IAW EO 13526

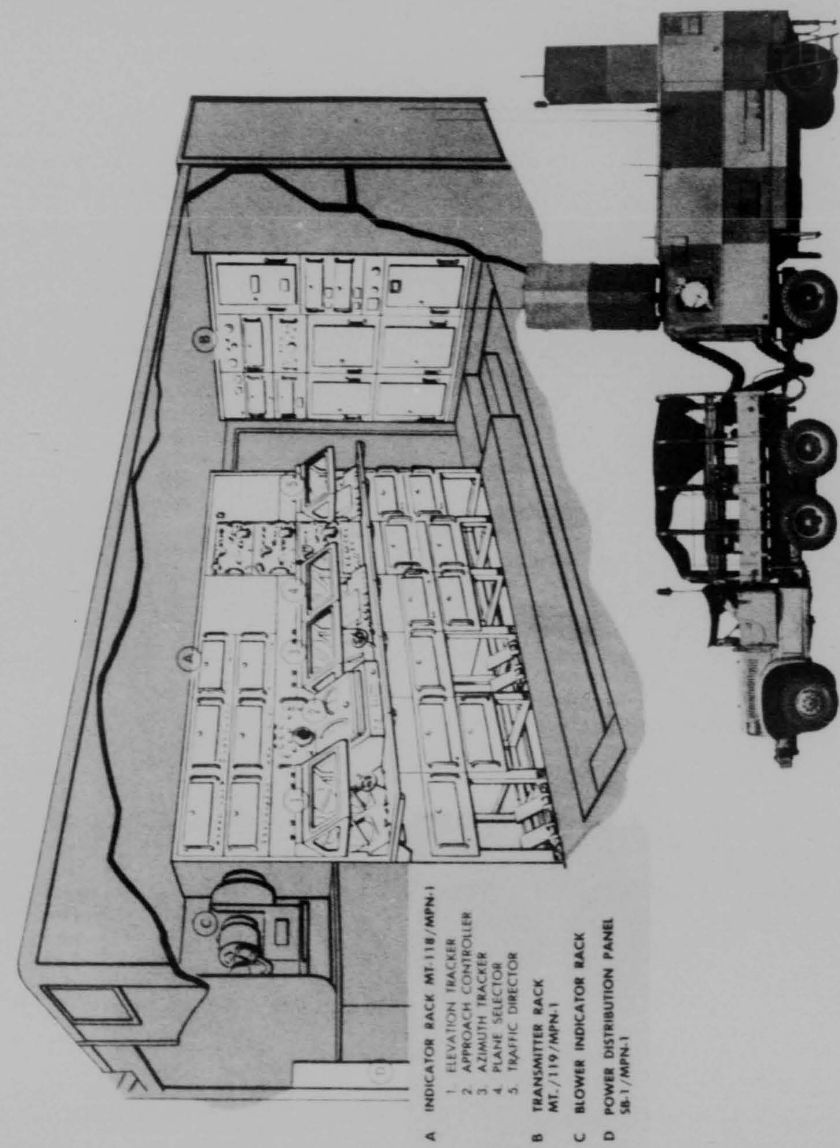

Figure 4-40 GCA Operations Trailer

Figure 4-41 Aircraft Radar Aids

be kept on a predetermined course. (This will permit the aircraft to carry a larger bomb load over the same distance or allow the radius of action to be increased when carrying a fixed fuel load.)

Scheduled rendezvous and assemblies can be kept.

The selected bombing target can be found, regardless of the conditions which exist at the bombing area.

The bomb run can be made at the proper time and in the proper direction.

Heavy flak areas can be avoided since the aircraft can be navigated around these and back on the proper course.

The aircraft can return to its home base with a minimum of difficulty.

In this discussion, only the broad requirements of the Air Force airborne radar equipment will be considered. The subject of special requirements of the Strategic, Tactical, and Air Defense Forces, will not be considered since these special requirements are adaptations of the same basic principles that will be discussed. Generally speaking, the requirements of any of these will be the same.

From a broad study of the mission of the United States Air Force, it becomes readily apparent that certain specific needs must be met. Chief among these are:

Physical requirements.

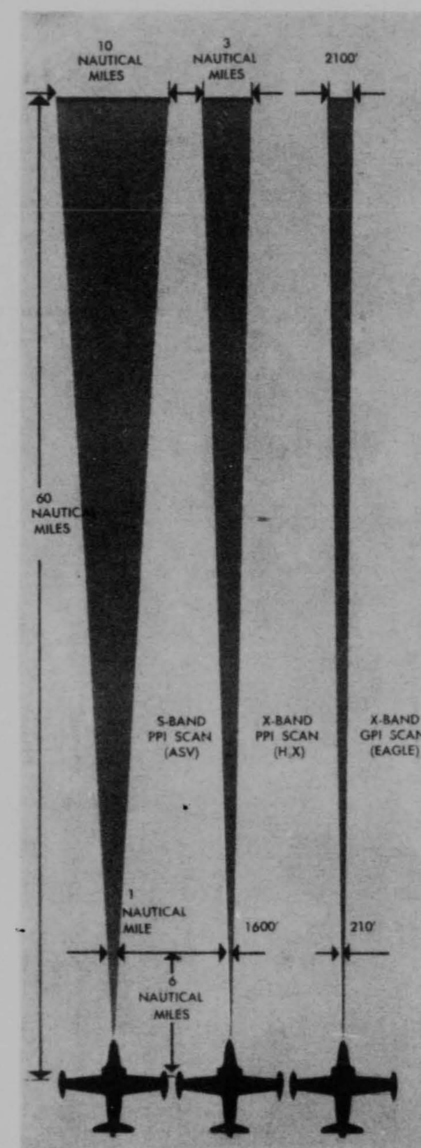
Navigation requirements.

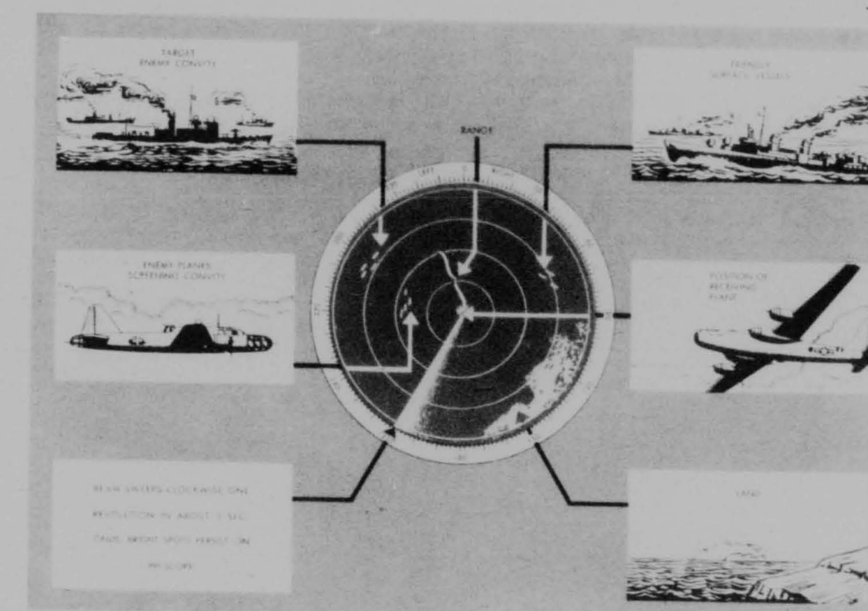
Bombing requirements.

Airborne defensive requirements.

Physical Requirements

Since the equipment must be installed in aircraft, there is a limitation on the total weight of the equipment. As the weight of the installed equipment is increased, there must be a corresponding reduction in the total load of the aircraft. Usually, the reduction can be applied only to the bomb load or fuel load, in either case causing a reduction of bombing effectiveness or range. With the very large types of aircraft employed in the bombardment field, the weight limitation will not be quite as critical as with smaller types of aircraft. It will, of course, reach its most critical stage with fighter-type aircraft. It is a factor that can never be neglected. Also, since the equipment must be installed in an aircraft, the component parts must be of such size that they can be fitted into the aircraft with a minimum disturbance of the basic interior design. Since some types of radar equipment require the presence of an additional crew member, the installation must take into account the space required for the radar operator. Again, the space requirements are more critical in the smaller types of aircraft than in the larger aircraft.





A further consideration that must be made is the effect on the flying characteristics of the externally mounted portions of the equipment. Usually, the antenna is mounted on the outside of the aircraft with a resulting increase in drag and a decrease in the air speed. This problem of drag becomes increasingly important as the speed of the aircraft increases since the drag increase is proportional to the second power of the velocity.

A third major physical requirement for airborne radar equipment is the ease or simplicity of operation. In all cases, the airborne radar equipment must be designed so that one man can operate it. Since the space for installation is limited, control and display units are designed to permit operation from a single position.

A fourth physical requirement imposed upon airborne radar equipment is that it must be entirely airborne and must not depend on any ground components or installations. An exception is the employment of airborne equipment with homing beacons. This is necessary since the range of operation of the aircraft will be far beyond the distance at which ground transmitted signals can be received.

The fifth physical requirement to be met is the initial electrical power supply of the aircraft. The power supply within the aircraft is comparatively small, is of low voltage, and is direct current. The equipment must be designed so that its power requirements are small and do not require the addition of more generators to the aircraft. The final requirement of airborne radar arises from the altitude at which it must work.

THIS PAGE IS DECLASSIFIED IAW EO 13526

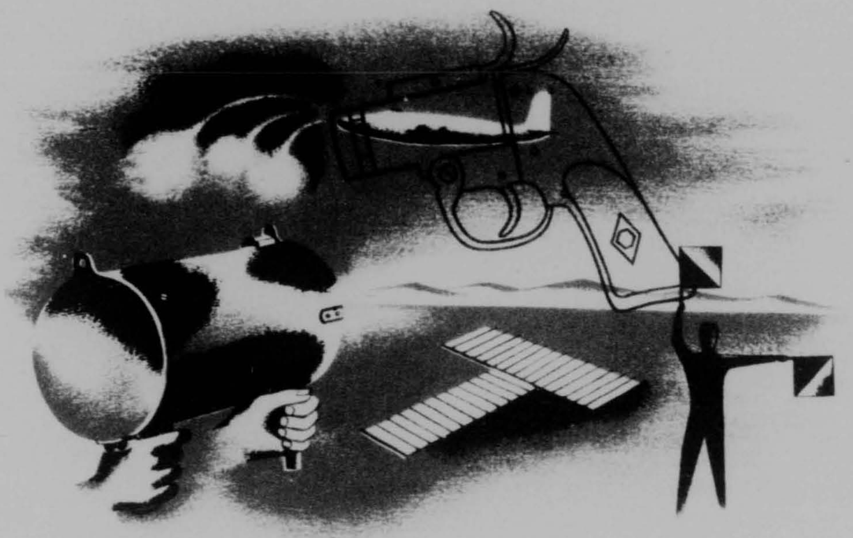
Owing to the decrease in atmospheric pressure as the altitude of flight increases, special provisions must be made for this decrease in the effect of reduced pressure. The reduction of pressure in the atmosphere causes the electrical equipment to arc over and become inoperative because of electrical breakdown.

The solution of the problem imposed is not one for the communications officer and is mentioned only as a matter of interest. The solution of this problem is one that requires the application of sound engineering principles. As previously discussed, it is readily seen that there are many conflicting items and the practical solution is one of compromise. It is to be hoped that the future developments, which will not be made under the pressure of war necessity, will be considerably more satisfactory than the present equipment. Before a completely satisfactory solution may be derived, great technical advances will have to be made in the improvement of materials and methods, as well as in circuit designs.

Other Requirements

Equipment designed to satisfy the navigation, bombing and airborne defensive requirements is so varied and in such variety that this subject will not be discussed here. It will be included, however, in Volume III, Chapter 5, in the sections on types of equipment employed in functional communications systems.

CHAPTER 5 - VISUAL AND AURAL COMMUNICATIONS



SECTION 1 - MILITARY USE

CAPABILITIES AND EMPLOYMENT

General

Visual communications includes all signals received by the eye regardless of transmission method. However, only the more important methods of visual communications, lights, flags, pyrotechnics, panels, and airplanes will be discussed here.

In areas served by other means of communications, visual communications is an auxiliary, supplementing wire and radio. The necessary equipment should be readily accessible at all times and in operating condition. For small isolated groups or units which are not equipped with electrical means of communication, the situation may sometimes be such that visual signaling with any means available is the only method possible. Its use depends upon the type of warfare, proximity of the enemy, terrain and weather. The relatively slow speed of transmission renders visual signal communications less suited for transmitting long messages than other means, but it is well adapted to transmitting prearranged messages and code groups over short distances. Visual signaling is especially applicable for use from front lines to the rear, from ground to air, and from ground to a vehicle in motion. The success of visual communications depends upon training, previous preparation, distribution of codes and prearranged messages.

Between Ground Stations

Attempts to attract attention of personnel with whom communications is desired must be persistent. All personnel must be trained to be on the alert for prearranged signals. If other effective means are available, visual communications should not be used, especially when it is likely to disclose a position or to draw fire on other troops. Where signals are being sent which are likely to disclose a position or to be seen and read by the enemy, care must be taken not to disclose information which may enable the enemy to take countermeasures in view of the time factor involved. Great care must be exercised in the selection of locations for visual signaling stations, especially those transmiting from rear to front.

Advantages. The advantages of visual communications between ground stations are:

Rapidity with which stations can be installed.

Speed with which short messages and prearranged signals may be sent.

The light weight, simplicity, and portability of the equipment.

Absence of need for metallic circuits between stations.

Disadvantages. Disadvantages of visual communications between ground stations as compared with wire and radio are:

Slowness, hence poor adaptability for sending long messages.

Dependence upon mutual visibility.

Difficulty of locating companion station, attracting its attention, and insuring receipt for traffic.

The vigilance necessary by operators to avoid missing signals.

Limited range.

Air-to-ground Usage

Visual communications from the ground to aircraft in flight is possible by use of panels, pyrotechnics, flags, and signal lamps. The aircraft may reply by radio, dropped messages, pyrotechnics, lamps or limited wing signals. An example of visual communications between ground and air in World War II was the marking of friendly front lines with pyrotechnics such as colored smoke.

2. METHODS

Lamps

Visual signaling by lamps is used more in the Navy for communications between ships and between ship and shore, than in the Army Field Forces or the Air Force. The equipment used for lamp-signaling or blinker is usually portable. It consists of a lamp which may be mounted on a tripod or carried by hand, necessary cords, box with necessary dry cell batteries, and a key for sending. The code used in the blinker system is the International Morse code. (Figure 5-1) Another very important use of lamps for signaling is in airdrome control towers. Lamps used for airdrome control are different from the blinker lamps in that they employ the use of two colors, red and green, and generally do not employ the use of other than color codes. Normally, the control lamp is used only when radio communication is not available or strict radio silence is required. By using red and green lights, the operator can give directions to craft in the air and on the ground.

Flags

There are two types of flag signalings; semaphore and wigwag. Suitable equipment is issued for signaling by either method. If no standard equipment is available, strips of cloth tied toward the outer end of sticks of wood or bayonets will serve for semaphore flags. For short ranges, when the use of flags would be unduly conspicuous, the hands or arms, or the headdress or handkerchief held in the hand may be used. The semaphore flagmen use the semaphore code. (Figure 5-2). Wigwag flagmen use the International Morse code.

Semaphore. A proficient semaphore flagman should be able to transmit and receive at the rate of 125 characters per minute at medium ranges. Under favorable conditions and with the aid of field glasses, semaphore flags can be read up to 2,500 yards.

Wigwag. For general use in lower units, wigwag signaling is more appropriate than semaphore because transmission is possible with improvised equipment and does not require an operator to expose himself by

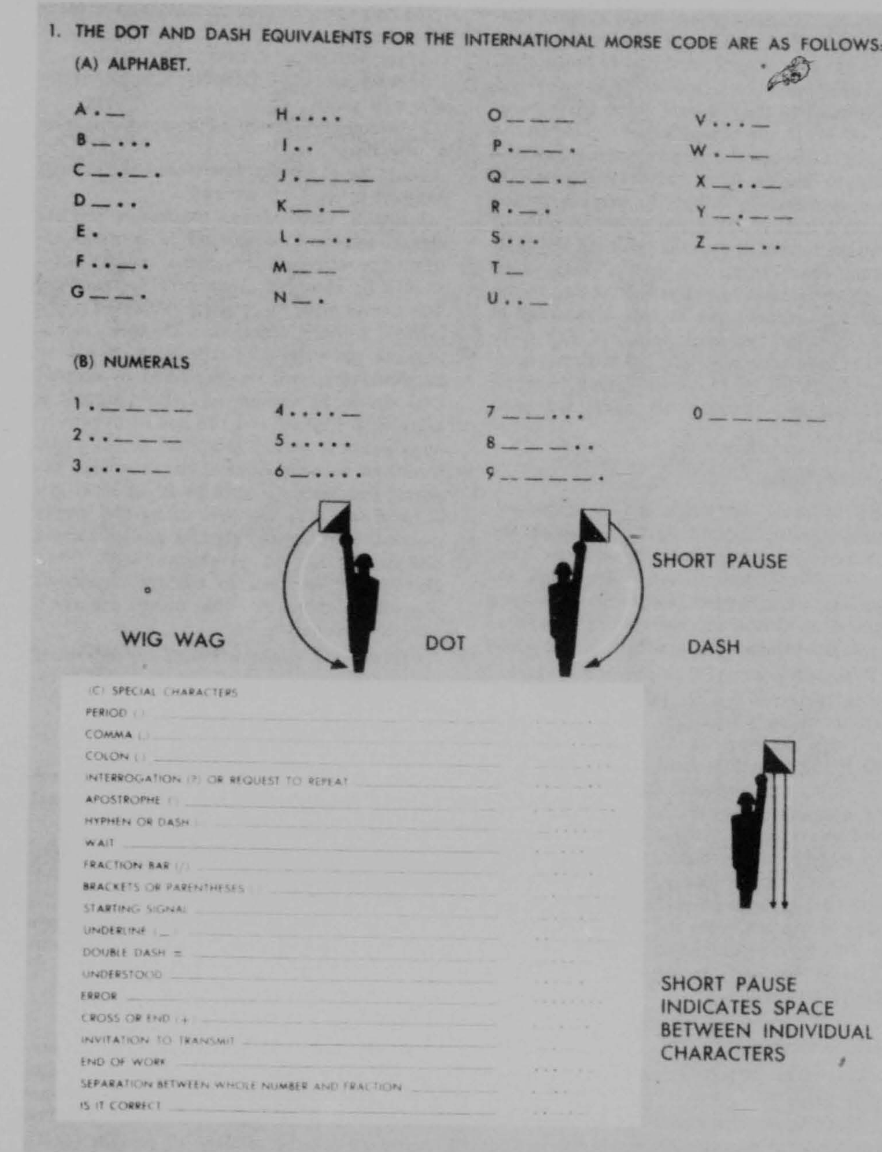


Figure 5-1 International Morse Code

THIS PAGE IS DECLASSIFIED IAW EO 13526

standing. Since wigwag flags, radios, telegraphs, and signal lamps employ the International Morse code, training is facilitated. A dot is made by a motion from overhead downward to the sender's right, through an arc of 90° in the plane perpendicular to the line of transmission and returning immediately to the starting point (overhead). A dash is made by a similar motion to the sender's left. A short pause in the vertical position indicates spacing between the individual characters. The end of a word or group is indicated by dipping the flag to the operator's front; the end of a message is indicated by two such motions. For communication with aircraft, the wigwag operator faces the airplane continuously while transmitting, turning his body for such purposes.

Pyrotechnics

Pyrotechnic devices used for communication are the ground signal projector, the pyrotechnic pistol, aircraft, and the Very pistol. Pyrotechnic devices are used for sending prearranged messages requiring immediate action or when other means of communications are uncertain or too slow.

Pyrotechnic Pistol. The pyrotechnic pistol, aircraft-type, is for use in airplanes. It consists of a heavy frame or receiver only, the cartridge serving as the barrel through which the signal is fired. The cartridge is about one and one-half inches in diameter and contains either a star cluster or a star blinker signal of various colors. The cartridge is inserted into the receiver of the pistol, held outside the airplane and fired. After firing, or in case of a misfire, the cartridge is ejected from the pistol. The pistol may be held in one hand and fired, but because of the fairly severe recoil, both hands should be used.

Use. Some of the principal uses of pyrotechnic signals are:

To cause artillery fire to commence, or to lift.

To indicate the arrival of certain front line units at certain points on the terrain.

To acknowledge receipt of lamp or flag transmission by a visual station which is not permitted to use lamps or flags.

To call for a display of markings or identification panels.

Identification of friendly aircraft.

Identification of friendly armored vehicles and units.

Intercommunication of armored vehicles and units.

Marking of enemy front lines for ground support by tactical aircraft.

Message Transmission. Meanings are assigned pyrotechnic signals in communication operation instructions (COI) and should be changed frequently for secrecy. The names given in catalog listings of pyrotechnic signals, together with their meanings as prescribed by the unit or higher headquarters, will be published in current COI. Since the number of distinct signals is extremely limited and the use of pyrotechnic signals is largely confined to the front lines and to emergencies, the meanings assigned invariably should be those most important to front-line operations and emergencies. Pyrotechnic signals are extremely difficult to see in bright sunlight. They should not be used to control important operations unless no other means are available or practicable.

Precautions. Observation of the following precautions will prevent the misuse of pyrotechnics:

Signals should be distinct from one another.

The most readily discernible signal should be assigned the most important meaning.

Promulgation and distribution of communication operation instructions pertaining to pyrotechnics should be timely.

Each unit commander should designate an officer to be responsible for the use of pyrotechnics by that unit.

Panels

Panels are used only as a means of communications from ground to air. They consist of either black, white, or tangerine-colored material and vary in size. The standard size is usually 12 feet in length and 2 feet 4 inches in width. Care should be taken in selecting the panel display area. The ground selected should be a fairly level

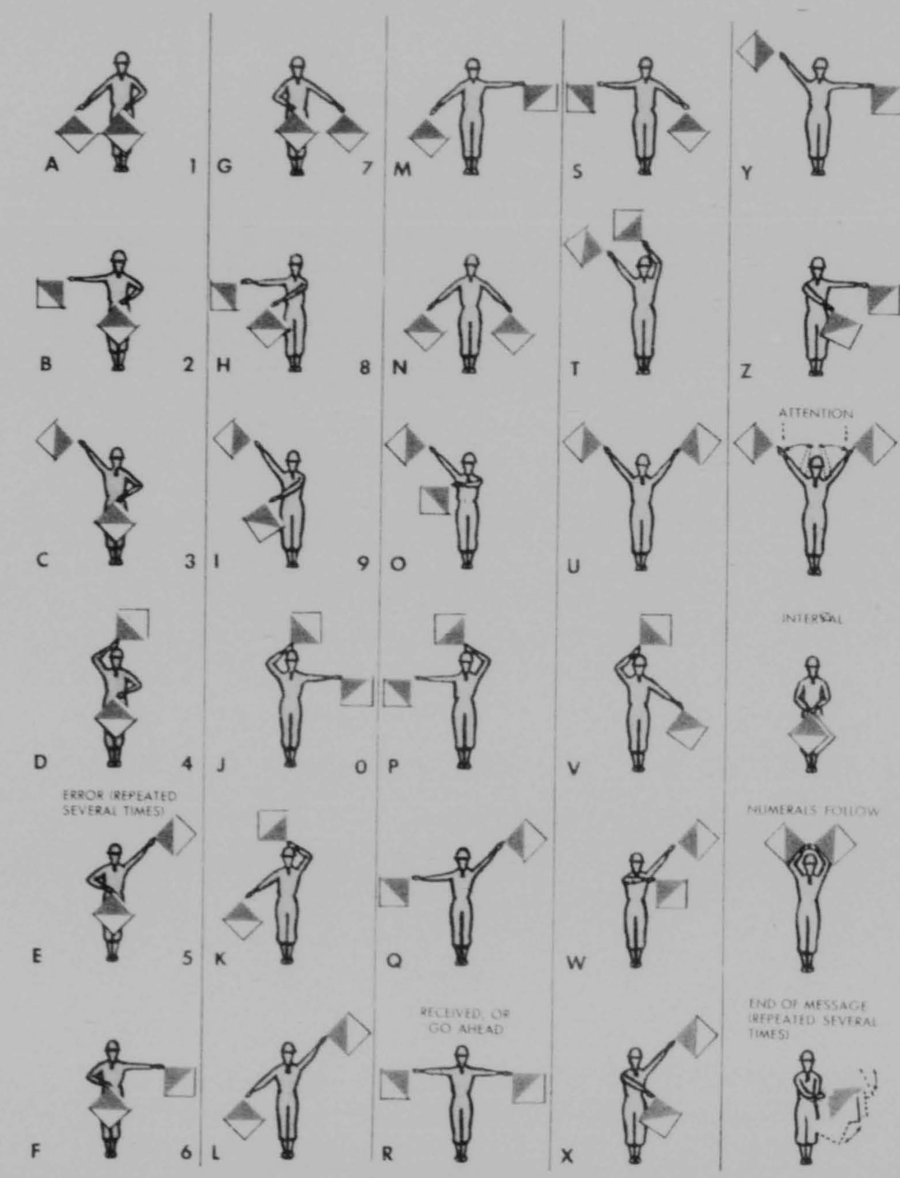

Figure 5-2 Semaphore Code

open space, free from rocks, high weeds, brush and removed from high trees and bodies of water. It should be screened from hostile ground observation if possible, but so located that the panels may be seen by airplane at wide angles from the vertical. The panels should be displayed in the best light available and be so placed that they will not be obscured by shadows. The basic visual components are used as indicated in Figure 5-3.

Airplane Maneuvers

In an emergency, when a ground station is not equipped for radio reception or when the radio transmitter of an airplane is silenced or out of commission, an airplane may communicate to a limited degree with a ground panel station by means of various maneuvers of the airplane while in flight. However, such signals are extremely limited in number. No standard code has been developed for this means of communication but any code used should be practicable of performance by the airplane used and preferably be prescribed in communication operation instructions. Individual units have devised such codes by prearrangement with other units designated to operate with them. Adjustment of the fire of field artillery batteries by the use of panel signals and airplane wing signals exclusively is rapid and often practicable.

Communications By Sound

The audible transmission of intelligence by mechanical or acoustical devices, excluding speech, and their direct reception by ear, is defined as sound communications. Such common sound-producing devices as whistles, horns, bugles, sirens and rattles, and the sound produced by small arms, artillery, and motors of airplanes in flight are frequently used for signaling. Orders, information, and other prearranged messages are represented by bugle sounds. Other sound-producing alarm devices are issued for use in the event of enemy gas or air attacks. The gas alarms are percussion sounds, such as those produced by bells, triangles, or iron rails which are struck rapidly and continuously. The air attack alarms are three long blasts of a whistle, motor horn, siren, or klaxon repeated several times. The chief value of communications by sound is the resulting economy of time, personnel, and equipment when utilized for alarms for attracting attention, and for the transmission of short prearranged messages.

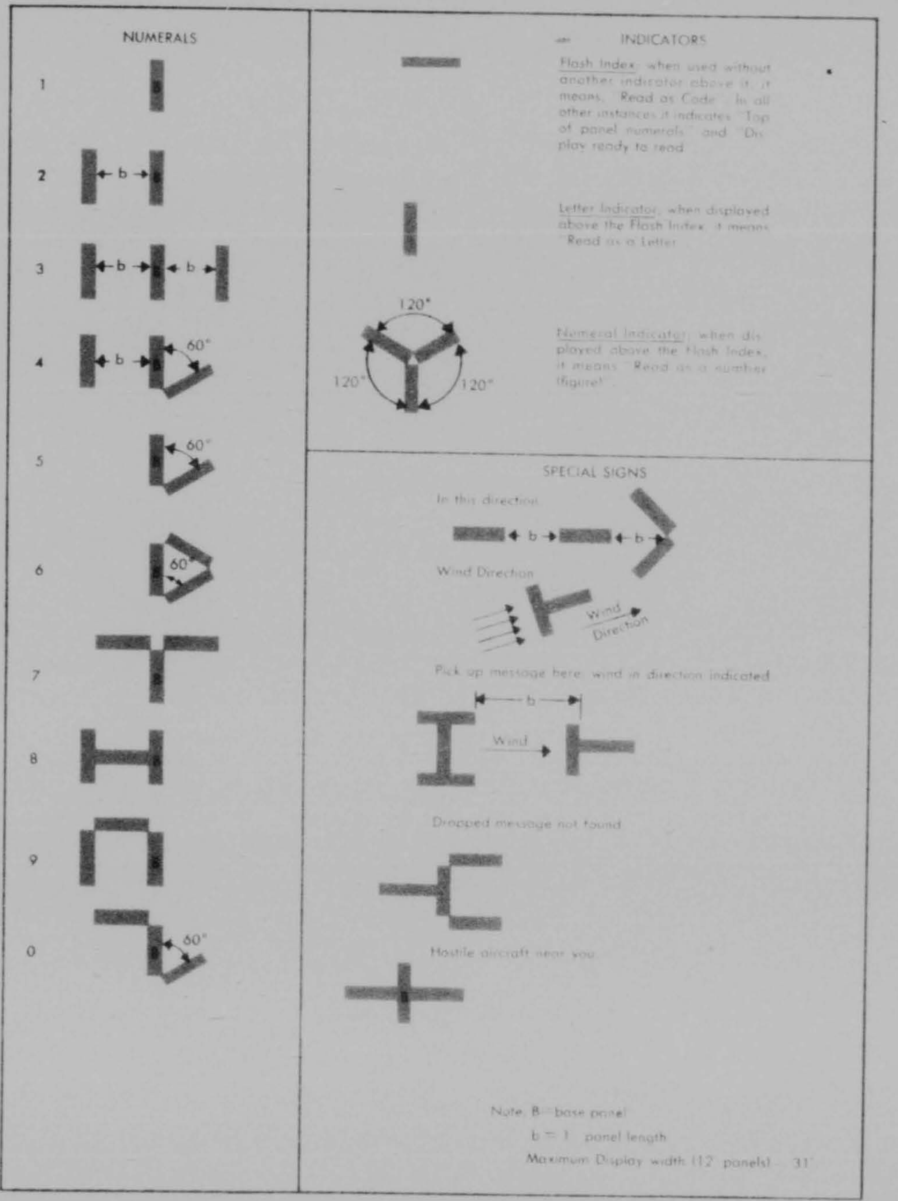

Figure 5-3 Panels

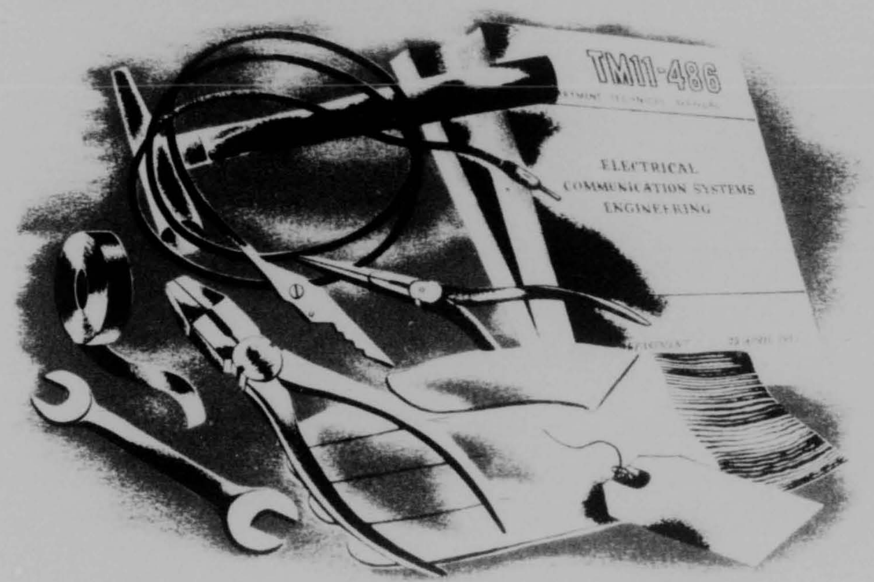
THIS PAGE IS DECLASSIFIED IAW EO 13526

CHAPTER 6-COMMUNICATION SUPPLY AND MAINTENANCE



1. GENERAL

One of the important functions of communications is in the field of logistics. Emphasis here is placed on the communications officer at squadron level; the operation of a communications supply section and the maintenance facilities required is the responsibility of the unit communications officer. It is true that the actual work is often done by a specialist in the field of communications supply or maintenance, but the responsibility falls upon the communications officer who reports to the commander. At squadron level, the supply and maintenance functions in communications are usually the responsibility of a single officer who also has duties in the communications fields of section administration, operation, intelligence, and inspection.

As this assignment involves a multiplicity of detail, the communications officer must have a basic knowledge of Air Force supply, maintenance, and inspection systems. This chapter, therefore, will indicate the scope of these subjects as they apply to the field of communication.

2. PUBLICATIONS FOR COMMUNICATIONS

The communications officer, in his continuous effort to keep abreast of existing and ever-changing conditions, new developments, policies, and operational or administrative procedures, must make frequent reference to literature of a general and technical nature. It is therefore important that he have a sound basic knowledge of the material contained in the various military publications in order to properly acomplish his work.

In recognition of this need, the USAF has authorized each communications organization to maintain its own file of communications publications. The file will include appropriate Department of the Army, United States Air Force, and commercial publications, in addition to command directives which apply to communications functions, equipment, and procedures of each AF organization. In general, the communications section will contain only that material which is closely related to its function. The responsibility for the basic selection, organization, and control of Communications Publications Files is a function of the major command involved. This responsibility may be delegated to the echelon of command immediately responsible to a major command but may not be further delegated.

The Communications Publication File is organized, administered, and maintained by the unit communications officer in acordance with the directives of the higher headquarters. An index is maintained and an inventory is made of this file every three months.

Itemized below is a general source list of publications to be found in a Communications Publications File:

Combined Communications Board Publications
Commercial Equipment Handbooks
DA Adjutant Letters
DA Catalogs (Signal Corps)
DA Circulars
DA Field Manuals
DA Lubrication Orders
DA Modification Work Orders
DA Pamphlets
DA Regulations
DA Supply Bulletins
DA Technical Bulletins
DA Technical Manuals
DA Training Circulars
Joint Army-Navy-Air Force Publications
Tables of Allowances
Tables of Organization and Equipment
USAF Confidential Orders
USAF Letters
USAF Manuals
USAF Material and Service Directives
USAF Regulations
USAF Stock Lists
USAF Technical Orders
USAF Training Standards

Frequent use of these many and varied references, together with the publications of the intermediate echelons, guide and direct the communications officer in the performance of his duties.

The contents of the different types of publications will be briefly described in the next paragraphs. Space limitations preclude a detailed discussion; consequently the future officer will be required to become more fully acquainted with them at the time he enters active duty. The publications may be divided into three classes for the purpose of this text: Department of the Army Publications, United States Air Force publications, and publications of other agencies.

Department of the Army Publications

Field Manuals (FM). Field Manuals constitute the primary means of promulgating the basic doctrines of military training and operations. They contain training instructions relative to tactics and techniques.

Technical Manuals (TM). Technical Manuals supplement Field Manuals, and cover subjects the separate treatment of which is considered essential to a full accomplishment of the training prescribed in the Field Manuals. They include manuals describing equipment and contain instructions for operation, care, and handling; guidebooks for instructors and specialists; material for extension courses; reference books; administrative materials; and similar specialized subject matter.

Technical Bulletins (TB). Technical Bulletins prepared by technical services disseminate new instructions and information pertaining to technical matters, concerning equipment procured and issued by the preparing agency, or to professional techniques, over which the preparing agency has exclusive jurisdiction. This medium is sometimes used to publish, without delay, technical material that may later be incorporated in manuals or changes to manuals. Technical Bulletins do not contain material pertaining to tactical training or tactical operations.

Supply Bulletins (SB). Supply Bulletins disseminate instructions and information on supply matters such as requisitions and issue, warehouse and depot administration and procedure, safety information, storage packing, marking, and shipping.

Modification Work Orders (MWO). Department of the Army Modification Work Orders provide authentic and uniform instructions for the alteration and modification of United States Army material. The abbreviated designation of the technical service preparing each Modification Work Order is incorporated in the number. For example, MWO ORD A37-W-15; MWO QM 1; MWO SIG 11-447-1. Modification Work Orders follow a standardized form detailing, in successive paragraphs, the major items affected; part modified; purpose of modification; drawings required to apply modification; special tools, test equipment, jigs, and fixtures; special instructions; and remarks.

Tables of Organization and Equipment (T O&E). These tables are published by both the Department of the Army and the Department of the Air Force. They prescribe the organic structure and equipment of military units, the organization, strength, and functions of which are not subject to frequent change. Each T O&E applies to one type of unit which is specified in a descriptive title and designation. Each T O&E is composed of three major sections. The first, **General**, includes a statement of the function, assignment, and capabilities of the organization. The other two, both in tabular form, are **Organization** and **Equipment**. The organization section prescribes the authorized number, grades and qualifications of personnel, and also shows, for information, the number and distribution of weapons, facilities for transportation, and principal items of equipment listed therein. Active units must maintain in their possession all authorized equipment unless otherwise directed by competent authority. The equipment section does not prescribe allowances of equipment required for temporary or special purposes, such as items of clothing and individual equipment; these items are provided for in the Table of Clothing and Individual Equipments. It does not provide items for which allowances are already prescribed in the supply catalogs of the various technical services; nor does it make provision for miscellaneous items including components parts, spare parts, accessories, and expendable items.

Tables of Allowances (T/A). These tables prescribe allowances of equipment authorized for posts, camps, bases, and stations, general and special schools, United States Military Academy, training centers, disciplinary and miscellaneous units or activities, auxiliaries, and overseas departments, bases, and theaters. Auxiliaries, as the term is used above, include activities of a military character which are supervised by the Department of the Army or for which the issue of equipment is authorized by law under regulations prescribed by the Secretary of Defense. Equipment authorized for issue to units by Tables of Allowances is in addition to that authorized in Tables of Organization and Equipment. Such additional equipment will not be taken with a unit into the field or on change of station unless specifically authorized by competent authority (usually indicated in the "basis of issue and remarks" column of the table). In addition to prescribing allowance of equipment for training, school, and all other units and installations whose personnel is provided by allotment, Tables of Allowances also prescribe allowances of training equipment for TO&E units.

A single table, subdivided according to technical services, is published for all items of equipment which are normally required and issued for use at posts, camps, bases, and stations, including training equipment, and which are not taken by units upon change of station. Special equipment for posts, camps, bases, and stations of the United States Air Force is covered in notes appended to the table.

Catalogs (Cat.). Catalogs contain information and instructions on the procurement, storage, issue, requisition, maintenance, and use of equipment and supplies furnished by the technical services. They are the official basis of issue for spare parts, tools, etc. They supplement Tables of Organization and Equipment and Tables of Allowances, and present authorized allowances and initial issues not shown in such tables. Catalogs are divided into sections, one for each technical service. These sections in turn are published in parallel sections having a similar purpose or content. Each such section bears the abbreviated designation of the initiating technical service (SIG, ENG, MED, etc.) followed by a basic number which identifies the content of the section (e.g., SIG 5, ENG 2, MED 3). A complete description and explanation of the catalog system of each technical service may be found in the respective section I pamphlets.

The Department of the Army, Signal Supply Catalog. The Department of the Army, Signal Supply Catalog consists of the following sections:

a) **SIG 1 and 2. Introduction and Index.** Section I, Introduction, explains the purpose and use of each section of the Signal Supply Catalog. It contains an explanation of symbols and abbreviation. Section II, Index, lists all available sections and pamphlets in the Signal Supply Catalog system. This section also indexes, alphabetically by nomenclature and type number, equipments listed in SIG 6, SIG 7, SIG 8 and SIG 10 pamphlets. Hence, it can be used to find any pamphlet in the above series if the user knows the type number or nomenclature of the equipment involved.

b) **SIG 3. List of Items for Troop Issue.** This publication lists alphabetically by nomenclature all type-numbered items which appear on Tables of Equipment (T E's) and Tables of Organization and Equipment (TO &E's) or similar tables. Items are cross-indexed by type number to find nomenclature. SIG 3 is published primarily for the use of unit commanders.

c) **SIG 4-1.** SIG 4-1 lists, as the title indicates, **Allowances of Expendable Supplies for Tactical Organizations**, and **SIG 4-2** lists **Allowances of Expendable Supplies for Schools, Training Centers, Boards, and Fixed Installations.**

d) **SIG 5. Stock List of All Items.** SIG 5 lists, in stock number sequence, all items of Signal Corps equipment to which stock numbers have been assigned. It furnishes stock numbers, nomenclature, complete description, unit of measure, shipping weight and volume, and expendability of each item included. SIG 5 is designed primarily for the use of depots, procurement agencies, and higher echelons. SIG 5 is not a basis of issue. There are four indexes to SIG 5 to assist in locating a stock number when only part of the description is known:

(1) **SIG 5-1. Index by Type Numbers to SIG 5 Stock List of all Items.** An index to all type numbered items in SIG 5.

(2) **SIG 5-2. Index by Manufacturers' Numbers to SIG 5 Stock List of All Items.** Cross-references manufacturer's number to item name and stock number.

(3) **SIG 5-3. Index to SIG 5, Alphabetical Listing of Signal Corps Equipment.** Alphabetical listing of items in SIG 5. A description of the item is cross-referenced to its stock number.

(4) **SIG 5-4. List of Interchangeable and Substitute Items in SIG 5 Stock List of all Items.** A list of items from SIG 5, in stock number sequence, cross-referenced to the stock number of the substitute item.

(5) **SIG 5-5. Pricing Guide for Signal Corps Equipment. Compiled in stock number** sequence and gives unit of measure and unit of cost.

e) **SIG 6. Sets of Equipment.** A series of pamphlets listing component parts of tool sets, test equipment sets, maintenance equipment sets, and similar assemblies. Ordinarily, one pamphlet is furnished for each set.

f) **SIG 7. Organizational Spare Parts.** This consists of a series of pamphlets, each of which lists the organizational spare parts allowances for a major item or major component common to several major items. SIG 7 is currently combined with SIG 8.

g) **SIG 8. Higher Echelon Spare Parts.** This consists of a series of pamphlets similar to SIG 7. Each pamphlet lists guide quantities for initial issue of spare parts to higher echelons of maintenance, army and base depots. SIG 7 and SIG 8 are currently combined in one book, called SIG 7 and 8.

h) **SIG 9. List of Service Parts.** (Not yet published.)

i) **SIG 10. Fixed Plant Maintenance List.** This consists of a series of pamphlets, each of which provides a list of maintenance parts for an individual item or group of items of

fixed-plant equipment. These pamphlets list authorized allowances for station stock and guide quantities for the initial issue of spare parts for field and base depot stock for fixed-plant maintenance.

j) **SIG 10-2.** The full title of this publication is: **Fixed Plant Maintenance Lists Factor Table, Manufacturer's Code Number List, Abbreviations.** SIG 10-2 contains a factor table to be used to determine the quantities of parts to be stocked at stations and to be used as a guide in making initial issues to supply depots where three or more units of a given type of equipment are maintained.

k) **SIG 10-3. Equipment for Which Fixed Plant Maintenance Lists Will Not be Furnished.**

l) **SIG 11-1. Parts Control Lists, Procurement and Issue Control Lists.** A compilation of Procurement and Issue Control lists on Signal Corps Equipment.

m) **SIG 11-2. Parts Control Lists, Component Applications Lists on Type-Numbered Items.** A list of type-numbered components and the sets or equipment in which the component is used, together with the number of times the component is used in each equipment. Components are listed in sequence by type number.

n) **SIG 11-3. Parts Control Lists, Components Applications Lists on Nontype Numbered Items and Substitution Information.** SIG 11-3 is divided into two sections; one section is a list of nontype numbered components and the sets or equipments in which the component is used, together with the number of times the component is used in each equipment; the second section lists the permissible substitute items for sets of equipments and components. Nontype-numbered components are listed in sequence by alphabetic description.

U. S. Air Force Publications

AF Regulations. AF Regulations are the primary administrative regulations for the government of the Air Force. They contain USAF policies, directives, and or instructions of a permanent nature which are of general application to all USAF activities under the command and control of the Commanding General, USAF, or which may be of application to specific USAF activities but where general distribution is necessary. These regulations are printed on standard lettersize (8" x 10½") paper and receive a wide distribution among all activities of the USAF in the United States and overseas. The title of each regulation consists of two parts; the subject classification or general title, and the subtitle naming the specific matter covered in the publication. Thus, an AF Regulation dealing with the subject of communications will bear the general title **COMMUNICATIONS.** The subtitle will cover the specific subject; for instance, **Fixed Communications Systems and Facilities,** or **Communications Publications File.**

The system of numbering used for AF Regulations is also used for AF Letters, AF Materiel and Service Directives, and AF Training Standards. This system has been adopted as the standard system of numbering administrative publications and is used by all commands and air forces and by all echelons thereunder including posts, stations, or air bases, in the issuance of regulations, memorandums, instructions, or other administrative publications. The number consists of two parts separated by a dash. The first part is the number of the subject classification or general title and is known as the "base number." The second part is the number assigned to the subtitle and is known as the "subnumber." Subnumbers within each base number run consecutively. AF Regulation 5-1, General Index of AF Standard Publications, establishes a basic index and numbering system for Air Force standard publications (AF Regulations, AF Letters, and AF Manuals) which are given base numbers indicating general subjects. The base numbers pertaining to communications and electronics are:

Base No. 100 Communications
Base No. 101 Electronic Systems
Base No. 102 Communications Systems

AF Letters. AF Regulation 5-1 serves as the general index by which AF Letters are classified and numbered. The title is in the form of a military or **Subject and To** letter, the subject describing the content of the publication. A numerical index of AF Letters, listing all of the publications currently in force, is published quarterly as AF Letter 5-2. A separate series of publications exists in the form of unnumbered letters. Unnumbered letters are used for announcements or instructions which require only one-time action or are purely informative in nature.

AF Training Standards. These publications set forth the standards of proficiency for the training of units and individuals. Whereas the numbering system is the same as that for AF Regulations and AF Letters, the subject classification corresponding to the base numbers differs widely from AF Regulation 5-1. AF Training Standard No. 0-1 sets forth the general index system of base numbers and corresponding subject classification for these publications. AF Training Standard No. 0-2, published quarterly, is the numerical index of all AF Training Standards currently in force.

AF Manuals. AF Manuals are a medium for publishing a compilation of material for the purpose of simplifying the presentation and understanding of diverse matters relating to a single subject, procedure or responsibility. They are titled, numbered, and indexed as prescribed in AF Regulation 5-5, and 5-1.

AF Materiel and Services Directives (M&S Directives). Published by the Commanding General, Air Materiel Command, in the name of the Chief of Staff, United States Air Force, these publications establish specific operating procedures and instructions for procurement; and operating instructions in materiel and service fields other than supply agencies within the USAF. The numbering system is the same as that used for AF Regulations. M&S Directive No. 5-1 sets forth the base numbers and general subject classifications which are given to AFM&S Directives. This general index, with minor changes and additions, is substantially in accord with AF Regulation 5-1, General Index of AF Administrative Publications. A numerical index of M&S Directives, listing all of these publications currently in force, is published quarterly as M&S Directive No. 5-2.

AF Technical Orders (T.O.). Published by the Commanding General, Air Materiel Command, in the name of the Chief of Staff, USAF, these publications disseminate specific technical directives and information on AF equipment with respect to the inspection, storage, operation, modification, and maintenance of such equipment, and prescribe items of equipment to be assembled in kits or sets. In general, Technical Orders are published in looseleaf form, letter-size, with the left-hand margin punched for filing. Thus the files of technical directives and associated data may be consolidated in numerical sequence. Further, all technical instructions and information relating to individual airplanes, engines and other items of equipment may be assembled in individual binders for the convenience of personnel whose duties require that they constantly refer to such material. Many of these publications are Technical Order Handbooks dealing with the operation or maintenance of specific items of equipment or with more general subjects, for example, T.O. No. AN 16-30-ARC 3-2 "Handbook of Operating Instructions for Radio Set AN/ARC-3," T.O. No. 30-20F-2 "Basic Radio Maintenance Trailing Guide," or, T.O. No. 16-1-2 "Flying with Radar."

In addition to the classification incident to the numbering system, explained below, Technical Orders are classified as to security and as to urgency. The security classifications used are **RESTRICTED** and **CONFIDENTIAL**, most are unclassified. Publications classified as CONFIDENTIAL are separately indexed and filed. As to urgency, Technical Orders (other than handbooks) are, broadly speaking, classified as Urgent or Routine. Urgent Technical Orders have a red cross border (X), a red diagonal border ( ) or the words "Immediate Attention," printed in red letters, at the top and bottom of each page. Routine Technical Orders are printed on plain white paper. Technical Orders, according to their urgency are classified as follows:

Immediate Action Technical Orders. Technical Orders specifying "work to be accomplished immediately" denote dangerous conditions which require grounding of the

aircraft pending compliance wi[illegible] e Technical Order. This class of Technical Orders is printed on white paper with a border of red "X"s. The red "X"s, in addition to providing a distinctive identification, correspond to the symbol (red "X" or red cross) used on the Maintenance Inspection Record for Airplanes (AF Form 41B) to indicate a defect or unsatisfactory condition of such a nature that it renders the aircraft unsafe for flight.

Immediate Attention Technical Orders. Technical Orders containing special operations, informative, precautionary, or restrictive instructions which vitally affect the safety of flight, operation, and use, or combat effectiveness, but requiring no work or inspections (other than placarding or marking of flight instruments, when specified) and therefore involving no grounding of aircraft, are printed on white paper with the words **Immediate Attention** in red letters at the top and bottom of each page. This class is also used for important modification or inspection instructions, which would normally require **Immediate Action** classification bear no **grounding** significance when applied to such equipment.

As soon as Possible Technical Orders. Technical Orders specifying "work to be accomplished as soon as possible and not later than the next .... inspection period" normally denote correction of defects affecting the flying or combat efficiency of aircraft which are not so urgent or dangerous as to require grounding of aircraft. This class of Technical Orders is printed on white paper with a border of red diagonals ( ). The red diagonals in addition to providing a distinctive identification correspond to the symbol ( ), used on the maintenance inspection records for airplanes to indicate a defect or unsatisfactory condition not sufficiently serious to render the aircraft unsafe or unfit for flight, but of such a nature that it must be corrected before the aircraft can be considered to be in first class mechanical condition.

Routine Technical Orders. This class of Technical Orders is printed on plain white paper. The following types of Technical Orders are included in this classification.

Technical Orders specifying "work to be done as soon as practicable," are those which can be accomplished within broader time limits, that is, whenever accomplishment will not interfere with flying schedules unless local conditions necessitate more urgent action, or when aircraft or equipment are in the depots and bases undergoing repairs or major overhaul. These Technical Orders normally denote conditions which are not necessarily serious, but which are essential to provide remedial action and to make sure that the required repairs will be made so as to forestall possible malfunctioning of equipment or failure of materials.

Technical Orders which provide **instructions for modification of equipment**, or installation of special equipment on selected aircraft, or equipment for the performance of special duties or missions, do not normally specify when the work is to be performed. Such special installations or modifications are not normally made to all equipment of the same model or series, and compliance is effected only upon issuance of additional instructions directing the work to be accomplished on equipment bearing specific serial numbers. Technical Orders of this nature contain a notation stating that the work will be accomplished "if necessary, when, and as directed by the Commanding General, Air Materiel Command."

The title of each Technical Order consists of three parts; namely, **the general title, the group title,** and **the subject title**.

The **general title** is that of the general AF property class of the equipment to which the Technical Order pertains.

The **group title** is a further natural grouping of related subjects under the general class.

The **subject title** indicates as precisely as possible the nature of the contents and the particular equipment or part to which the order pertains. As a complete example, the title for T.O. No. 16-5-53 would be "Communications Equipment" (General title), "Aircraft Radio" (Group title), and "Radio Compass SCR-269-( )-Resealing of Loops and Maintenance of Dehydrators" (Subject).

THIS PAGE IS DECLASSIFIED IAW EO 13526

Technical Orders are assigned numbers consisting of two or more parts separated by dashes. The numbers serve for identification, indexing, and filing. The first part of the number normally corresponds to the number of the AF property class covered. Thus, the number "16" is the first part of the number of all Technical Orders pertaining to Communications Equipment, AF property class 16. The "( )" series is established for indexes, for orders pertaining to the subject of publications, and for miscellaneous instructions that cannot be otherwise classified. The second part is a number assigned to identify all the Technical Orders pertaining to a particular subdivision (type, model, etc.) of the general property class covered. This second part of the number corresponds to the **group title** mentioned above. The third part consists of numbering in series, beginning with the number "1" in the order of issue, the individual Technical Orders of each subdivision of a general property class, a separate series of numbers being used for each subdivision.

A "Numerical Index of Technical Publications," published in loose-leaf form as T.O. 00-1, is reissued on 1 February of each year and at intervals during the ensuing twelve-month period. In addition, cumulative supplements to T.O. 00-1 are issued every two weeks.

The importance of Technical Orders as directive and informative media cannot be overemphasized. All USAF personnel must have a general understanding of the Technical Order System. Further, those concerned directly with the operation, maintenance, or inspection of USAF equipment must be conversant with the contents of each technical publication pertaining to that equipment. More complete information on these publications is contained in T.O. 00-5-1 "General Provisions—Explanation of Technical Order and Stock List System," and in T.O. 00-5-2 "Distribution of Technical Publications."

Stock Lists. Stock Lists are the official published item identification lists, arranged by property class, of active items of USAF equipment, supplies, and spare parts which the SAF stores and issues. Stock lists constitute the official media for directing the accomplishment of item identification changes by field supply and maintenance installations, and the official reference for classification and requisitioning information, and for establishing, maintaining, and reporting stock record data. Stock lists contain part numbers, standardized nomenclature, regulated item information, classification as to status in accordance with the provisions of AR 850-25, unit of issue, unit cost, and stock numbers of USAF property that is either in stock or being procured. Application of items, source of procurement, action directive phrases, authorization for local manufacture or local purchase, etc., is also included when applicable. In addition, illustrations and other pertinent information are included in Stock Lists of certain classes.

Dead Item Stock Lists are the official publications, arranged by property class, listing items of USAF property for which disposal action has been determined, and which serves as directions to field supply and maintenance activities for accomplishment of such action.

The **Part Number Index** is a numerical listing of part numbered items of USAF property indicating property classification to serve as a guide to Stock Lists and Dead Item Stock Lists.

Stock Lists are assigned basic numbers consisting of the AF property class symbol preceded by the letter "S" to avoid conflict with Technical Orders. Thus, the basic number of the Stock List for Class 16-A property, "Airborne Communication and Test Equipment," is "S-16-A." Dead Item Stock Lists are distinguished from the stock list (active) by suffixing the word "dead" to the basic number, e.g., "S-16A Dead." Part number Indexes are numbered "S-00-1."

Stock Lists, like Technical Orders, are filed in numerical sequence as listed in T.O. 00-1, "Numerical Index of Technical Publications," which includes an index of Stock Lists.

Publications of Other Agencies

Combined Communications Board Publications (CCBP). These publications are numbered pamphlets compiled by the Combined Communications Board, establishing operating procedures for combined use. (Definition of "Combined": Among all of the services of one nation and all the services of another nation, but not necessarily within a particular service of either nation or between the services of either nation.) CCBP-7 "Combined Communication Instructions" explains these publications in greater detail.

Joint Army-Navy-Air Force Publications (JANAP). These publications are numbered pamphlets compiled by the Joint Communications Board for joint use. (Definition of "Joint": Among all of the services of one nation, but necessarily within the services of that nation.) This series has been adopted as the medium for publishing a compilation of **Joint Communications Instructions** containing all existing agreements and such further agreement with respect to communications procedures as may be necessary to eliminate differences in Army, Navy, and Air Force.

3. USAF PROPERTY CLASSES

The USAF, as well as the Technical Services of the Army, subdivides its supplies into property classes for convenience of administration. There are approximately thirty USAF property classes. Each of these main classes are further subdivided into subclasses in order to group items of similar characteristics. AF Manual 67-1 is the basic supply publication.

Class 16—Communications Equipment

The communication officer should understand the general scheme of the AF property system and know the setup of class 16 property thoroughly, since the major portion of his supplies will be found in this class.

AF Property Class 16 consists of all items of radar and communications equipment, accessories and parts, which are stored and issued by the USAF. Class 16 is intended to include communications equipment peculiar to (i.e., used exclusively by, or of primary interest to) the USAF and all components and associated items of this equipment, even though some of these components and associated items may also be used in equipments not peculiar to the USAF. Accordingly, Class 16 supplies properly fall within the general category of AF supplies. Consequently, communications supplies which properly fall within the general category of Common Supplies are not normally listed in Class 16 Stock Lists. Such common items of communications supplies are procured, stored, and normally issued by the Signal Corps and are listed in the Department of the Army Signal Supply Catalog; hence, they are items of Signal Corps Property rather than USAF Property.

An appreciable number of common items, however, are included in AF Property Class 16 by virtue of the necessity for including all components, accessories, maintenance parts, and associated items of major equipments. Such components, accessories, and maintenance parts are often widely employed in communications equipments generally, as well as in those equipments peculiar to the USAF. Thus, a certain ground radio set may be used exclusively by Air Force Units; however, the transmitter or the receiver of that set may be used in one or several other sets which are used extensively by ground units of the Army. Many items of test equipment included are likewise employed generally, as are also many of the maintenance parts such as vacuum tubes, condensers, resistors, etc.

AF Property Class 16 is subdivided into six lettered subclasses as follows:

16-A Airborne Communications Equipment. This subclass includes all airborne communications equipment such as radar, radio, and countermeasures. Test equipments are also stocked in this subclass. Examples of included equipments are: electronic altimeters, communications countermeasures equipment, radio compasses, frequency meters, airborne radio sets, and test sets including special purpose test sets for airborne communications equipment and test sets whose general purpose application is restricted to airborne and ground communications equipment.

16-B Ground Radio Equipment. This subclass includes all ground, radio and navigational aids equipment peculiar to the United States Air Force, except ground radar. Examples are: ground radio navigational aids such as radio homing beacons and radio ranges, antenna systems, VHF fighter control systems, and other ground radio sets peculiar to the USAF. This class does not include those many ground radio sets used for general communications purposes by both the Army and Air Force. Because of such general usage, most of the Army radio sets are common supplies; therefore, they are not listed in Class 16; but are listed in the Department of the Army Signal Supply Catalog.

16-C Ground Radar Equipment. This subclass includes all ground radar sets and components, associated modification and improvement kits, and ground radar special test sets. Ground radar equipment includes aircraft warning sets, radar beacons, and other navigational aids such as GCA (Ground Controlled Approach), radar countermeasures equipment, ground interrogators for identification equipment, and other ground radar sets peculiar to the USAF. Note that this subclass, like 16-B, includes only ground components or equipments. Class 16-A, as noted before, includes the airborne sets and components.

16-D AF Installation Parts for Radar and Communications Equipment. This subclass includes all special purpose airborne-installation parts for radar and communications equipment whether or not designed for application to a specific aircraft. There are the installation parts for 16-A equipments: the various brackets, channels, plates, supports, etc., for mounting receivers, transmitters, dynamotors and other communications components used in airplanes. Also included are radomes and their retracting mechanisms, and chaff dispensers.

16-E Radio and Radar Maintenance Parts. This subclass includes all special purpose maintenance parts for equipment classified in subclasses 16-A, 16-B, and 16-C, as well as those general purpose items whose predominant USAF usage is for maintenance of radar and communications equipment. Examples of materials listed in this subclass are: bulk cable and wire (other than general purpose) capacitors, plugs, relays peculiar to radio and radar equipment, resistors, electronic tubes, transformers, and so forth.

16-F Radio Crystals. This subclass includes all types of quartz crystals for radio communications equipment.

4. COMMUNICATION INSPECTION AND MAINTENANCE

It is essential to successful Air Force operations that the communications system operate at peak efficiency at all times. In order for this to be acomplished, it is necessary that each communication officer operate an effective system of technical inspection and maintenance so that equipment failure may be reduced to a minimum.

There are only two kinds of equipment, two kinds of maintenance, two kinds of technical administration: **good** and **bad.** The purpose of inspection is to insure the **good** outweights the **bad** by a margin commensurate with the high ideals of the USAF mission.

Responsibility

Inspection is a command function. Commanders of each and every echelon of command are charged with the creation and maintenance of an efficient inspection system which will operate to assist materially in the discharge of such responsibility. Inspection, concerned primarily, as it is, with maintaining a high standard of efficiency, enables the command officer to ascertain the extent to which orders are enforced and is a means whereby the state of efficiency of commands may be determined. The mere creation and carrying on of an inspection system does not relieve a commanding officer of his responsibility for accomplishing efficient employment of men and materials. It is, however, an essential aid to the proper discharge of that duty.

Unit Supervision. Inspection is continuous. In an informal sense, it begins with the operator, or the person using the equipment or handling the material. He will consider this a portion of his duty rather than an inspection. Likewise, the section chief, in exercising his supervision of the operators and technicians in his section, conduct daily or weekly checks upon the performance of their operation and upkeep of the equipment used. The weekly inspection tours of the unit commanding officer are further examples of supervision within the unit involved. Although check lists probably will be kept, and such inspections are manifestly for the increased efficiency of the unit, they are not, by definition, inspections in the sense applied to the formal inspections made by air inspector personnel.

An inspection is an official examination of a military unit, facility, or activity made in the course of an inspector's prescribed routine to determine and report on the extent and degree of compliance with laws, regulations, orders or other standards, and on the condition of personnel and material.

Organization. Commanders of air forces, independent commands, subordinate commands, groups, air bases, and similar organizations organize under one head all air inspection activities and air inspection personnel assigned to their respective headquarters. The senior inspector is designated the air inspector of the command, subordinate command, group, base or other organization concerned. Adequate personnel qualified to examine, appraise, and report upon the efficiency and economy of administration, services, supply, maintenance, operations, training and other assigned functions of the activity are assigned to the office of the air inspector to conduct inspections. Inspection is the primary duty of such personnel.

Air inspectors and assistant air inspectors selected by commanders are assigned only with the approval of the next higher echelon of command.

Frequent and thorough inspection is imperative in order to maintain full and efficient control and employment of men and material at all times. Although the frequency of inspection is not limited, the following are considered the minimum requirements:

The Air Inspector, Headquarters, USAF, will conduct semiannual inspections of those command headquarters, reporting directly to Headquarters, USAF. One of these will be the annual general inspection. He must also conduct annual inspections of the headquarters of air forces operating outside the continental limits of the United States and of such subordinate echelons as the Chief of Staff, USAF, may deem necessary.

Each echelon below Headquarters, USAF, level down to and including groups, air bases, separate detachments, and comparable units and activities must be given a complete and formal inspection at least semiannually by an air inspector of a higher echelon of command. One of these inspections will be the annual general inspection.

The command of each air force and independent command will require his air inspector to make inspections of a sufficient number of subordinate echelons, including groups, air bases, and similar organizations, to keep informed concerning the efficiency and economy of operations of the command.

Inspection of air bases, operational satellite bases, groups and other comparable operating units by their own inspectors is a continuing process. Such inspections are made to assure coverage of all activities under the command jurisdiction of their respective headquarters at least once each month unless otherwise prescribed by regulations or by the Chief of Staff, United States Air Force.

Whenever practicable, inspections of lower echelons by wings and higher headquarters are made by inspection teams. Teams are composed of the necessary qualified specialists in order to cover adequately every phase of the activity. Air inspectors hold to a minimum any possible interference with the normal activities of the organization being inspected.

Policies. Whenever an inspection has been made, a written report is prepared. Such a report is in the form prescribed by the commander ordering the inspection.

Upon completion of the inspection, the air inspector discusses his findings and the data contained in his report with the commander and staff of the activity examined. In the discussion of matters to be reported upon, the air inspector affords the commander and his staff ample opportunity to present any modifying instructions from higher headquarters or other circumstances which may have a bearing on the statements to be included in the report. Prompt action will be taken by commanders on irregularities and deficiencies reported, both to correct the specific case and to prevent recurrences.

Supply and Maintenance Inspections. AF Regulations direct that supply and maintenance inspections be of such frequency and scope as to insure fulfillment of the broad overall responsibilities of commanding officers. The scope and detail of supply and maintenance inspection include every USAF technical phase or subject, and all subjects covered by technical publications which are pertinent to equipment furnished to, and maintained by the Air Force.

5. UNSATISFACTORY REPORTS

Importance and Use

The **unsatisfactory report** (UR) (AF Form No. 54) is a means whereby individuals in the Air Force may submit through channels reports of unsatisfactory conditions and recommendations to preclude recurrences.

The communications officer is in close touch with both the methods and machines which compose the great ground organization behind the personnel who fly. It should be borne in mind, however, that there is always room for improvement. Information concerning even the smallest failure may be of great value if reported to the proper authority in time. Everyone is encouraged to submit unsatisfactory reports whenever he sees an opportunity to contribute to greater efficiency by suggesting correction of faults.

Forwarding authorities are required by AF regulations to forward all unsatisfactory reports whether or not they concur in the originator's findings and recommendations.

The purpose of the unsatisfactory report system is to aid the Air Materiel Command in accomplishing its task of maintaining all AF equipment in its best operating condition. Unsatisfactory reports are, in effect, field reports on how AF equipment is standing up under the conditions for which it was intended. It is through these reports that AMC is able to bring about improvement in equipment before its delivery to combat areas, and fill in gaps in established maintenance procedures.

Unsatisfactory reports are required to be initiated by any individual assigned or attached to the Air Force upon the first, and all subsequent, observations of any of the unsatisfactory conditions mentioned below. It is extremely important that all failures of equipment be reported immediately. This includes repetitive failures since the number of failures reported often determines the action required. Commanding officers are required to insure that all personnel concerned are advised of the importance and use of these reports and the necessity for their prompt submission whenever any unsatisfactory conditions are described or encountered. It is the responsibility of the officer in charge of the office or activity where the unsatisfactory condition exists to insure prompt submission of an unsatisfactory report as prescribed in T.O. 00-35D-54.

If deemed necessary for expeditious processing of unsatisfactory reports, the base commanding officer may establish a central clearing office under the direction of the base maintenance officer for the supervision, preparation and submission of unsatisfactory reports.

A more specific and detailed study of UR's, their form and application in the field of communication will be considered later.

BIBLIOGRAPHY

The following bibliography, although not intended as definitive, should provide a representative cross section of material available in the field of communications. It is believed that the civilian references, with their supplemental bibliographies, will provide a sufficiently wide variety of references to afford adequate coverage of all subjects examined by this text. The military bibliography has been selected to illustrate the general scope of military publications which are available to the communications officer.

$$R_{EQUIV} = \frac{R_1 \times R_2}{R_1 + R_2}$$

2. A-c Circuits

a. CURRENT, VOLTAGE, IMPEDANCE.

$$E = I \times Z;\ I = \frac{E}{Z};\ Z = \frac{E}{I}$$

b. INDUCTIVE REACTANCE.

$$X_L \text{ (ohms)} = 2\pi fL$$

c. CAPACITIVE REACTANCE.

$$X_C \text{ (ohms)} = \frac{1}{2\pi fC}$$

d. IMPEDANCE.

$$Z \text{ (ohms)} = \sqrt{R^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2}$$

e. INDUCTORS IN SERIES.

$$L_{TOTAL} = L_1 + L_2 + L_3 + \ldots$$

f. INDUCTORS IN PARALLEL.

$$L_{EQUIV} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \ldots}$$

g. CAPACITORS IN SERIES.

$$C_{EQUIV} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \ldots}$$

h. CAPACITORS IN PARALLEL.

$$C_{TOTAL} = C_1 + C_2 + C_3 + \ldots$$

i. CONDITION OF RESONANCE.

$$X_L = X_C$$

$$2\pi fL = \frac{1}{2\pi fC}$$

j. RESONANT FREQUENCY OF A TUNED CIRCUIT.

$$f \text{ (cps)} = \frac{1}{2\pi\sqrt{LC}}$$

3. Radio Frequency

Frequency and wavelength relations:

$$\text{Wavelength (in meters)} = \frac{300{,}000{,}000}{\text{Frequency (in cycles)}}$$

$$\text{Frequency (in cycles)} = \frac{300{,}000{,}000}{\text{Wavelength (in meters)}}$$

4. Horizon Distance (optical line-of-sight)

a. Horizon distance can be calculated from the formula:

$$S = 1.42\sqrt{H}$$

where S is the distance in miles and H is the height of the observer's eyes in feet.

b. The table which follows gives the horizon distance for various heights of antenna above ground level.

Height of antenna above ground (feet)	[illegible]
5	3.2
20	6.4
50	10.0
100	14.2
500	32.0
1,000	45.0
2,000	63.5
3,000	78.0
5,000	100.0

5. Horizon Distance (radio line of sight)

a. $D = \sqrt{2h} + \sqrt{2H}$

where D = total distance in miles between transmitting and receiving antennas

h = height of transmitting antenna in feet

H = height of receiving antenna in feet.

SUMMARY OF FORMULAS

EXAMPLE OF AN NOMENCLATURE FOR A COMPLETE SET- RADIO SET *AN/ARC-6A

*AN COMPLETE SET	/	A AIRBORNE	R RADIO	C COMMUNICATION	—	6	A
ARMY-NAVY	SLANT	INDICATOR LETTERS		INDICATOR LETTERS		NUMBER	MODIFICATION LETTER

ARMY-NAVY

Indicating nomenclature is being applied to a complete set - not a component.

*UNITED NATIONS STANDARDIZATION.

A star,*, used as a prefix to a type number identifies the item as having been standardized by the Army or Navy and another United Nation.

SLANT

Assigned no meaning when preceded by AN.

INDICATOR LETTERS

INSTALLATION

A—airborne (installed & operated in aircraft)

C—air transportable (designed to be transportable as stated in specification or military characteristics)

F—ground, fixed

G—ground, general ground use (includes) two or more ground installations)

M—ground, mobile (installed as operating unit in a vehicle which has no function other than transporting the equipment)

P—ground, pack or portable (horse or man)

S—shipboard

V—ground, vehicular (installed in vehicle designed for functions other than carrying radio equipment, etc., such as tanks)

T—ground, transportable

U—general utility (includes two or more general installation classes, airborne, shipboard and ground)

TYPE OF EQUIPMENT

B—pigeon

C—carrier (wire)

F—photographic

G—telegraph or telephone (wire)

I—interphone and public address

M—meteorological

N—sound

P—radar

R—radio

S—special types (heat, magnetic, etc.) or combination of types

T—telephone (wire)

V—visual and light

X—facsimile or television

EXAMPLES OF AN TYPE NUMBERS

Type Number	Indicates
AN/ARC-3	Airborne radio communications set No. 3.
**AN/ARR-4*	Airborne radio receiving set No. 4, standardized by the Army or Navy and another United Nation.
AN/CRT-7 (XA-1)	Aircraft Radio Laboratory developmental model No. 1 of air transportable radio transmitting set No. 7.
AN/FPS-5-T1	Training set No. 1 for fixed radar search set No. 5.

PURPOSE

A—auxiliary assemblies (not complete operating sets)

C—communications (receiving & transmitting)

D—direction finder

H—recording (includes sound recording and picture taking equipment

G—gun directing

L—searchlight control

M—maintenance and test assemblies (including tools)

N—navigational aids (including altimeters, beacons, compass & instrument landing)

P—reproducing (includes sound reproducing and picture projecting equipment)

Q—special or combination of types

R—receiving

S—search and/or decting

T—transmitting

W—remote control

X—identification and recognition

NUMBER

The number following the set or equipment indicator letters designates a specific complete set.

MODIFICATION LETTER

Modification letters will be assigned for each modification not affecting interchangeability of the sets or equipments as a whole, except in some special cases they will be assigned to indicate functional interchangeability and not necessarily complete electrical and mechanical interchangeability.

The suffix letters X, Y and Z will be used only to designate a set or equipment modified by changing the input voltage, phase or frequency. X will indicate the first change, Y the second, Z the third, XX the fourth, etc., and these letters will be in addition to other modification letters applicable.

ADDITIONAL INDICATORS

Experimental Sets. In order to identify a set or equipment of an experimental nature with the development organization concerned, the following indicators will be used within the parentheses:

XA—Aircraft Radio Laboratory
XC—Camp Coles Signal Laboratory
XE—Camp Evans Signal Laboratory
XM—Fort Monmouth Signal Laboratory
XN—Navy
XO—Eatontown Signal Laboratory
XP—Army Pictorial Service
XR—NDRC — Division 14
XT—Toms River Signal Laboratory
XW—Watson Laboratories

Example: Radio Set AN/ARC-3( ) might be assigned for a new airborne radio communication set under development. The cognizant development organization might then assign AN/ARC-3 (XA-1), AN/ARC-3 (XA-2), etc., type numbers to the various sets developed for test. When the set was considered satisfactory for use, the experimental indicator would be dropped and procurement nomenclature AN/ARC-3 would be assigned thereto.

Training sets. A set or equipment designed for training purposes will be assigned type numbers as follows:

A set to train for a specific basic set will be assigned the basic set type number followed by a dash, the letter T, and a number. Example: Radio Training Set AN/ARC-6A-T1 would be the first training set for Radio Set AN/ARC-6A. A set to train for general types of sets will be assigned the usual set indicator letters followed by a dash, the letter T, and a number. Example: Radio Training Set AN/ARC-T1 would be the first training set for general airborne radio communication sets.

Summary of Joint Army-Navy Nomenclature System ("AN" System) For Communication and Associated Equipment.

EXAMPLE OF COMPONENT TYPE NUMBER: T-2B/ARC-6A

MEANING: T — **RADIO TRANSMITTER**

TABLE OF COMPONENT INDICATORS

Comp. Ind.	Family Name	Definations or Examples — Not to be construed as limiting the application of the component indicator to those items.
AB	Antenna Supports	Antenna mounts, mast bases, mast sections, towers, etc.
AM	Amplifiers	Power, audio, interphone, radio frequency, panoramic, etc.
AS	Antenna Assemblies	Complex: Arrays, parabolic type, masthead, etc.
AT	Antennae	Simple: Whip or telescopic, loop, dipole, reflector, etc.
BA	Battery, primary type	B-batteries, battery packs, etc.
BB	Battery, secondary type	Storage batteries, battery packs, etc.
BZ	Audible Signal Devices	Buzzers, Gongs, horns, etc.
C	Control Articles	Control box, remote tuning control, control unit, etc.
CG	R.F. Cables & Transmisson Line	R.F. cables, wave guides, etc. with terminals.
CK	Crystal Kits	A kit of crystal units.
CM	Compararators	Analyzes or compares two or more input signals.
CN	Compensators	Electrical & or mechanical compensating, regulating or attenuating apparatus.
CP	Computers	A mechanical & or electronic mathematical calculating unit.
CR	Crystal Units	Crystal in crystal holder.
CU	Coupling Units	Impedance coupling devices, directional couplers, etc.
CV	Converters (electronic)	Electronic apparatus for changing the phase, frequency, or from one medium to another.
CW	Covers	Cover, bag, roll, cap, radome, nacelle, etc.
CX	Cords	Cord with terminals, also composite cables of R.F. and non-R.F. conductors.
CY	Cases	Rigid and semi-rigid structure for housing or carrying equipment.
DT	Decting Heads	Magnetic pick-up device, search coil, etc.
DY	Dynamotors	Dynamotor power units.
F	Filters	Band-pass, noise, telephone, wave traps, etc.
FN	Furniture	Chairs, Desks, Tables, etc.
G	Generators (see PU)	Electrical power generators without prime movers.
GO	Goniometers	Gonimeters of all types.
GP	Ground Rods	Ground Rods, stakes, etc.
H	Head, Hand & Chest Sets	Also includes earphone unit.
HC	Crystal Holders (without crystal)	
HD	Air Conditioning Apparatus	Heating, Cooling, dehumidifying, pressure units, vacuum units, etc.
ID	Indicators	Azimuth, plan position, elevation, panoramic, calibrated dials & meters, indicating light, etc.
IL	Insulators	Strain, stand-off, feed-through, etc.
J	Junction Units	Junction, jack & terminal boxes; connector panels, etc.
KY	Keying Devices	Mechanical, electrical and electronic keyers, coders, interrupters, etc.
LC	Line Construction Tools	Includes special apparatus such as cable plows, hoists, etc.
LM	Illuminating Lamps and Bulbs	
LS	Loudspeakers	Separately housed loudspeakers.
M	Microphones	Radio, telephone, throat, hand, etc.
MD	Modulators	Device for varying amplitude, frequency or phase of alternating current.
MK	Maintenance Kits or Equipments	Radio, telephone, general utility, etc.
ML	Meteorological Apparatus	Barometer, hygrometer, thermometer, scales, etc.
MT	Mountings	Mountings, frames, stands, etc.
MX	Miscellaneous	Equipment not otherwise classified.
O	Oscillators	Master frequency, blocking, multivibrators, etc. For test oscillators see TS.
OA	Operating Assemblies	Operating units mounted together not otherwise covered.
PF	Pole Fittings	Cable hangers, clamps, etc.
PG	Pigeon Articles	Container, loft, vest, etc.
PH	Photographic Articles	Camera, projector, sensitometer, etc.
PP	Power Supplies	Non-rotating machine type such as vibrator pack, rectifier, thermo-electric, etc.
PT	Plotting Equipments	Exact meteorological. Boards, maps, plotting table, etc.
PU	Power Equipments	Rotating power equipment except dynamotors. Electric motors, combustion type engines, etc.

2	B	PART OF OR USED WITH	A	R	C	6	A
NO. & MOD. LETTER		SLANT	TABLE OF SET OR EQUIPMENT INDICATOR LETTERS			NO. MOD. LETTER	
Modification letters will be assigned for each modification when parts are no longer interchangeable. Different numbers will be assigned to components not electrically & mechanically interchangeable as a whole. The component will retain its original nomenclature even though later made part of other equipment.		Slant separates component and set designations. Indicates component is part of or used with the set or equipment designated.	Installation See Table I	Type of Equipment See Table I.	Purpose See Table I.	See Table I.	

EXAMPLES OF AN TYPE NUMBERS

Type Number	Indicates
R-10 CRN-8A	Radio receiver No. 10, part of or used with air transportable radio navigation set No. 8A.
C-11 VRC-T1	Control box No. 11, part of or used with training set No. 1 for general vehicular radio communications.
TK-4 GR	Tool kit No. 4 for general ground radio equipment, not part of a specific set.

Table of Component Indicators (Cont'd)

R	Radio & Radar Receivers	Radio or radar receivers, combined unit such as Receiver-Indicator, etc.
RD	Recorders & Reproducers	Tape, facsimile, disc, magnetic, etc.
RE	Relay Assemblies	Electric, Electronic, etc.
RF	Radio Frequency Units	Miscellaneous radio frequency apparatus.
RG	Bulk R.F. Cables & Transmission Line	R.F. cable, wave guides, etc. without terminals.
RL	Reel Assemblies	Antenna, field wire, etc.
RP	Rope & Twine	Non-electrical cord, etc.
RR	Reflectors	Target, confusion, etc. Except antenna reflectors. (see AT)
RT	Receiver and Transmitter	Radio and Radar transceivers, transmitter and receiver in one unit, etc.
S	Shelters	House, tent, protective shelter, etc.
SA	Switching Assemblies	Manual, impact, motor driven, pressure operated, etc.
SB	Switchboards	Telephone, fire control, power, panel, etc.
SM	Simulators	Flight, aircraft, target, signal, etc.
SN	Synchronizers	Equipment to co-ordinate two or more functions.
ST	Straps	Harness, straps, etc.
T	Radio & Radar Transmitters	Communications, range, marker beacon, interrogator, combined Transmitter-Modulator, etc.
TA	Telephone Apparatus	Miscellaneous telephone equipment.
TD	Timing Devices	Mechanical and electronic timing devices, etc.
TF	Transformers	Transformers when used as a separate units.
TH	Telegraph Apparatus	Miscellaneous telegraph apparatus.
TK	Tool Kits or Equipments	Miscellaneous tool assemblies.
TL	Tools	All types except line construction.
TN	Tuning Units	Receiver, transmitter, antenna, etc.
TS	Test Equipments	Test & measuring equipment including dummy antenna, pickup probes, etc.
TT	Teletypewriter & Facsimile Apparatus	Miscellaneous tape, teletype, facimile equipment, etc.
U	Audio & Power Connectors	Unions, plugs, sockets, adapters, etc.
UG	R.F. Connectors	Unions, plugs, sockets, choke couplings, adapters, elbows, flanges, etc.
V	Vehicles	Carts, dollies, trucks, trailers, etc.
VS	Visual Signaling Equipments	Flag sets, aerial panels, signal lamp equipment, etc.
WD	Two Conductor Cables	Includes non-R.F. wire, cable & cordage in bulk.
WF	Four Conductor Cables	Includes non-R.F. wire, cable & cordage in bulk.
WM	Multiple Conductor Cables	Includes non-R.F. wire, cable & cordage in bulk.
WS	Single Conductor Cables	Includes non-R.F. wire, cable & cordage in bulk.
WT	Three Conductor Cables	Includes non-R.F. wire, cable & cordage in bulk.

TYPE	FREQUENCY RANGE (Mc)	RATED TRANS OUTPUT (Watts)	TYPE EMISSION	TYPE MOD	FREQUENCY CONTROL	PRESET CHANNELS	INSTRUCTION BOOK	REMARKS
AN/CRC-2	100 to 156	8	voice	am	xtal	4	AN 16-30CRC2-2	For communication with aircraft. Provides for simultaneous reception on six frequencies, and at the same time; voice transmission on any one of four frequencies. Eight vertical half-wave antennas mounted in pairs on 50 ft. ply wood masts.
AN/CRN-5	100 to 156	90 105	tone voice	am	xtal	—	AN 16-30MRN2-2	Vertically polarized two course aural radio range equipment with station identification, periodic quadrant identification and simultaneous voice transmission.
AN/CRN-11	0.2 to 0.4	50	tone voice	am	mo or xtal	—	TM 11-1077	Loop type four-course radio range ground station. Transmits tone modulated signal, using A-N keying, to provide courses for aircraft.
AN/MRC-1	trans. (incl. ampl.) 2.0 to 13.0 trans. (less ampl.) 2.0 to 18.0 2 receivers, 1.5 to 18.0	2000 400 300	cw cw voice	am	mo or xtal	—	TM 11-602	Ground, mobile; provides facilities for high power, high-speed automatic c-w transmission and reception employing Boehme equipment in addition to the normal functions of Radio Set SCR-399. The radio transmitter power amplifier and one radio receiver are housed in the transmitting Shelter HO-17, with three radio receivers and the Boehme equipment housed in the operating Shelter HO-17 or HO-27. Requires three 2½-ton, 6 x 6 cargo trucks for transportation. 15-ft. whip or half-wave doublet antenna.

Characteristics of Ground Radio Equipment

TYPE	FREQUENCY RANGE (Mc)	RATED TRANS OUTPUT (Watts)	TYPE EMISSION	TYPE MOD	FREQUENCY CONTROL	PRESET CHANNELS	INSTRUCTION BOOK	REMARKS
AN/MRC-2	trans. 2.0 to 18.0 rec. 1.5 to 18.0	2000 (incl. ampl.) 400 (less ampl.) 300 (less ampl.)	cw & special cw voice	am	mo or xtal	—	TM 11-624	Ground, mobile; provides a single - channel radio - teletype system using carrier-shift keying and dual space-diversity reception in addition to the normal facilities of Radio Set SCR-399. Equipment housed in three shelters HO-17 or HO-27. Frequency range of 2 kw power amplifier is 1.0 to 18.0 Mc. Frequency Conversion Kit MC-509 gives transmitter coverage down to 1.0 Mc. Half-wave doublet antenna.
AN/TRC-1	70 to 100	50 or 10	voice	fm	xtal	—	TM 11-2601	For single channel, or multi-channel operation with spiral-four carrier terminal equipment. High or low power by switch control. Three element directional array on 40 ft. mast.
AN/TRC-3	70 to 100	50 or 10	voice	fm	xtal	—	TM 11-2601	Radio terminal set *similar to AN/TRC-1* except has sufficient equipment to insure continuous service. High or low power by switch control. Three element directional array on 40-ft. mast.
AN/TRC-4	70 to 100	50 or 10	voice	fm	xtal	—	TM 11-2601	Radio relay set *similar to AN/TRC-1* except has sufficient equipment to insure continuous service as a repeater station. High or low power by switch control. Three element directional array on 40-ft. mast.

Characteristics of Ground Radio Equipment

THIS PAGE IS DECLASSIFIED IAW EO 13526

TYPE	FREQUENCY RANGE (Mc)	RATED TRANS OUTPUT (Watts)	TYPE EMISSION	TYPE MOD	FREQUENCY CONTROL	PRESET CHANNELS	INSTRUCTION BOOK	REMARKS
AN/TRC-2	2.0 to 3.4 and 3.8 to 6.5	20/10* 7/5* 7/5*	cw tone voice	am	mo or xtal	—	TM 11-2603	Two receiver-transmitters for use by isolated units. Quarter-wave inverted L antenna with counterpoise or half-wave antenna without counterpoise. Lower values of power than those indicated may be obtained by switch control.
AN/TRC-5	1350 to 1500	200	voice	pulse	magnetron	—	TM 11-626	Radio terminal or relay set. Provides simultaneous two-way communication on eight voice frequency channels. Parabolic reflector type antennas.
AN/TRC-6	4300 to 4900	2	voice	pulse	klystron	—	TM 11-632	Radio terminal or relay set. Provides simultaneous two-way communication on eight voice frequency channels. Parabolic reflector type antennas.
AN/TRC-7	100 to 156	0.5	voice	am	xtal	2	TM 11-617	Transportable; light weight radio set, transportable by a 4-man team. Quarter-wave whip, or vertical broad-band antenna on 30 ft. mast.

*When two values of power are shown separated by a slant bar (/), the higher value in general applies to ground, transportable, and vehicular operation; the lower value to pack operation.

Characteristics of Ground Radio Equipment

RESTRICTED

TYPE	FREQUENCY RANGE (Mc)	RATED TRANS OUTPUT (Watts)	TYPE EMISSION	TYPE MOD	FREQUENCY CONTROL	PRESET CHANNELS	INSTRUCTION BOOK	REMARKS
AN/TRC-8	230 to 250	12	voice	fm	mo (temp. compensated)	—	TM 11-618	For single channel or multi channel operation with spiral-four carrier terminal equipment. Half-wave dipole and 90 corner reflector on 40 ft. mast.
AN/TRC-11	230 to 250	12	voice	fm	mo (temp. compensated)	—	TM-11-618	Radio terminal set SIMILAR TO AN TRC-8 except has sufficient equipment to insure continuous service. Half-wave dipole and 90 corner reflector on 40 ft. mast. mast.
AN/TRC-12	230 to 250	12	voice	fm	mo (temp. compensated)	—	TM-11-618	Radio relay set SIMILAR TO AN TRC-8 except has sufficient equipment to insure continuous service as a repeater station. Half-wave dipole and 90° corner reflector on 40 ft. mast. on 40 ft. mast.
SCR-188-A	trans, 1.5 to 12.5 rec. 1.5 to 18.0	75	cw tone voice	am	mo	—	TM 11-233	Ground, transportable: for semi-fixed use arranged for remote control; 1/4 or 3/4 wave inverted L antenna with counterpoise. Transported by vehicle or cargo aircraft.
SCR-277	trans. 0.2 to 0.4 rec. 1.5 to 18.0	810	cw tone voice	am	mo	—	AN 16-10-10	Mobile, loop type four-course radio range ground station. Transmits tone modulated signal, using A-N keying, to provide courses for aircraft navigation.

Characteristics of Ground Radio Equipment

Characteristics of Airborne Radio Equipment

TYPE	AN/CPS-1 EW, Air-trans	AN/CPS-4 Mobile, air-transportable height finder	AN/CPS-5 Air-Transportable EW, Mobile (when Modified)
WEIGHT (tons)	66	15	19
MAX. RANGE (miles)	210	80	200
FREQUENCY (Mc)	2700-2900	2700-2900	1280-1350
PULSE-LENGTH (MICRO-Sec.)	1	.9	4
PEAK POWER (Kw)	700	750	250-500
ANTENNA TYPE	Parabolic cylinders fed by linear dipole arrays.	Elliptical section of a paraboloid fed by a waveguide horn. (Beavertail)	Parabola mounted on 25' tower
POLARIZATION	Lower beam—Vertically High beam—Horizontally	Horizontal	Horizontal
ANTENNA GAIN		Approx. 3500	1000
BEAM WIDTH Azimuth Elevation	0.8 degree 3.0 degrees	4.8 degrees 1.2 degrees	2 degrees 9 degrees
INDICATORS A PPI B RHI J	Standard No. / Max. No. 1-5" 5-12" / 12-12" 5-7" / 8-7"	2-5" 2-12" 1-12"	1-5" 2-12"
ACCURACY Range Azimuth Elevation	½ mile ½ degree None	1 Mile .24 degrees	1 Mile 1 Degree None
SHELTERS	4 Jamesway	2 Jamesway	4 Jamesway or 2½ ton trucks for mobile operation
ASSEMBLY TIME	3 days, 90 men	24 hours, 30 men	24 hours, 30 men
ADVANTAGES	High traffic handling capacity, good continuity of plotting, good low and high angle coverage, freedom from siting difficulties		Very mobile
LIMITATIONS	Heavy. No height-finding provision		No height-finding provision
REMARKS	Modified it becomes the AN/CPS-5 mounted on 11 vehicles. When used with a height-finder forms a good ground control radar	Adaptable as a height-finder to almost all of the heavy search radars such as the AN/CPS-1	

Characteristics of Ground Radar Equipment

TYPE	AN/CPS-6 Air-trans. - long-range EG GCI and general traffic control	AN/TPS-1 Transportable, LWEW long-range search	AN/TPS-10 Transportable Height-finder
WEIGHT (tons)	145	2½	2½
MAX. RANGE (miles)	210	175	60
FREQUENCY (Mc)	2700-3019	1220-1280	9090 (3Cm)
PULSE-LENGTH (MICRO-Sec.)	1		
PEAK POWER (Kw)	750	600	80
ANTENNA TYPE	2 parabolic set at 45° to each other	Dipole in 4 zone of 15' paraboloid	Cut paraboloid reflector.
POLARIZATION	Horizontal	Horizontal	Vertical
ANTENNA GAIN	10,000, 4800, 2200, 3800 & 2500	560	17,000
BEAM WIDTH Azimuth Elevation	1.0 degree 0.7 degree	3 degrees 11 degrees	2.0 degrees 0.7 degree
INDICATORS A PPI B RHI J	Standard No. / Max. No. 8-12" / 12-12" 5-7" / 10-7" 4-12" / 6-12"	1-5" 1-7"	1-3" 1-7"
ACCURACY Range Azimuth Elevation	½ mile ½ mile 500'	1 mile 3 degrees	1 mile 500' at 50 miles
SHELTERS	5 Jamesway	10 cubical tent	10 cubical tent
ASSEMBLY TIME	1 week—90 men	30 minutes, 6 men	3 hours, 6 men
ADVANTAGES	Furnishes three dimensional data on targets	Portability, can be hand carried	Portability
LIMITATIONS	Heavy	No height-finding provision, not designed for continuous operation.	Limited range
REMARKS	Characterized by high traffic handling capacity, good low angle coverage. High resolution with good accuracy.	Good for presiting heavy- search radar sets.	Finds height by means of a narrow pencil-like Beavertail beam.

Characteristics of Ground Radar Equipment

TYPE	SCR-270 Mobile, EW	SCR-527 Mobile, EW GCI	SCR-584 Gun-laying Mobile, TC
WEIGHT (tons)	41.5	45	10
MAX. RANGE (miles)	150	150	70,000 yards
FREQUENCY (Mc)	106	209	3,000
PULSE-LENGTH (MICRO-Sec.)			
PEAK POWER (Kw)	100	150	300
ANTENNA TYPE	Dipoles & Reflectors	Dipoles and Wire screen reflectors—Separate antennas for receiver and transmitter.	Rotating dipole in 6 Paraboloid Reflector
POLARIZA-TION	Horizontal	Horizontal	Horizontal
ANTENNA GAIN	140	60	1200
BEAM WIDTH Azimuth Elevation	28 degrees 10 degrees	12 degrees 24 degrees	4 degrees 4 degrees
INDICATORS A PPI B RHI J	1-5 1-12	1-12 1-12	1-7 2-3
ACCURACY Range Azimuth Elevation	1 Mile	½ mile 2 degrees 1000	15 yds. .6 mils. .6 mils.
SHELTERS	2 vans, 1 stake body truck, antenna trailer.	2 vans 2 antenna trailers	1 van
ASSEMBLY TIME	3 hours, 15 men	4 hours, 30 men	2 hours, 10 men
ADVANTAGES	Designed for continuous operation	Good medium and high angle coverage	Automatic tracking
LIMITATIONS	Heavy, no height-finding provision, low traffic-handling capacity.	Critical to site, low traffic-handling capacity	Low traffic handling capacity
REMARKS			

Characteristics of Ground Radar Equipment

SET NUMBER	AN/CPN-1	AN/CPN-3	AN/CPN-6	AN/CPN-8	AN/PPN-2	AN/TPN-1

WEIGHT (lbs.)	265	1013	2107	1200	33	167
FREQUENCY	3267-3333	3256	9310	3256	214-234	214-234
RANGE	Line of sight 100	Line of sight	Line of sight	100	28 miles Antenna Height 28'	50 miles
PEAK POWER		10 kw	25 kw	3 kw	8-20 watts	15 watts
ANTENNA TYPE	Linear array of 6 circular dipole units on a common vertical shaft. Omnidirectional.	Linear array of 6 triple-dipoles on 21' 3" mast. Separate Rec. & Transmitter ant.	Linear array of 12 slotted wave-guide elements. Both Rec. and Transmitter ant.	Linear array of 14 triple dipoles. Separate Antennas for Trans. & Rec.	Antenna rod mounted on 9½-foot collapsible mast.	12 inch Quarter-wave antenna fed by coaxial cable.
CODING TYPE	Reply Constant and pulsating.	Reply Range	Reply Range	Reply 6 code pips give range-coded reply.	Reply Pulse Length	Reply Morse code
PULSE LENGTH (micro-seconds)		0.5	0.5	0.5-0.6	6 to 12 narrow 12 to 24 wide	8 to 10 or 15 to 20
REMARKS:	Used to provide Navigational and homing aid for aircraft equipped with S-band radar.	Uses same as AN CPN-1.	Used in conjunction with aircraft equipped with 3-cm radar.	Designed to provide range, direction and identification for guidance of aircraft equipped with 10-cm radars.	Commonly called (EUREKA) used with planes equipped with Rebecca interrogators.	Same as AN PPN-2

Characteristics of Radar Beacons

SET NUMBER	AN/TPN-2	AN/UPN-1	AN/UPN-2	YJ-1 (NAVY)
TYPE	Transportable responder beacon	Ultraportable responder beacon	Ultraportable responder beacon	Ground or ship-based responder beacon
WEIGHT	110 lbs.	87	100	100
FREQUENCY (Mc)	214-234	3256	3256	171-181 510-530
RANGE	Line of sight	Line of sight	Line of sight	100
PEAK POWER	50 to 100 watts	50 watts	50 watts (min.)	15 to 150 watts
ANTENNA TYPE	Quarter wave dipole about 11½" long, mounted above a 4-section counterpoise made of 12" rods.	Duplex linear array of six triple-dipoles for transmitting and six for receiving.	Duplex linear array: Six triple-dipoles for receiving, six for transmitting.	2 vertically stacked folded dipoles on a 21' mast for high frequency, 1 for low frequency.
CODING TYPE	Interrogation and reply - Any combination of 2 Morse-code letters.	Reply Range	Reply Range	Reply Gap, any 1 or 2 letters of Morse code.
PULSE LENGTH	10-20	0-6	0.5	10
REMARKS:	Homing beacon for co-operation with Rebecca installation especially for parachute supply missions.	Installation on ground and on ships for use by paratroops.	Beacon answers interrogation by airborne, ship, or ground S-band radars.	Used as a navigational aid to airplanes equipped with search radars that operate on the frequency bands of 171-181 and 510-130.

Characteristics of Radar Beacons

SET NUMBER	AN/CPX-1 (CPX-2)	RC-150	SCR-695
TYPE	Interrogator responsor	Interrogator responsor	Airborne transponder
WEIGHT	5800 lbs.	755 lbs.	44 lbs.
FREQUENCY	157-187	157-187	157-187
RANGE	200	200	Line of sight
ANTENNA TYPE	Dipoles and screen reflectors	Two dipoles with reflectors	Quarter-wave antenna mounted on underside of fuselage.
REMARKS	This system interrogates transponders installed in aircraft from all of which a coded reply is displayed on control-unit A-scope.	Used to interrogate airborne transponders from all of which coded reply is displayed on associated radar scope.	Receives pulses from the interrogator, is tripped into operation and retransmits coded pulses back to original interrogator in the form of the code of the day.

RADIOLOGICAL DEFENSE COURSE FOR SURVEY AND MONITOR PERSONNEL

HEADQUARTERS, CONTINENTAL AIR COMMAND
MITCHEL AIR FORCE BASE, NEW YORK

Subject course is published for the information and guidance of all concerned.

BY COMMAND OF LIEUTENANT GENERAL WHITEHEAD:

CHARLES T. MYERS
Major General, U. S. Air Force
Acting Vice Commander

OFFICIAL:

Neal J. O'Brien

NEAL J. O'BRIEN
Colonel, USAF
Adjutant General

TABLE OF CONTENTS

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

NOTES TO INSTRUCTORS

1. The attached course has been prepared for the purpose of training Officers and Noncommissioned Officers to function as unit radiological defense personnel capable of performing survey officer and monitoring duties.

2. Airmen should possess a high school education and have a minimum AGCT level of 90 as prerequisites to attendance. An individual obviously unfitted for the course should be dropped, as he will impede instruction.

3. Graduates of one of the Armed Services Radiological Defense Schools are the only individuals qualified to present the bulk of this instruction. Certain individuals, without such training, but with specialized training in a particular field may present the portions dealing with medical aspects, classical physics and nuclear physics.

4. Course material has been developed to present the maximum amount of material possible in a short time. It is recommended, therefore, that the course outline and subject material be presented, essentially, verbatim. A lesser amount of instruction is not deemed adequate to train individuals effectively in radiological defense duties.

5. Lecture outlines are complete with the exception of those periods devoted to monitoring field problems. Local variations in availability of instruments, radium sources and training facilities make it desirable that these periods be left to local instructors for detailed preparation. The instructor should spend at least two hours in preparation for each hour of instruction in order that students' questions may be answered promptly, accurately and simply. The charts which are included with each subject outline are considered an integral part thereof. Local reproduction of these charts is desirable but, if impractical, they can be reproduced on a blackboard with a minimum of effort.

6. Considerable simplification of highly involved phenomena has been employed in the interests of easier teaching. This simplification has impaired strict scientific accuracy, in a few instances, but this is felt permissible for the scope of training envisioned.

7. Adequate facilities are essential for the conduct of this course. These include a classroom with student tables, facilities for evening study by students, a level, secluded area or well-lighted building for calibration work and a restricted area for survey exercises.

8. It is recommended that the theory of calibration and instrument operation be taught during the interim period pending the procurement and distribution of radiation sources and detection instru-

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

ments. The practical application and field problems for this training will of necessity have to be postponed until such time as the required materiel is available.

9. It is recommended that each student's final grade be based on a composite score tabulated as follows:

Item	Maximum Number of Points
General Attitude	10
Exam I	45
Preparation of Calibration Curve (Tng Outline 12)	5
Calibration of 263A Survey Meter (Tng Outline 16)	5
Calibration of 247A Survey Meter (Tng Outline 18)	5
Survey Exercise w/263A (Tng Outline 23)	5
Survey Exercise w/247A (Tng Outline 24)	5
Exam II	20
TOTAL	100

An individual scoring less than 70 should not be considered as successfully completing the course. Successful students should be awarded a suitable certificate.

SCHEDULE

FIRST DAY

0800-0850	Tng Outline 1	Class Organization (Administrative Time)
0900-0950	Tng Outline 2	Introduction and History
1000-1050	Tng Outline 3	Atomic Particles. Structure of Matter
1100-1150	Tng Outline 4	Electro-magnetic Radiation & Radioactivity
1300-1350	Tng Outline 5	Nuclear Reactions, Atomic Fission and Chain Reactions
1400-1450	Tng Outline 6	Explosion Phenomena
1500-1550	Tng Outline 7	Effects of the Atom Bomb on the Human Body
1600-1650	Tng Outline 7	" " " " " " " " "

SECOND DAY

0800-0850	Tng Outline 8	Review of Basic Arithmetic
0900-0950	Tng Outline 9	Practice on Assigned Mathematical Problems
1000-1050	Tng Outline 10	Logarithms & Calculation of Multiple Half-Life Decay
1100-1150	Tng Outline 11	Preparation of Instrument Calibration Curves
1300-1350	Tng Outline 12	Student Preparation of Instrument Calibration Curves
1400-1450	Tng Outline 13	Principles of Radiation Detection Instruments
1500-1550	Tng Outline 14	Operation of 263A G-M Survey Meter
1600-1650	Tng Outline 14	" " " " " "

THIRD DAY

0800-0850	Tng Outline 15	Examination I
0900-0950	Tng Outline 15	" "
1000-1050	Tng Outline 17	Operation of 247A Ion Chamber Survey Meter
1100-1150	Tng Outline 19	Radiation Dosimetry
1300-1350	Tng Outline 16	Student Calibration of 263A Survey Meters
1400-1450	Tng Outline 16	" " " " " "
1500-1550	Tng Outline 16	" " " " " "
1600-1650	Tng Outline 20	Monitoring Techniques

FOURTH DAY

0800-0850	Tng Outline 18	Student Calibration of 247A Survey Meters
0900-0950	Tng Outline 18	" " " " " "
1000-1050	Tng Outline 18	" " " " " "
1100-1150	Tng Outline 21	Individual and Collective Protection
1300-1350	Tng Outline 23	Monitoring Field Problem - 263A Survey Meter
1400-1450	Tng Outline 23	" " " " " "
1500-1550	Tng Outline 23	" " " " " "

TRAINING OUTLINE NO: 2

LECTURE: Introduction and History.

TIME: One (1) hour.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: None.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Projector, Screen, Film "Operations Crossroads" (Misc No. 1323, running time 31 minutes).

1. When the numbered air forces, presently assigned to the Continental Air Command, instituted their post-war chemical training programs, it was generally recommended that only the best qualified commissioned officers and airmen be detailed as unit gas officers and noncommissioned officers. Security considerations at that time precluded giving full reasons for that recommendation, but plans had been drawn for the training of unit gas personnel in radiological defense and biological warfare defense. It was and is considered imperative that personnel of the highest calibre be selected for training in defense against these new modes of warfare. The fact that you are here has placed a grave responsibility on you with respect to your commanding officer and the Continental Air Command as a whole.

2. This course is the "Radiological Defense Course for Survey and Monitor Personnel". Its object is to train radiological survey officers and monitors to be capable of using instruments to detect dangerous radioactivity and qualify these personnel to advise and assist the unit commander in defense against atomic attack. This will be in addition to present gas defense duties. In a tactical situation, effective defense will depend to a great degree upon the recommendation for action given to the unit commander.

3. This course will explore the atom and what goes on inside the atom. It will describe how the atom bomb works, what occurs during atomic fission and what the A-bomb can do to the human body and to buildings. Intensive training will be given in the use of instruments to detect dangerous radioactivity resulting from atomic explosions. And finally there will be instruction in the defensive measures to be taken to minimize casualties in an atomic attack.

4. The work with radiation detection instruments is the essence of the course. Thorough training in the use of these instruments is imperative for an area heavily contaminated with radioactive products looks just like any other terrain. The danger cannot be seen, heard,

[redacted]

1559

[redacted]

felt, tasted or smelled; it is only by the use of instruments that it can be detected and the necessary measures taken to prevent casualties.

5. This course requires certain simple calculations. This is not a course in mathematics but approximately five hours will be spent in the basic problems of calculation.

6. The need for trained men in this field is urgent; it is no secret that the United States will not always hold its present monopoly on the atomic bomb. Unofficial guesses on the time we have before another major power develops the bomb, range from one to ten years.

7. With reference to security, no "TOP SECRET" material will be presented in this course. Portions of the material are classified as restricted and other sections are not classified at all.

8. A security classification used by the Atomic Energy Commission is that of "RESTRICTED DATA". It is applied to highly classified information about the atomic bomb and atomic energy; it is an Atomic Energy Commission classification, not military, although it may be found in military correspondence. The point to remember is that "RESTRICTED DATA" applies to information of the highest classification, and and must never be confused with the military classification of "RESTRICTED". "RESTRICTED DATA" is to be safeguarded as "TOP SECRET" matter.

9. As an introduction to Radiological Defense, the film, "Operation Crossroads", taken at the Bikini tests in 1946, will be shown. The film gives some idea of the forces against which we must defend ourselves. Besides the blast and the flame, close inspection will show a battleship standing right up on its stern. What is not visible is the flash of deadly radiation - it can kill at a mile at the moment of the burst, or be poisonously radioactive material that is thrown up in the mushroom-shaped atomic cloud, and which is carried downwind to fall invisibly on land and sea, creating a danger for miles. At times in this course the material presented may be slightly at variance with some of the techniques shown in this film. This is due to the fact that Operation Crossroads was a scientific test conducted under conditions differing from combat. In addition, many new developments have occurred since this film was made.

10. There are many precautions to be taken to protect a military unit against the blast of an atomic bomb, but a very important part of the work will consist of being able to detect the "fall out" of radioactive material from the atomic cloud and to take proper action when such contamination is detected.

(FILM, "OPERATION CROSSROADS" WILL BE SHOWN)

TRAINING OUTLINE NO:	3
LECTURE:	Atomic Particles. Structure of Matter.
TIME:	Fifty (50) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	Paragraph 2.01, 2.05, 2.07, 5.01-6.01, 6.09, Radiological Defense Manual, Vol 1; Page 12-18, "All Hands", 1 July 1946, Navy Department; Chapter 1, "Atomic Energy for Military Purposes", Smyth; Chapters 1, 2, 3, 4, 11, 12, 13, "General Chemistry" Deming; Chapters I, XXI, XXII, "Outline of Physical Chemistry", Getman and Daniels; Paragraphs 14, 15, 16, 19, 22, 27, 28, 35, 39, 117, 91, 61, "Introduction to Atomic Physics", Semat. (See Footnote*)
STUDENTS' REFERENCES:	Page 12-18, "All Hands", 1 July 1946, Navy Department.
TRAINING AIDS REQUIRED:	Charts appended hereto.

1. Development of the atomic bomb was made possible by an understanding of the minute particles which are the building blocks of all matter. To understand the reason why an atomic bomb works and what results from its detonation requires some knowledge of these particles. It is necessary to know what an atom is, how it is constructed, how it is fissioned (or split), and the results of such a step. While somewhat complicated at first sight, the answers are neither impossible to understand nor difficult to comprehend.

2. The many different kinds of matter which compose the universe are called compounds. Each compound is identified as such by its own characteristic molecule. In other words a molecule is the smallest portion of a compound which can exist and still be that compound. Table salt, a compound called sodium chloride, might be used as an example.

*Chart 3-7 is included for possible use by the instructor. Its purpose is to illustrate the manner in which all matter is built up.

[redacted]

Suppose we take some table salt and divide it into successively smaller portions. This process could not go on indefinitely, even if we had the proper tools to work with smaller and smaller quantities, since we would reach a point finally where we would have only one molecule of sodium chloride left. This particle would be very small indeed since about one billion of them, laid side by side in a straight line, would only cover one inch. It would still be sodium chloride however and identifiable by chemical analysis, as such.

3. There are about 200,000 different kinds of molecules found in nature and over 500,000 additional kinds have been prepared in the laboratory; making a total of approximately 700,000 compounds known to science today. This figure is very large and if a chemist had to study each separately, his science would be very complicated. This is not necessary, however, because all 700,000 different molecules are combinations of less than one hundred elements. These elements will be considered next.

4. In the example cited above, sodium chloride was broken down to a point where only one molecule was left. Going a step farther and making one more subdivision produces a totally different result. Now the two parts are no longer sodium chloride but one is a substance called sodium, while the second is called chlorine; the table salt exists no longer. These substances, sodium and chlorine, are two elements. There are only 92 elements occurring in nature and these elements are substances which ordinarily cannot be broken down in the chemical laboratory. Some of the more common elements which are found free (i.e., not combined chemically with other elements) in nature are carbon, nitrogen, oxygen, iron, gold, sulfur and silver. If we take a lump of pure silver and carry out the subdivision process that was applied to the molecules of sodium chloride, a point is reached where only one atom of silver is left. This atom of silver is the smallest particle of silver which can exist and still be silver. What happens when this atom of silver is divided will be discussed later.

5. Atoms are the building blocks of chemistry and are the "particles" from which molecules are built. Thus, one atom of sodium combines with one atom of chlorine to form one molecule of sodium chloride which we know as table salt. This may be shown as:

> 1 atom of sodium plus 1 atom of chlorine yields 1 molecule of sodium chloride (table salt)

or as it is written:

$$Na \quad Cl = NaCl$$

Likewise, two atoms of hydrogen combine with one atom of oxygen to form one molecule of water. This is shown as:

[redacted]

1562

2 atoms of hydrogen plus 1 atom of oxygen yields 1 molecule of water

or

$2 H_2 \; O_2 = 2H_2O$

6. By the year 1919, the existence of 92 elements was known to scientists. The atoms of these 92 elements were thought to be the basic indivisible particles of matter at that time, and the method whereby atoms of these elements combined to form molecules was well understood. It was somewhat of a shock to scientists at large, therefore, when Rutherford found that atoms were divisible and constructed from smaller and still more fundamental particles. With the discovery of fission, four (4) new elements have been added and now there are a total of 96.

7. Before we study these new particles it might be well to point out that the 92 elements which are listed on the sheets distributed,

(INSTRUCTOR - PASS OUT COPIES OF CHART 3-1)

are still the building blocks of modern chemistry and engineering. To break down the atoms of these elements into the really "basic" particles of matter lies outside the field of the modern chemical laboratory and is possible only through use of the giant cyclotrons and other machines of the nuclear physics laboratory. With that point in mind it is now time to investigate the structure of the atoms.

8. Atoms can be compared to miniature solar systems with a heavy central sun which is called the nucleus. This central nucleus if made up of one or more particles which we call protons and, with the single exception of the common hydrogen atom, one or more particles which we can call neutrons. Around the nucleus revolve very much smaller particles called electrons. These three particles; the electron, the proton and the neutron, are the basic particles of matter from which all atoms are constructed.

9. Each of the 92 different atoms is made up of a combination of electrons, protons, and with one exception, neutrons. Thus a generalized picture of the atom may be illustrated by the following diagram:

(INSTRUCTOR - REPRODUCE CHART 3-2)

10. The general properties of these particles may be summed up as follows:

a. The proton is a particle of matter which has a unit

[redacted]

positive electrical charge and is so small that 20,000,000,000.000,000,000,000 of them would weigh only one ounce.

b. The neutron is a particle of matter which is electrically neutral and very slightly heavier than the proton.

c. The electron is a particle of matter which has a unit negative electrical charge equal in magnitude to the unit positive electrical charge of the proton but is only $\frac{1}{1840}$ as heavy.

(INSTRUCTOR - REPRODUCE THE FOLLOWING TABLE AS THE ABOVE INFORMATION IS PRESENTED)

Particle	Relative Weight	Electrical Charge
Proton	1	Plus 1
Neutron	1	Zero
Electron	1/1840 (Practically zero)	Minus 1

11. The chemical nature of each of the 92 elements is determined by the number of protons in the nucleus of its atom. Thus the Hydrogen atom contains one proton in its nucleus, the Helium atom two protons, the Lithium atom three and so on up to the 92nd element, Uranium, which has 92 protons in its nucleus. Since each atom as a whole is electrically neutral, the plus one charge of each proton must be balanced by an electron containing a minus one charge, and there is one orbital electron present for each proton in the nucleus. Thus the Hydrogen atom has one orbital electron the Helium atom has two orbital electrons, the Lithium atom has three orbital electrons and the Uranium atom 92 orbital electrons. Neutrons are present in the nucleus to the extent of slightly more than a 1 to 1 ratio with protons. By this, we mean that while a Helium atom has two protons and two neutrons in its nucleus, the number of neutrons per proton increases in the larger nuclei so that a Uranium atom is found to have 92 protons and 143 neutrons in its nucleus. Over the entire range the ratio is slightly more than 1 to 1.

12. Elements are assigned atomic numbers in accordance with the number of protons in their respective nuclei. Thus Hydrogen has an atomic number of one, Helium of two and so on. In addition, each element has an assigned mass number. How these mass numbers are arrived at will be taken up later. The difference between this mass number and the atomic number of an element gives the number of neutrons present in the nucleus. An example is Oxygen which has a mass number of 16 and an atomic number of 8. The atomic number of 8 tells us that there are 8 protons in the nucleus. It tells us also that there are 8 orbital electrons. By subtracting the atomic number of 8 from the mass number of 16 we obtain the difference.

[redacted]

1564

[redacted]

8, and this tells us that there are 8 neutrons in the nucleus.

13. Isotope is a word much used today. To explain its meaning we must dig deeper into the details of atomic structure. In the example quoted above, the element Oxygen was used. We might represent it as follows:

(INSTRUCTOR - REPRODUCE CHART 3-3)

14. There are atoms of oxygen, however, which are represented by the following diagrams:

(INSTRUCTOR - REPRODUCE CHART 3-4)

15. Now each of these three types of the oxygen atom are definitely oxygen atoms because each has 8 protons in its nucleus, however, each has a slightly different weight due to the different number of neutrons present. These different types of oxygen atom are known as isotopes of oxygen. The oxygen present in the atmosphere is a mixture of these isotopes; consisting of 99.76% Oxygen 16, 0.04% Oxygen 17 and 0.20% Oxygen 18. Therefore, in the field of atomic physics we deal not only with elements but with the different isotopes of one element. Some elements have only one isotope while one (tin) has ten isotopes. Each isotope has a definite assigned mass number which is the sum of the total number of particles in its nucleus. It should be emphasized that chemically all the isotopes of one element are identical - the difference is in their weight and therefore their reactions to physical forces.

16. One of the most important tools of the atomic physicist is the cyclotron. This instrument is capable of taking basic particles, such as protons, electrons or neutrons, accelerating these particles to tremendous speeds and then firing them into a target consisting of any one of the 92 elements. There is nothing mysterious about this procedure or its results. A baseball thrown through a glass window produces broken glass. An atomic bullet produces the same result when fired into an atom, although not with the same degree of breakage in most cases. Generally only one proton, one beta particle or one neutron is knocked loose from the nucleus. If a proton is knocked loose from the target atom the atom becomes an atom of a different element, whereas if a neutron is knocked loose the target atom changes to a different isotope of the same element. Two examples will illustrate this:

(INSTRUCTOR - REPRODUCE CHART 3-5 and 3-6)

17. Thus we see that it is possible to smash or fission atoms. These changes are called nuclear reactions and, by proper choice of bullets and target atoms, is the method by which elements are changed into other elements or the isotope of an element is changed into

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

other elements or the isotope of an element is changed into another isotope of the same element.

18. Examining the properties of a nucleus more closely, a very curious fact is noted. The nucleus does not weigh as much as it should. A nucleus consisting of six neutrons and six protons should weigh the same as the sum of the weights of six protons plus the weights of six neutrons, thus:

Weight of protons + weight of neutrons = weight of neucleus (REPRODUCE) but, instead, it weighs about 1% less. To explain this unusual situation we must look to Dr. Einstein for assistance. Among the many interesting facts shown by his theory of relativity is the proof that matter may be converted into energy. This relationship is expressed by the simple formula

$$E = mc^2$$

which may be stated in words as, "Energy equals mass times the square of the speed of light." The speed of light is a very large number, 186,272 miles per second, and this means that very small amounts of matter are equivalent to very large amounts of energy. Two examples of the enormous energy involved in infinitesimal amounts of matter are:

a. One pound of matter, of any kind, equals 11.4 billion Kilowatt hours of energy.

b. The total energy equivalent of some 25 pounds of matter is equal to all the power produced in the United States in a year's time.

19. These facts provide a clue as to why the nucleus weighs 1% less than it should. The loss in weight is due to the fact that about 1% of the mass of the components has been transformed into energy. This energy, called the binding energy, is stored in the nucleus where it binds the particles together. Whenever a particle is "smashed" loose from the nucleus, some of this binding energy is no longer required and is released. The energy which is released is what we call atomic energy.

Are there any questions?

<u>INSTRUCTOR'S QUESTIONS:</u>

1. What is the difference between an atom and a molecule?

2. What are the basic particles that are found in an atom?

3. What are isotopes?

[redacted]

[redacted]

4. What is the significance of $E = mc^2$?

5. Why does a nucleus weigh 1% less than it should?

6. What is atomic energy?

TRAINING OUTLINE NO: 4

LECTURE: Electro-magnetic Radiation and Radioactivity.

TIME: Fifty (50) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Paragraph 4.01 - 5.01, 5.07 - 5.11, 6.01 - 6.09, Radiological Defense Manual, Volume 1; pages 21-25, "All Hands", 1 July 1946, Navy Department; Chapter 1, "Atomic Energy for Military Purposes", Smyth; Paragraphs 29-35, 46-51, 66-71, 53-56, 107-115, 120, "Introduction to Atomic Physics", Semat; Chapter 14, "General Chemistry", Deming. (See Footnote*)

STUDENTS' REFERENCES: Pages 21-25, "All Hands", 1 July 1946, Navey Department.

TRAINING AIDS REQUIRED: Charts appended hereto.

1. To complete the picture of atomic structure, it is necessary to look into the matter of radioactivity. This is especially important since radioactive contamination is one of the principle hazards resulting from an atomic explosion. It is of major importance because an overdose of radioactivity is just as lethal as the effects of more conventional weapons. Several terms applicable to this field must be defined.

2. Energy is the first term encountered and it may be defined as "the ability to do work". There are many forms of energy - electrical energy, heat energy and chemical energy are the best known. Chemical energy is stored in wood, coal, oil, plants and food and is released by the burning of these materials. The burning of these substances changes the chemical energy into heat energy and this heat

*The explanations in this lecture have been simplified insofar as practicable. Within the objective and scope of this course, it was felt mandatory to do so. It is encumbent on instructors to familiarize themselves thoroughly with all the basic principles of energy, work, electro-magnetic radiation, radioactivity and ionization in order that they may answer any questions presented by technically qualified students.

[redacted]

1575

[redacted]

energy may be used to generate electrical energy which is used to operate machines which perform work. Energy which is stored-up or which only has the ability to do work is what we call potential energy, but energy which is actually doing work, we call kinetic energy. This work being performed may not be useful at all, but some definite thing is happening which requires energy to make it happen. The importance of this point lies in the fact that a particle, of some definite mass, moving through space with some definite velocity is said to possess kinetic energy. Some of the kinetic energy which this shooting particle has is being consumed (doing work) on the air through which it is passing with the result that the temperature of the air is being increased. This loss of energy to the air is very small, however, and most of the energy is simply being transferred from the starting point of the particle to the point where it eventually strikes something and stops (figuratively "hits a brick wall"). It is therefore easy to visualize the transmission of energy by fast moving particles which give up their kinetic energy on collision with stationary targets. Less obvious, but equally true, is the transfer of energy by wave motion.

3. Wave motion is most easily explained by a consideration of radio waves. These waves are usually pictured by a snakelike diagram.

(INSTRUCTOR - REPRODUCE CHART 4 - 1)

At this time it is well to state that no one is quite sure as to what these waves are. We might ask "how do we know such waves exist?" Mathematically, their existence and properties can be determined just as we know that the "wild blue yonder" exists and has certain obvious properties, but we are no more certain of what waves actually are than we are of what the "wild blue yonder" is. Fortunately we are only interested in the effects of waves, not their composition, in this course. Let us consider wave motion as a beam of oscillating particles, composition unknown, traveling through space in straight lines with a constant velocity of 186,272 miles per second.

4. Each type of wave is distinguished by the distance between successive peaks of oscillation. This distance is known as the wave length

(INSTRUCTOR - REFER TO CHART 4 - 1)

and covers the entire scale of distance from almost zero inches to hundreds of miles. This wave motion results in the transfer of energy and so we define the transfer of energy by wave motion as electromagnetic radiation, or as it is normally called, radiation. Some of the better known forms of radiation are cosmic rays, radar waves, X-rays, ultraviolet rays, visible light rays (the different colors being due to difference in wave lengths), infra-red rays and radio waves. The following table will give you some idea of the wave lengths of these different forms.

(INSTRUCTOR - REPRODUCE CHART 4 - 2)

[redacted]

[redacted]

The next step is to determine the amount of energy transmitted by the various forms of radiation. The shorter the wave length, the greater the amount of energy transmitted. Several analogies could be drawn to illustrate the point, one being that a ship sailing through a long, slow ocean swell (long wave length) does not take half the pounding that it does when going through a choppy sea (short wave length). Thus X-rays, which have a very, very short wave length, have a very high energy content compared to radio waves, which have a very long wave length.

5. The fact that radiation has several forms, each distinguished by its characteristic wave length, should not be allowed to confuse us on the general properties of radiation. These properties may be summed up as follows:

a. Velocity - 186,272 miles per second.

b. Visibility - invisible except in the visible light range.

c. Energy content - depends on wave length.

d. Physical perception - none, except heat in certain ranges.

e. Composition - unknown but may be thought of as oscillating particles.

(INSTRUCTOR - REPRODUCE ABOVE DATA AND QUESTION CLASS ON ITS UNDERSTANDING OF THE MATERIAL)

6. One form of radiation which is not commonly known but which we will deal with primarily is gamma radiation. Gamma radiation is most nearly comparable to X-rays but has a shorter wave length and is therefore of higher energy content.

7. On the theory that gamma radiation may be considered a beam of high energy oscillating particles (as discussed above) traveling in a straight line, the assumption is that gamma radiation is not greatly different from a beam of electrons, or protons, or neutrons or any other high energy particles. Certainly the gamma radiation is somewhat different because:

a. It travels faster.

b. It oscillates.

c. It has no detectable size or mass and normally cannot act as an atomic bullet to smash particles loose from the nucleus of an atom, but the gamma radiation IS transferring energy, and this is what we are interested in. Because of this fact, any beam of high energy particles may be considered as ionizing radiation. "High Energy Radiation" may be defined as any ionizing radiation which con-

[redacted]

1577

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

tains enough energy to cause bodily harm.

8. The element Uranium has a most unusual property in that the atoms of Uranium spontaneously give off energy. This is not a freak case, however, since several other elements such as radium, thorium and radon do likewise, but we will consider the case of Uranium as typical.

9. Radioactivity is the term applied to the process wherein certain atoms emit energy spontaneously. The nature of this radioactivity was established after much research and found to be threefold in composition:

a. Alpha particles traveling at high velocities.

b. Beta particles traveling at very high velocities.

c. Gamma radiation traveling at the speed of light.

All three of these components fall under our definition of high energy radiation and thus radioactivity is high energy radiation.

10. An alpha particle is the nucleus of a helium atom, containing 2 protons and 2 neutrons very firmly bound together. These alpha particles have an initial velocity of about 1/10 the speed of light and possess great kinetic energy but have little penetrating power due to their relatively large size.

11. The beta particle turned out to be nothing but an electron in different form. There is a difference between beta particles and electrons as concerns their origin. Beta particles originate in the nucleus, while electrons are outside the nucleus. Beta particles have an initial velocity of about 99% of the speed of light and possess substantial amounts of energy. Because of their small mass, although not because of smaller size, beta particles have much greater penetrating power than do alpha particles.

12. Gamma radiation is true electromagnetic radiation traveling with the speed of light, is quite energetic and has enormous penetrating power.

13. Some idea of the relative penetrating power of these particles is shown by the following diagram.

(INSTRUCTOR - REPRODUCE CHART 4-3)

14. It is beyond the scope of this course to explain why certain elements found in nature spontaneously emit energy. The simplest idea that can be presented is to say that at the instant of formation of a radioactive atom, that atom was forced to store up more energy than was required to bind the protons and neutrons together. The excess energy

[redacted]

[redacted]

is not needed and therefore escapes as fast as it is possible to do so. When non-radioactive elements are split or fissioned in the laboratory the energy balance of the remaining nucleus is always slightly "out" and the nucleus becomes artificially radioactive. The same escape procedure immediately starts to function. In elements which are naturally radioactive the escape procedure is very slow, requiring many thousands of years to complete. In elements which are made artificially radioactive the escape procedure is relatively fast and may be completed in from a fraction of a second to a few years.

15. This escape procedure is called "Radioactive Decay" and the rate at which it occurs is called the decay rate. If we take 1000 radioactive atoms of an element, A, and examine the decay process, we will find that after some definite period of time, half - or 500 - of these atoms will have completely decayed and will have changed into some different element, B. Assume that this requires one hour. We now have 500 radioactive atoms of element A left. At the end of the second hour, we will have 250 radioactive atoms of element A left and so on, as shown by the following table.

At the End of		Radioactive Atoms of Element A Left
Start	-	1000
1 hour	-	500
2 hours	-	250
3 hours	-	125
4 hours	-	63
5 hours	-	32

(INSTRUCTOR - REPRODUCE ABOVE TABLE)

It is apparent that each hour, one-half of the remaining radioactive atoms are decaying to a different isotope. The time that it takes for one-half of the radioactive atoms of an element to decay is called the "half-life". Each radioactive isotope has a characteristic half-life of its own and no two are the same. These half-lives cover an enormous range of time - from a fraction of one second to thousands of years. The military significance of this will be brought out later.

16. Finally it is necessary to discuss the process known as "ionization" in order that the methods used for the detection and measurement of high energy radiation may be understood. A series of charts will help in an understanding of this process.

17. Ionization is a process in which orbital electrons, of atoms, are struck by high energy radiation passing through their orbits, and,

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

as a result of these collisions, the orbital electrons are ejected from their orbit.

(INSTRUCTOR - SEE CHART 4-4)

18. These ejected electrons fly over to an adjoining neutral atom and arbitrarily attach theselves. This causes the neutral atom to become negatively charged (the electron is a negative charge of electricity) and leaves the atom from which the electron was ejected, positively charged due to the protons in the nucleus.

(INSTRUCTOR - SEE CHART 4-5)

19. At the conclusion of these two steps Atoms A and B are said to be ionized. This is important since these ionized or electrically charged atoms can be effected by magnetic fields whereas neutral atoms cannot.

20. High energy radiation is capable of ionizing all material through which it passes. To ionize this material, however, takes energy and the incident high energy radiation if finally stopped or absorbed when it loses all of its kinetic energy. Thus an alpha particle causes heavy ionization but only travels a short distance since it loses energy very fast; a beta particle causes lighter ionization but travels farther since it loses energy more slowly; and gamma radiation which causes still lighter ionization travels quite far, because it loses energy very slowly. Neutrons are also a form of high energy radiation and are comparable to gamma radiation in penetrating properties.

Are there any questions?

INSTRUCTOR'S QUESTIONS

1. What is energy?

2. What distinguishes one type of wave from another?

3. What determines the amount of energy transmitted by waves?

4. What may gamma waves be considered similar to?

5. What is high energy radiation?

6. Name four particles which may be found in high energy radiation?

7. What is the relative penetrating power of alpha particles, beta particles and gamma radiation?

TRAINING OUTLINE NO: 5

LECTURE: Nuclear Reactions, Atomic Fission and Chain Reactions.

TIME: Fifty (50) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Paragraphs 7.01 - 8.14, Radiological Defense Manual, Vol 1; Pages 24-47, "All Hands", 1 July 1946, Navy Department; Chapters II, IV, VI, VIII, XII, "Atomic Energy for Military Purposes", Smyth; Paragraphs 115-126, 127, 133, 135-145, "Introduction to Atomic Physics", Semat.

STUDENTS' REFERENCES: Pages 24-47, "All Hands", 1 July 1946, Navy Department.

TRAINING AIDS REQUIRED: Charts appended hereto.

1. The preceding two periods have been devoted to a study of atomic structure, electro-magnetic radiation and radioactivity. These phenomena are essential to an understanding of nuclear reactions, atomic fission and chain reactions.

2. Nuclear reactions may be thought of as changes in the nuclei of atoms. These changes are brought about by firing a "bullet" into a target nuclei. Either neutrons, protons, alpha particles or beta particles may be used for "bullets" depending on what type of change is required. A variety of types of nuclear reactions are known; the more important ones being:

a. Reactions induced by neutrons.

b. Reactions induced by protons.

c. Reactions induced by alpha particles.

d. Reactions induced by electrons.

e. Reactions induced by electro-magnetic radiation.

3. Neutron reactions are of paramount interest because neutron "bullets" are used to "break-up" uranium atoms and thereby cause an atomic explosion. In addition neutron reactions are responsible for certain additional hazards following an atomic explosion.

4. Proton reactions are of interest because, due to their wide

[redacted]

1586

[redacted]

variety, they make possible all sorts of "building" in the field of nuclear chemistry.

5. Reactions induced by alpha particles, beta particles and electro-magnetic radiation are of value in the field of nuclear research and do not greatly concern us. At this point it is well to point out that we are not speaking about the effects which neutrons, protons, alpha particles, electrons and electro-magnetic radiation produce in the human body. The physiological effect of high energy radiation is due to ionization of tissue (a process involving orbital electrons of the atoms in our flesh, bones and blood) and not to changes within the nuclei of body atoms.

6. Two general types of neutron induced reactions are worth additional study. These are:

a. Simple neutron capture. In such reactions, the target nucleus "captures" the neutron "bullet". This serves to increase the target nucleus's mass (atomic weight) but leaves its atomic number (and therefore, chemical properties) unchanged. The effect is to produce a heavier isotope of the element being bombarded. An isotope produced in this manner is usually radioactive and therefore dangerous to personnel. The military significance of this type of reaction is apparent when it is understood that a neutron flux or "hail" occurs in the vicinity of an atomic detonation. This flux bombards everything within its range, over 1000 yards, and induces radioactivity therein.

b. Neutron capture with particle emission. This type of reaction may be thought of as an atom smashing reaction. A neutron "bullet" strikes the target nucleus and knocks something out. In the majority of cases, this is a one-time affair which begins with a neutron hitting the nucleus and ends with a proton, or alpha particle being ejected from the nucleus. A few rarer cases exist where TWO neutrons are ejected from the target nucleus. Finally a half-dozen very rare cases are known where MORE THAN TWO neutrons are ejected. This last case is very interesting indeed since we, so to speak, get more than "two for one" and the chances of running a non-stop neutron parlay are better than "sporting". In effect this means a reaction, wherein more bullets come out than were put in, will continue once started. Factors beyond the scope of this course are present which prohibit most of these incipient chain reactions from developing but two isotopes, U235 and Pu239 will do so. Nuclei of these two isotopes, when struck by a neutron bullet split into approximately two equal parts, eject more than two neutrons which were left over as spare parts and liberate a large amount of surplus energy (considering the amount of material involved). This is the fission reaction which makes possible an atomic weapon.

(INSTRUCTOR - REPRODUCE CHART 5-1)

[redacted]

[redacted]

The ejected neutrons are very important and are the key with which we unlock atomic energy. This is possible because they are expelled with sufficient force to act as new bullets and cause the fission of more than one additional U235 or Pu239 atom. The manner in which this reaction may build up is shown on the following chart and this is what we call a chain reaction.

(INSTRUCTOR - REPRODUCE CHART 5-2)

7. There are many complicating factors in the production of U235 and Pu239 on a scale large enough for use in atomic weapons. One of these factors is the absolute purity to which the isotopes must be refined. Another is the scarcity of material; U235 being generally present only to the extent of 1 part in 140 parts of natural uranium, while Pu239 must be made in piles from U238 one atom at a time, a task that staggers the imagination as to its difficulty, expense and amount of equipment required.

8. In order to cause a chain reaction, quite a large quantity of fissionable material must be used. If a small quantity of material is used, most of the neutrons escape through the surface of the material and the reaction stops. The relatively large ratio of surface area to volume in a small geometric solid allows this neutron escape. If you have a somewhat larger quantity, however, the neutrons produced by the first atom splitting cannot fly out of the mass. They split more atoms, these produce more neutrons and split more atoms and so on until an explosion may occur due to the sudden release of energy. The size at which the Uranium mass is just large enough to sustain the chain reaction is called the critical mass. Less than that mass will not sustain a chain reaction because practically all the neutrons produced by fission escape through the surface area without causing additional fission. More than critical mass will sustain a chain reaction since almost all of the neutrons produced by fission will cause additional fission. It is important to understand that there are many stray neutrons in the air and any one of these stray neutrons will start a chain reaction in a greater than critical mass.

9. Whether or not there is an explosion depends on whether the chain reaction develops in a short enough time. If the mass of fissionable material is made strongly over-critical in size the chain reaction develops very rapidly. Energy is then released at an explosive rate and the fissionable material expands until it becomes diluted; with dilution more neutrons escape through the surface area and the reaction stops. But before this expansion stops the reaction, a tremendous quantity of energy is released and a violent explosion results. This is how the atomic bomb works. So your bomb might look like this:

(INSTRUCTOR - REPRODUCE CHART 5-3)

[redacted]

1588

[redacted]

10. A question at this point might be, "Why doesn't the bomb blow apart and the explosion stop before it gets any greater in violence than that resulting from a hand grenade?" One answer lies in the fact that nuclear reactions occur in very short intervals of time. One generation of neutrons will cause fission of uranium atoms in about one hundred millionth of a second. Each successive generation of neutrons will be twice as large in number as the previous generation of neutrons and this means that if we started with 2 neutrons and doubled the number for 100 successive times we would fission a fantastic number of uranium atoms with the 100th generation of neutrons. This would liberate a very large amount of energy and the entire process would occur in about one millionth of a second - a very short time indeed. By placing a heavy tamper or shield around the bomb it is possible to hold it together for a few additional millionths of a second and this additonal increment of time means the difference between a small explosion and a very large one.

11. Natural Uranium consists of three isotopes; U-234, U-235 and U-238, which are present to the extent of 0.006%, 0.7% and 99.3% respectively. Uranium ore is very scarce, and, if we use only the isotope U-235, less than 1% of this scarce ore can be utilized. Obviously it is desirable to find some method whereby the U-238 isotope can be used and thus all but a fraction of the ore utilized.

12. Under certain conditions U-238 can be made to fission but these conditions are such that they make the use of U-238 in a bomb impracticable. However, it is possible to make a new element, Plutonium, from the U-238 and Plutonium makes an excellent material for bombs. One manner in which this might be accomplished is illustrated by the following chart:

(INSTRUCTOR - REPRODUCE CHART 5-4)

13. Students will not be held responsible for knowledge of these reactions, and they are only shown as a matter of interest. The vast Atomic Energy Commission plants at Hanford, Washington, called piles, are used for the production of Plutonium.

Are there any questions?

<u>INSTRUCTOR'S QUESTIONS</u>:

1. What three things happen when an atom of U-235 fissions?

2. What limits the availability of atomic energy?

3. Why is it necessary to produce Plutonium?

4. Can small atomic bombs be made? If so, why do we not use them? If not, why not?

5. What is meant by the term critical mass?

[redacted]

1589

[redacted]

6. What is the effect of making a bomb much larger than critical in size?

7. What are two types of neutron induced reactions?

TRAINING OUTLINE NO: 6

LECTURE: Explosion Phenomena.

TIME: Fifty (50) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Pages 3, 44 - 47, "All Hands", 1 July 1946, Navy Department; Chemical Corps School Mimeographs No. 21 and No 202; "Medical Aspects of Nuclear Energy", Armed Forces Special Weapons Project, National Military Establishement, 1949.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Projector, Screen, Film "A Tale of Two Cities" (ANSM 74). Charts as noted in text.

1. Thus far this course has been concerned with what an atom is, what radioactivity is, what is meant by a chain reaction, and the principle of the atomic bomb.

2. This talk on "Explosion Phenomena" will give an account of what goes on in an atomic explosion and discuss the hazards that exist during and after atomic explosions.

3. Certain people have stated publicly that the atom bomb is "just another big bomb". The A-bomb cannot be dismissed that simply. No other bomb known can send invisible rays through reinforced concrete to kill personnel taking shelter there and no other single bomb can effectively wipe out a modern city.

4. Comparing the HE and the atomic explosion will provide some interesting material. The characteristics of the HE explosion are well known. The HE explosion is a chemical reaction. This reaction, which proceeds with great velocity is set up in the body of the explosive and converts a small volume of solid material into great quantities of heated gases. Due to the temperature and pressure of the generated gas, a shock wave is set up in the air, or other surrounding medium. The energy expended in this manner is quite large per pound of the explosive, but it is trivial, perhaps only a millionth part of the energy developed by the same amount of uranium or plutonium.

5. The shock wave which is set up in the air by an explosion, whether due to HE or to an atomic explosion, moves outward from the

[redacted]

1595

[redacted]

center of the explosion with a velocity which is generally greater than the speed of sound. This wave is a compression wave in the air. Normal air pressure is about 15 pounds per square inch. In the shock wave, two conditions exist. There is a region in which the air pressure is greater, by quite a few pounds per square inch, than normal air pressure. Then there is a second region in which the air pressure is a pound or two lower than normal. These two regions constitute the shock wave. The greater the intensity of the explosion, the greater the increase in the positive part of the shock wave, and the lower the pressure in the negative region. Also, the more powerful the explosion, the greater the velocity with which the shock wave moves outward from the point of the explosion.

(INSTRUCTOR- REPRODUCE CHART 6-1)

6. Assume that instruments to measure air pressure are set up at some distance from the point at which several pounds of HE are to be exploded. The explosion develops the shock wave which moves outward and crosses the position of the recording instruments. These instruments will show an increase in pressure which is followed immediately by a decrease in pressure. It is this negative pressure which blows out windows and often causes the collapse of structures that survived the original positive shock. The positive shock wave lasts for about one millionth of a second, and this is followed by the negative pressure which lasts for about three millionths of a second. Thus, the shock wave for the HE explosion comes as a sharp blow or pulse of pressure increase followed by a pressure decrease. Finally, as the shock wave travels outward, its intensity falls off until it finally vanishes.

7. The atomic bomb explosion also produces a shock wave which has much the same characteristics as does the HE wave. Since the atomic explosion is far more intense it could be expected that the shock wave which accompanies it should show a higher pressure in the positive phase, and a lower pressure in the negative phase. Also the shock wave should travel at a far higher rate of speed for the atomic explosion. This is exactly what is observed. The positive phase of the atomic shock wave may show increases in pressure which are several times the increase for the HE explosion. The duration of the positive wave may last for one tenth of a second, which is 100,000 times as long as that of the HE explosion. It can be stated that if the positive phase increases the normal air pressure by five pounds per square inch, the shock wave will be most destructive. There are 144 inches to the square foot, and if a positive wave of five pounds per square inch strikes the wall of a building, it means that every square foot of surface of the building on the side facing the explosion would be subjected to a force of 144 x 5 = 720 pounds. Further, this pressure would persist for about one tenth of a second.

8. If you assume that a small building, eight feet high and ten feet long stands facing the point at which an atomic explosion takes

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

place, the total force against this side of the building would be (8 x 10) x 720 or about 29 tons on that small surface alone. It is easy, then, to see why most buildings will not withstand the shock wave due to the atomic explosion if they are located anywhere near the blast. Thus, at Hiroshima multi-stoned brick buildings were severly damaged if they were within a radius of one mile from the point of the explosion. Even modern reinforced concrete buildings were severely damaged if they were within a radius of 2,000 feet from the point of the explosion. These concrete buildings were designed to be earthquake proof, which required them to be more shock resistant than comparable buildings in the United States.

9. In any explosion, there is a reflection of the shock wave from solid surfaces, and the reflected waves reinforce the primary wave. It looks like this:

(INSTRUCTOR - REPRODUCE CHART 6-2)

and a reinforcing effect is brought about. This effect, called blast reflection, is well known in HE explosions, but its reinforcing effect in the atomic bomb burst is even more pronounced.

10. Up to this point, little new has been mentioned concerning the effect of atomic explosions. That is, the shock wave develops for this type of explosion about as it does for the HE explosion. It is true, of course, that the shock wave is more intense, by a factor of thousands, and is therefore, far more destructive; but the mechanism by which the shock wave is developed is the same as for the HE explosion.

11. However, as was pointed out earlier, the atomic explosion is accompanied by radiation effects which are entirely missing from the HE explosion. These effects can be divided into two groups. The first consists of those radiations which accompany the actual explosion of the bomb, and the second group those which linger or persist after an explosion.

(INSTRUCTOR - REPRODUCE CHART 6-3)

The radiation accompanying the explosion can be classified as follows:

a. Electro-magnetic radiation.
b. Neutron flux.
c. Beta radiation.
d. Alpha radiation.

12. The electro-magnetic radiation can further be sub-divided into visible light, ultra-violet, infra-red and gamma radiation. The ultra-violet is the same ultra-violet radiation which is found in sunlight. It has the same effect upon the skin; that is, it produces sunburn. This burn can be severe enough to kill. Any light weight shielding material is sufficient to protect against the ultra-violet radiation.

[redacted]

1597

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

13. The visible light radiation is responsible for the blinding flash of light which occurs. The intensity of this flash is many times more brilliant than the sun and, at worst, may cause injury to the eyes. At best it causes only temporary blindness.

14. The infra-red radiation is heat radiation. That is, it is the infra-red portion of the sun's spectrum which transmits most of the heat. This radiation is very intense in an atomic explosion. It can set fires at considerable distances. It will produce flash burns on exposed skin tissue at considerable distance from the explosion. Shielding will give considerable protection. It was found at Hiroshima that individuals who were exposed to the infra-red radiation and who were wearing light colored clothing escaped flash burns while those who wore dark clothing received severe burns. It was also noticed that loosely fitted clothing gave more protection than did tight clothing.

15. The gamma radiation has the same general characteristics as does X-ray radiation. However, it is more energetic and it will penetrate greater thicknesses of shielding materials. It was estimated that, at the instant of the Baker explosion at Bikini, the gamma radiation was equivalent to that of several hundred tons of radium. Since the world supply of radium is measured in pounds this is truly an astronomical figure. Light weight shielding affords no protection. Gamma radiation is not completely stopped by any amount of shielding. All the shielding does is to reduce the intensity of the radiation. Thus, if the shielding is heavy enough and the energy level of the radiation is not too intense, the individual does not receive enough radiation to cause serious effects. It was estimated that, at Hiroshima, twenty-four inches of concrete would have been sufficient to protect an individual at a distance of one mile from the explosion. For nearer points, the thickness of concrete would have to be greater. Five inches of compact clay will reduce the intensity of the gamma radiation by about one-hafl, but the initial intensity is so great that the intensity must be reduced by nearly 100 per cent if the individual is to escape fatal injury. It is to be noticed that if five inches of clay reduces the intensity by 50 per cent, then 10 inches will reduce the intensity by 75 per cent and 15 inches will reduce the intensity by 87.5 per cent. In general the heavier materials are the most efficient in reducing the intesity of gamma radiation. Thus less thickness of lead shielding would be required than would be the case for paper or wood. The walls of a wood house would afford excellent protection against ultra-violet and infra-red radiation but almost none against the gamma radiation.

16. The neutron has been mentioned in an earlier lecture. It was also mentioned that the neutron causes the fission of uranium and plutonium and that neutrons are ejected from nuclei when they undergo fission. These fission neutrons are high energy neutrons and they can penetrate great thickness of matter. Thus, at Bikini, neutrons penetrated the steel bulk-heads of ships and induced radioactivity in table salt and soap chips in the galleys. The neutron itself can cause harmful effects in the human body, but it also acts in another way. It will induce radioactivity in many substances. Thus at Bikini, and expecially in the Baker test, the neutrons from the explosion caused the formation

[redacted]

[redacted]

of a radioactive salt from the normal salt in the sea water. This radioactive salt then decayed, and in the process, emitted a great deal of gamma radiation. Thus, the neutron flux, which was generated at the instant of the explosion gave rise to a lingering type of radioactivity. One saving feature is that fact that neutrons do not have a range greater than one mile.

17. Beta particles are emitted at the instant of the explosion, but they are not a serious threat. The beta particle is a charged particle and will, therefore, have a short range in air. The most energetic beta particles from an atomic explosion have ranges of only about 10-11 yards in air Thus, while they are harmful, their range is so short that they need not be seriously considered, unless active beta particles are ingested.

18. Alpha particles also arise in the explosion. They are massive, compared with the beta particle, therefore their ranges may be measured in inches. If an alpha emitter becomes lodged in the body it can be a very serious hazard, but it is not a serious hazard as long as it is outside the body.

19. This concludes the list of harmful radiations which arise at the instant of the explosion. These include gamma radiation, visible light, ultra-violet and infra-red radiations, neutron flux, beta radiation and alpha radiation.

20. The radiation which arises at the instant of the explosion is not the only harmful radiation. There are types of radiations which persist after the explosion. This radiation arises from three sources. They are:

a. Unfissioned bomb material.
b. Fission products of the bomb material.
c. Radioactivity induced in the materials of the land or sea.

21. All of the material of a bomb does not undergo fission. This unfissioned material, either uranium-235 or plutonium is reduced to a powder and scattered by the explosion. This material is an alpha particle emitter. It is not much of a hazard, due to the short range of alpha particles in air, unless it is taken into the body through the lungs, mouth or open cuts. It then becomes a really dangerous hazard. This effect will be discussed in a later period.

22. A part of the bomb material undergoes fission. It has been pointed out that, in the fission process, the atoms of uranium or plutonium break up to form lighter atoms and that these newly formed atoms are radioactive. They decay by the emission of beta particles and gamma radiation. The beta particles are a lesser hazard than the gamma radiation since they, like the alpha particles, do not have a great range in air. The gamma radiation is very dangerous for considerable distances and, since the fission products will also be widely scattered by the explosion, may be dangerous over a large area after an explosion.

[redacted]

[redacted]

23. The hazard due to induced radioactivity can be great in some types of explosions. This hazard is produced by the neutrons which are released at the instant of the explosion. These neutrons enter the nuclei of some atoms and cause a physical reaction which leaves a radioactive atom as a product. The induced radioactivity for the atomic explosion over land is variable depending on what type of soil exists. The Bikini test showed that for underwater bursts great amount of radioactivity are induced. This is due to the fact that the salt in the sea takes up neutrons to form a radioactive isotope of sodium. This radioactive sodium decays by emitting gamma and beta radiation and ends up as a stable isotope. Considerable gamma radiation, due to this reaction, was present after the Baker test at Bikini.

24. In the air burst of the atomic bomb, as in Japan, or the Able test at Bikini, the mass of fissionable material is dispersed by the explosion and a rapidly growing fireball is formed. This ball is white hot gaseous matter and has a temperature of well over a million degrees centigrade.

25. As the fireball radiates its immense heat, it becomes cool, then contracts, and the surrounding debris-laden air rushes in with hurricane velocity; at the same time the air above the fireball, being extremely hot, rises rapidly. These two forces combine to create the huge towering pillar of dark smoke which is characteristic of an atomic explosion. The cloud is laden with fission products and unfissioned bomb material. The latter material is due to the bomb is not one hundred percent efficient.

26. This radioactive material is carried high into the air, the column reaching more than 40,000 feet. In the case of an air burst, practically all radioactive material is carried up into the cloud.

27. Now this is very important since that radioactive material is very finely divided and is carried by the wind for long distances before it finally falls to the ground. Normally, after being carried many miles away from the bomb burst, the particles are so scattered as to be capable of little harm, but danger <u>can</u> exist up to quite a few miles.

28. A Radiological Defense Officer will be given adequate weather data by the Weather Officer. He can then calculate with fair accuracy just how far dangerous contamination will be carried and can plot the "fall-out" and "rain-out" areas which will be relatively safe, dangerous and extremely dangerous. The method by which this fall-out pattern is plotted is somewhat complicated and slow. Due to this the procedure is not included in this course.

29. In practice, if an atomic bomb falls on a city, port, or industrial concentration fifty miles or so from your base, you will be expected to note the presence of any radioactivity in your area, its intensity, degree of danger to personnel, and its extent.

30. With suitable instruments it is possible to detect the presence

[redacted]

1600

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

of radioactivity for many miles. It has been said that the atomic cloud from the Alamorgordo test was traced to Canada. Of course, after a relatively few miles, the particles were so dispersed that no damage was done, except in one case, that of a photographic manufacturing concern which used strawboard to pack a large quantity of film. The strawboard was made from plants on which radioactive particles had settled, many miles from the blast. As a result, several thousand dollars worth of film was ruined.

31. The underwater burst at Bikini on Baker Day had different results.

(INSTRUCTOR - REPRODUCE CHART 6-4 ON BLACKBOARD)

The bottom is coral, and water here was a little over 200 feet deep. The bomb had been lowered in a sealed caisson the night before, and was hanging somewhere below the ship. When everything was cleared the next morning, the bomb was detonated. Upon detonation, as was anticipated, an extremely great quantity of energy was emitted which formed a ball of incandescent gas. The water was simply thrust away and much of it vaporized. The pressure in the gas bubble was over a million pounds per square inch. The surface broke, and the water vapor went straight up. The "Prompt" radiation came out before the bubble broke and was absorbed in the mass of water. The shock wave of the explosion was bounced off the bottom and was reflected just in time to pick up much of the water that rushed in to fill the hole that had been made. The column of water rose rapidly. It was really not very dense, in spite of its ominous appearance in the film; it was largely foam with only a few massive chunks of solid water included in it. The water reached its peak, then fell around the rest of the ascending column, and upon reaching sea level it made a collar effect around the base of the column. This collar, called the base surge, moved outward at about 80 miles an hour, and grew rapidly in its vertical dimension. It reached a total height of over 300 feet and was over one quarter of a mile across on one side. From this base surge, and from the still overhanging cauliflower above, heavy rain fell on everything below. This rain was of cloudburst intensity and very heavily contaminated. Even the salt in the sea water had become radioactive, due to the neutron flux, and decayed with a half life of about 15 hours. Some fission products attached themselves to water droplets or dust particles and fell with them. The later progress of a base surge would depend on weather conditions. With normal wind velocities, a danger area of roughly 2 miles crosswind by 5 miles downwind may exist.

32. Had the Bikini bomb gone off in a harbor the contaminated rain could have enveloped buildings in the adjacent city, buildings with windows already broken by blast. Enduring contamination would have resulted.

33. After two years, some of the Bikini ships were still heavily contaminated. Some had to be sunk, others are being used for experiments in decontamination techniques, and others have been cleaned and returned to service.

[redacted]

1601

[redacted]

34. The following factors relative to an air burst and water burst should be stressed; in the air burst there is immense, so called prompt, radiation of gamma rays and neutrons. The fission products, themselves radioactive, and unfissioned bomb material, all are taken into the air and dispersed by normal weather processes. Only a relatively small amount of radioactive material settles to earth to cause significant contamination.

35. As for the time available for self protection; in an air burst, there is absolutely none. In the water burst, the base surge takes perhaps 10 seconds to form. The radiation, therefore, doesn't fall immediately. It might take 15 minutes to reach four miles downwind. Closer to the blast area, however, the danger comes very quickly.

36. Finally, in the water burst there is very little heat liberated. Most of it is absorbed by the water and therefore there is very little fire effect.

Are there any questions?

INSTRUCTORS' QUESTIONS:

1. How does the shock wave from an atomic explosion compare with that from an HE explosion?

2. What four types of radiation accompany the actual atomic explosion?

3. How far do the fission neutrons travel?

4. From what three sources does the residual alpha, beta and gamma radiation come?

5. What is one major hazard that is not present in an underwater ab atomic explosion?

6. What is meant by the term "fall-out"?

(NOTE TO INSTRUCTOR: Film "A Tale of Two Cities" will now be shown)

TRAINING OUTLINE NO: 7

LECTURE: Effects of the Atom Bomb on the Human Body

TIME: One Hundred (100) Minutes.

PLACE: Classroom

INSTRUCTORS' REFERENCES: "The Effects of the Atomic Bombs on Health and Medical Services in Hiroshima and Nagasaki" USSBS, 1947; Chemical Corps School Mimeographs No. 21 and No. 202; Medical Aspects of Nuclear Energy", Armed Forces Special Weapons Project, National Military Establishment, 1949.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Projector, Screen, Film "A Tale of Two Cities" (ANSM 74). Charts as Noted in text.

1. The two atomic bombs used in warfare up to the present time killed more than one hundred thousand people and injured a minimum of one hundred and fifty thousand. This talk on the medical aspects of the atomic bomb will tell us how these people died and will discuss the nature of the non-fatal casualties.

2. Japanese in authority have stated since the Hiroshima and Nagasaki bombings that, with proper organization, they could have saved ten percent of the fatal casualties. That means that twenty thousand men, women and children who might have been living today died - swiftly or slowly - because the defense was inadequate.

3. The estimated pre-raid population of Hiroshima was about two hundred and fifty five thousand, which is comparable to Providence, Rhode Island, or Dallas, Texas. The estimated deaths ranged from 70,000 to 80,000, with an additional 100,000 injured. In Nagasaki, a somewhat smaller town, with a normal population of about 195,000, there were 25,000 to 45,000 dead, and somewhere between 50,000 to 60,000 injured.

4. In both cities, approximately one quarter of the people were killed outright, and about half were injured, more or less seriously. The effects of the more efficient Nagasaki bomb were felt at a greater distance from Ground Zero, that is, the point on the ground directly underneath the air burst, than was the case at Hiroshima, but total damage was somewhat less in the Nagasaki explosion because the city was situated in a narrow river valley, and portions of the city were protected by hills and spurs projecting into that valley.

5. Before discussing the dead and wounded, let's give ourselves

[redacted]

1607

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

a reference point, that is, just how far from the explosion of the bomb does a man have a chance of being unharmed.

6. Averaging figures from both Japanese bombings with respect to distance from Ground Zero is interesting:

From Ground Zero to 1,000 feet approximately 95% killed
From 1,000 feet to 2,000 feet approximately 92% killed
From 2,000 feet to 3,000 feet approximately 86% killed
From 3,000 feet to 5,000 feet approximately 49% killed
After 10,000 feet there were many injured, but few or no fatal casualties.

7. These figures include all personnel of whom some were in shelters and many others protected by walls, buildings, or other shielding. For people outdoors, casualty figures were much higher.

8. This chart illustrates the emenations from an atomic explosion.

(INSTRUCTOR REPRODUCE CHART 7-1)

These include:

a. Blast from the explosion
b. Electro-magnetic radiation

Instantaneous:
(1) Infra-red
(2) Visible light
(3) Ultra-violet
(4) Gamma

c. Neutron Hail
d. Alpha
e. Beta
f. Beta and Gamma Radiation

Residual:
(1) From fission products
(2) From neutron induced isotopes

g. Alpha Radiation - From unfissioned bomb materials

9. At the detonation of the atomic bomb, a large fireball is produced which emanates all the above.

10. The infra-red radiations are heat waves of very high intensity. Many people were incinerated instantaneously at the moment of the explosion, and others suffered first, second, or third degree flash burns.

11. These flash burns were very productive of casualties. Temperatures, of course, were not accurrately measured, but the temperature possibly went as high as 2000°C up to over 1000 feet from Ground Zero. Clothing was instantaneously ignited up to 1500 feet away. There was scorching

[redacted]

1608

[redacted]

of telegraph poles 6000 to 9000 feet away. There were some odd effects from the infra-red waves; where they struck the unprotected skin, charring occurred and most victims died quickly. This effect was noted from 4000 feet to 5000 feet from Ground Zero. Second degree burns were inflicted up to 12,000 feet. Some persons reported feeling intense heat to the point of pain, up to 25,000 feet.

12. But there were some modifying factors such as clothing. Black clothing absorbed the infra-red rays, and severe burns resulted. White or light clothing, on the other hand, deflected the heat, and was definitely of good protective value. In many cases an odd piebald effect was created; as for instance where a man was wearing a striped or dotted garment, the darker portion of the pattern was burned into the skin beneath.

13. Thickness of clothing was a factor. The more layers a person wore, the more protection. Seams could be traced on the bodies in many cases, since they offered more protection, and superficial burning of the skin beneath was less severe. Burns were more serious also where the clothing was drawn tight against the skin.

14. Objects such as trees, fences, and blinds protected the skins of people who were behind them.

15. The visible light radiations have an intensity two or three times that of normal sunlight and affect the eyes. No permanent injury was caused in those persons far enough from Ground Zero to survive the blast, but there was a temporary blindness, lasting for minutes up to days, due to over-fatigue, or saturation, of the light-sensitive nerve surfact at the rear of the eyeball. There is some mystery as to why people did not have their eyes literally burned out or seared. The only reasons that can be ascribed for this are:

a. The overhanging bone or supradbital ridge over the eyes gives partial protection.

b. The blink reflex might have operated in the minute fraction of a second before the film of moisture on the eyeball was boiled away.

16. There are also the ultra-violet rays which are present in ordinary sunlight but are normally filtered out by the atmosphere. It was as though a small piece of the sun were instantaneously created just overhead. The ultra-violet rays may have caused first, second, or third degree flash burns, but this is not known, as such burns cannot be differentiated from those caused by heat.

17. Gamma radiation is highly penetrating and powerful. They cause interesting, but not attractive, biological effects which we will touch on later. Important to us is the fact that gamma radiation can penetrate and kill even through heavy concrete construction, or several inches of lead. The gamma radiation, together with the neutrons which we will

[redacted]

[redacted]

discuss shortly, are responsible for the much publicized radiation sickness which killed many people who might have survived the atomic bombings otherwise. These people received an overdose of radiation sufficient to produce drastic changes in the body. In cases where exposure was of a lower order, effects might not be noticed until days or weeks later.

18. There is the phenomena of neutron-induced radioactivity that should be mentioned. The neutron flux or cloud of high-speed neutrons that are driven in every direction from the atomic explosion has the property of inducing radioactivity in other substances, notably metals.

19. Several interesting oddities occurred in the Japanese bombings. In one case, during an autopsy, a Geiger Counter showed a high order of intensity when brought near the head of a corpse. Further investigation showed that the subject's gold teeth had become radioactive. In another case, a man who must have been some distance from Ground Zero in order to survive at all, showed up days later with severe burns from a metal key and a cigarette lighter he was carrying in his pocket. They had become highly radioactive from the neutrons emanated in the explosion.

20. The direct effect of pressure on the human body was actually at a minimum since the body is rounded, streamlined, so to speak, and there is little direct impact effect. Of 92 cases examined in Nagasaki, only 2 showed ruptured eardrums. Of 106 cases at Hiroshima, only three were so afflicted. There were very few cases of intestines and other internal organs being blown out, and those were of people so close to Ground Zero that they would have died in any case.

21. It must be remembered that the indirect effects of pressure were a tremendous factor in causing personal injuries. We do not know how many people were killed by falling walls, broken glass flying, ceilings coming down, or loose bricks sailing through the air. All in all, it is estimated that the non-radiological hazards, that is, the heat and blast effects, were responsible for 75 percent of the casualties. To that extent, the atom bomb acted just as a giant explosive fire bomb, which indeed it is, to some degree.

22. Another aspect is the radiation hazard of the atomic explosion. An understanding of these hazards is essential to insure adequate protection and reduce casualties.

23. All radiation is to some degree destructive, since it produces ionization in the atoms composing the cells and tissues of the human body. Ionization is the stripping off of one or more electrons from an atom, and radiation causes this to take place in the body. When a few cells in a given organ or tissue are affected, no damage is done, but when a few million atoms in a given tissue are ionized, damage to that tissue results.

24. When elements that emit alpha particles are taken into the body, whether by mouth, or inhaled, or introduced through wounds, the ionization is caused directly by the alpha particles emitted from the radioactive

[redacted]

atoms lodged in the body. Alpha particles cannot cause any trouble as long as substances emitting them are not taken into the body in some way. Beta particles have similarly poor penetrating properties and are essentially an internal hazard except for a caustic action on skin resulting from very high intensities.

25. On the other hand gamma radiation, X-rays and neutrons, all of which are emitted in immensely high intensities at the moment of the atomic explosion, (prompt radiation) can pass to the interior of the body, and cause wholesale ionization of atoms forming body cells, with consequent drastic tissue damage. These, therefore, constitute an external hazard.

26. The injury to tissues caused by radiation resembles that caused by nitrogen mustards.

27. As you can see, the ionization produced in the tissues is a direct measure of the damage done. There are some variable factors however:

a. Sensitivity of the particular tissue. The tissues which produce the red and white blood cells are most susceptible. Brain, and nervous tissue are least affected.

b. Ability of tissue to regenerate. Beyond a certain dose of radiation, all cells die, but with lesser amounts regeneration may take place, that is, the tissue may actually renew its destroyed portion. Muscle, brain, and eye tissue cannot regenerate. Liver, among others, can regenerate after almost complete destruction. In any case, however, repetition of radiation injury must be avoided.

c. Destruction and penetration. Radiation must reach vital tissues. Alpha particles have great energy but little penetration power in human skin. But, when alpha-emitting substances are ingested, the alpha particles given off cause grave damage within the tissues. Beta particles have considerably greater penetrating power and can produce greater penetrating power, and can produce skin irritations much like burns. It is when beta emitting substance are inhaled or ingested that damage is severe. The gamma rays penetrate deeply, as do the neutrons.

28. Now to consider radiation sickness in detail. It is an inescapable effect of overexposure to radioactivity. There are several definite effects.

a. On the Hair, Skin and Nails:

(1) The commonest effect of overexposure to radiation is loss of hair. In Hiroshima and Nagasaki, 75% of those within 1500 feet of Ground Zero who survived the blast, lost all the hair from the top of the head. Eyelashes,

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

eyebrows, and beard are rarely lost. Very little effect on pubic or under-arm hair. Hair lost grows in again if the individual survives other effects.

(2) The fingertips may show damage to the point where fingerprints are affected, though this would be seen only under conditions of long continuing low intensity exposure. Similarly, the nails in such exposure may show brittleness and lonitudinal ridging.

b. On the Gastro-Intestinal Tract:

(1) This includes the mouth, esophagus, stomach, and intestines, in a word, the path that food takes through the body.

(2) This is often the first system to show damage effects of radiation. In milder over-exposures there may be nausea, vomiting, and perhaps diarrhea. Cramps may be noted. In heavier exposures, severe nausea, vomiting, and bloody diarrhea occur.

(3) Ulcerations of the muccus membrane of the mouth will be seen. Post mortem examination will show such ulcerations extending through the entire digestive system.

c. On the Reproductive Organs:

(1) All males examined showed lack of spermatogenesis, that is production of living sperm cells. It was more than a passing effect, for the sperm counts of survivors were low for months.

(2) Loss of sexual urge for extended periods was generally claimed, as was lack of potency. Malnutrition was the cause of this impotency and not the effects of radiation. It is agreed by all that temporary sterility can be caused by radiation but not imptence.

(3) Effects on the female occurred in various forms. Usually there was normal menstruation the following month, but after that menstruation was inhibited for varying periods.

(4) Many pregnant women had miscarriages, possibly a radiation effect but primarily due to fear, worry, and malnutrition as contributing factors.

(5) Vaginal ulcerations were noted; a usual effect on mucous membrane.

[redacted]

[redacted]

(6) According to official statements, none of the expected mutations, that is, monstrosities or abnormal children have been born to survivors of the Japanese bombings. It is probabably too early to look for that sort of thing, but it is possible that the penetrating gamma rays may have brought about changes in the germ cells of a few survivors, and that these changes will eventually emerge. There is a long-range project in Japan for observing such effects, but so far, no abnormalities have been reported. It should be understood, however, that any such thing as future Japanese turning into two-headed people, and so forth, is improbable.

d. On the Blood Forming System:

(1) This consists of those organs which make or contribute to the making of blood. The red blood cells, the white blood cells, and the platelets are the most important cellular parts of the blood, and the developing cells of these are very sensitive to, and easily affected by radiation. Several definite effects follow:

(a) First, on the red blood cells. These are the cells which carry oxygen from the lungs to the tissues of the body, and carry carbon dioxide from the tissues to the lungs to be thrown off. When overexposed to radiation, the bone marrow which produces these red blood cells is damaged, and the result is anemia, of greater or lesser severity depending upon exposure.

(b) Next the white blood cells. These cells combat infection in the body by actually devouring invading bacteria, and "walling off" any points of entry of infection in the body. When the tissues that produce these white cells are damaged, the resistance of the body to stray infection is much reduced, and a person whose white blood cells are depleted falls an easy victim to disease. This condition is known as leukopenia.

(c) Then there are the platelets, which aid in the clotting of blood. Without them, or when their numbers are drastically reduced, the individual may hemorrhage from any small wound. Some Japanese had blood oozing from the unbroken skin due to platelet damage.

(2) Mortality figures indicate that destruction of these three types of cells is the most important single effect of radiation. With massive doses, all three

[redacted]

1613

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

elements are destroyed. With smaller doses, recovery may take place.

29. Now, a little more detailed discussion of the two types of radiation hazards. There are both external and internal hazards. These must be understood separately and in combination. External is defined as radiation from outside the body. Internal hazard refers to radioactive materials working from within the body after inhalation, ingestion, or penetration by other means.

a. External Hazards.

(1) Exposure to the atom bomb burst simulates overexposure to a giant X-ray machine. However, X-rays from a machine come normally from a point source, whereas with the bomb, the source is a large and expanding one. The difference is that radiation from a point source usually effects only one part of the body, whereas that from an extended source effects the entire volume of the body. Also, with the bomb, we have the deadly neutron flux, with a range extending over 800 yards.

(2) The accepted medico-legal tolerance dose that is set as a standard is .1 Roentgen units per day, that is, 100 milliroentgens. That is, we say that a man can safely take exposure to .1R per day indefinitely. Should he be exposed to, say, .2R in working with radioactive material, or on contaminated ground, that man should be kept away from radioactivity the day after. If he has exceeded his allowed .1R dose by .2, .3, or .4R, he should be kept out of contact with radioactivity for 2, 3, or 4 days as the case may be. That is, it is assumed that the body can throw off any damaging effect from exposure to .1R. For additional exposure a recovery time of one day per .1R must be allowed.

(3) Medically, as much as 2,000R can be used from a point source on a limited body area. It is claimed that as much as 14,000R has been used in treatment of brain cancer.

(4) The factors in external radiation having effect on extent of injury are:

(a) Size of Dose: In general, the greater the intensity of radiation, where the entire body is exposed, the greater is the absorption, and the more injury follows.
The accepted scale is as follows:

.1R per day. Completely safe. Our working tolerance.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(Following doses are assumed one-time total over a 2-week period)

.1R to 25R. Little risk.

25R to 100R. Some injury possible. Probably not incapacitation.

100R to 300R. Possible serious injury. Some early incapacitation. Some deaths, possibly delayed.

300R to 600R. Serious injury or probable death. Early incapacitation.

400R is LD 50. (Lethal dose for 50% of exposed personnel)

It is quite possible that the military wartime tolerance will be raised from .1R upward at some future time.

(b) Size of body area irradiated. This we have discussed. The greater the area, the greater the tissue damage.

(c) Energy of radiation: The greater the energy the greater the damage.

(d) Duration of exposure: This is not as important in itself as one might think. In general, one large all at once will do more damage than several smaller ones, all other factors being equal.

(e) Individual variations: Depending upon constitution, state of health, and other variables; some men die at 200R/day, others are known to have survived 500.

b. Internal Hazards.

(1) These hazards are well known from the radium industry. Radium coupounds, and many radioactive materials have a tendency to deposit in the bones, usually in the high-calcium portions, at which places the emission of alpha, beta, and gamma radiation works on the production of blood cells by the marrow in the bones. It results in a slow and rather unpleasant death. Some of you may may recall the case a few years ago where a group of women who had been employed as radium watch dial painters, slowly absorbed minute amounts of radium by pointing their brushes with their lips. They accumulated a fatal dose of radioactive salts, but it took them a few years to die.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(2) The hazard, of course, is from the fall-out after an air burst or the contamination following an underwater burst. Quantities of radioactive bomb material and raioactive fission products are carried downwind, and deposited on the earth often miles from the point of explosion. Precautions must be taken against inhaling any of this material, taking it in through the mouth, or getting it into open cuts or wounds. For that reason, under certain conditions such as dust, you may wear a gas mask in such a contaminated area, and you never eat, drink, or smoke until you are in an uncontaminated area.

(3) Looking at the over-all picture of casualties from radiation sickness in Japan, several general groups seem to be distinguished:

(a) Death occurring within first two weeks:

1. There were those who died immediately. There was a shock-like state, with weakness and general prostration. Such deaths were probably due to simple mass tissue destruction.

2. Those who lingered a few days or a week or more, didn't have time to develop all typical symptoms of radiation sickness. Patients showed nausea, vomiting, and possibly bloody diarrhea, but no loss of hair. Temperature rose and fell on a mounting curve, until death ensued.

(b) Death after six weeks. These cases were largely of people who survived above manifestations, and died of secondary infections, because of depletion of white blood cells and a variety of contributing factors.

(c) There were practically no deaths after six to eight weeks. General health appeared good in those who recovered, though our teams reached bombed cities too late for accurate assessment of all data. The possible incident skin cancer in the future is still in doubt.

(d) It is estimated that about 10% of fatal casualties could have been saved with adequate medical care. A possible course of treatment for future similar casualties is being developed. Extreme sterile techniques are indicated because of low white blood cell count of victims. Careful nursing is necessary, with special attention to skin. Generous transfusions of whole blood are indicated, as is use of certain vitamins.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

30. Summing up, the best avaiable statistics for both Hiroshima and Nagasaki indicate that blast and secondary injuries were responsible for between 50 and 60 percent of the casualties. Flash burns accounted for 20 to 30 percent more, and radiation sickness for about 15 percent. Those figures are necessarily approximations. We must suppose, also, that a goodly number of casualties were victims of blast, burns, and radiation, and even if the effects of blast and fire had been lacking, the casualties from prompt radiation would have been nearly as great.

31. This chart gives an over-all picture of death and injuries.

(INSTRUCTOR - REPRODUCE CHART 7-2)

It is intended to give you a general idea of what might occur and the order of magnitude for range of casualty effect that might reasonably be assumed.

32. To review briefly: At the moment of the atomic bomb burst, there are blast, heat, and prompt radiation. This prompt radiation is all considered as external hazard. Then, as the atomic cloud drifts downwind, and the unfissioned bomb material and fission products fall out, there is an invisible layer of radioactive material on the ground. This emits beta and gamma radiation which is an external hazard; it is also an internal hazard in that the very finely divided material may be breathed in, find entrance through wounds, or be swallowed, in which case the alpha and beta radiation given off does grave damage within the body.

33. Radioactive dusts, which can be used as a weapon, present the same picture as this residual contamination after an explosion, except that an enemy using them deliberately can pick a material that will keep an area uninhabitable for pretty much as long as he chooses - days, weeks, months, or years.

Are there any questions?

INSTRUCTOR'S QUESTIONS:

1. What effect does infra-red and ultra violet radiation have on the human body?

2. What effect does gamma radiation have on the human body?

3. What effect do alpha particles have on the human body when outside the body? When inside the body?

4. What effect do beta particles have on the human body?

5. What is the present tolerance dose of radiation?

6. What is meant by internal and external hazards?

TRAINING OUTLINE NO: 8

LECTURE: Review of Basic Arithmetic.

TIME: Fifty (50) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Any available arithmetic text.

STUDENTS' REFERENCES: Any available arithmetic text.

TRAINING AIDS REQUIRED: None.

Certain problems and procedures which arise in radiological defense work require mathematical calculations to arrive at an intelligent answer. These calculations are made more laborious by the fact that the large and small numbers, involving decimals, are involved. Experience has proven that the major difficulties encountered in this phase are due, not to complicated methods being involved but to errors in simple arithmetic. To brush up on this arithmetic a short review of the subject will be presented. In effect we are going to jump back to grammar school for an hour and study addition, subtraction, multiplication and division. Following this hour each student will be given a set of short problems to work similar to those covered in the review.

(INSTRUCTOR - REPRODUCE ALL EXAMPLES GIVEN IN THIS LECTURE)

a. Addition: Addition is the operation of finding the sum of two or more numbers. The simple addition of

$$2 + 2 = 4$$

presents no difficulties. Even the addition of

$$9 + 6 = 15$$

is very simple although the answer is a number consisting of two figures. The addition of larger numbers such as

$$29 + 76 = 105$$

requires closer attention however, since it is generally necessary to place them in a column, so

$$\begin{array}{cc} 2 & 9 \\ \underline{7} & \underline{6} \end{array}$$

add the right hand column first

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

```
 9
 6
15
```

record the figure 5, carry the figure 1 to the column next left and add it in there, thus

```
 2
 7
+1
10
```

and giving us a final answer of

```
(+1)
  2 9
  7 6
1 0 5
```

Errors are likely to creep in when we tackle a problem like the following

```
 278
   9
9593
  28
9908
```

since there is a tendency to forget the number carried to the column next left or to line the columns up incorrectly. The possibility of error increases when quantities like the following are dealt with

```
 278.13
   9.017
9593.003
  28.0
9908.150
```

since decimal quantities seem to be a stumbling block.

A decimal is a fraction whose denominator is 10, 100, 1,000 or any other power of 10. The denominator is not written, but is indicated by the position of the decimal point. For example

2.5 = 2 + 5/10
2.53 = 2 + 53/100
2.536 = 2 + 536/1000

Decimals should not be confused with common fractions such as 1/2, 1/4, 21/45 which have a denominator other than 10. Common fractions may be converted to decimals, however, through a process of division which will

[redacted]

be covered later.

With reference to addition of decimals the essential point is to carry the figures in columns to the RIGHT of the decimal point. Example

3.	0	0	1	2
8.	1	9		
5.	0	4	1	
2.	0	3	0	8
18.	2	6	3	0

The value of a decimal is not changed by adding zeros to the right of the figures. Thus

1.2 is the same as 1.20000

Therefore, for convenience, it would be permissable to write the above sums as

3.	0	0	1	2
8.	1	9	0	0
5.	0	4	1	0
2.	0	3	0	8
18.	2	6	3	0

in order that the proper arrangement of columns is made simpler.

The value of a decimal is changed by adding zeros between the decimal point and the left significant figure. Thus

0.2 is not the same as .02

and

$$\begin{array}{r} 0.2 \\ +\ 0.02 \\ \hline =\ 0.22 \end{array}$$

The cardinal rule to remember in addition is that whole numbers should be arranged with the columns in order from right to left while decimals are added with the columns in order from left to right using the decimal point as a guide.

b. Subtraction: Subtraction is the operation of finding the difference between two numbers. As such it is an exact reversal of the process of addition. The most frequent source of error lies in the following type of problem.

$$\begin{array}{r} 93478 \\ -24589 \\ \hline 68889 \end{array}$$

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

where it is necessary to "borrow" one unit from the column next left, so

```
         9 3 4 7 8
         2 4 5 8 9

first    9 3 4 6 (18)
         2 4 5 8   9
                   9

second   9 3 3 (16) (18)
         2 4 5   8    9
                 8    9

third    9 2 (13) (16) (18)
         2 4   5    8    9
               8    8    9

fourth   8 (12) (13) (16) (18)
         2   4    5    8    9
         6   8    8    8    9
```

and, involved in the actual subtraction, we forget "what" was "borrowed" from "where".

The best method of checking subtraction is to re-add the answer obtained with the number subtracted and see if we obtain the original quantity, thus

```
          ->  9 3 4 7 8    (subtraction)
         /   -2 4 5 8 9
        /     6 8 8 8 9
Same  <
        \     6 8 8 8 9    (check)
         \   +2 4 5 8 9
          ->  9 3 4 7 8
```

therefore, the answer, 68889, is correct. Again care should be exercised to line up the columns as outlined in the section on addition.

c. <u>Multiplication</u>: Multiplication is a process of wholesale addition. It is assumed that each student can recall the multiplication table up to the number 10. On this basis the straight-forward multiplication of two whole numbers is quite simple, as shown by the example

```
 283
 x47
```

first multiply through by 7

[redacted]

1623

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

```
 2   8     3
           7
14  56 (2)1
+5  +2
19(5)8            or 1981
```

then multiply through by 4

```
 2   8     3
           4
 8   32 (1)2
+3  +1
11 (3)3           or 1132
```

adding the two results with the second number set one column to the left

```
 1981
1132
13301
```

gives our answer.

Errors are more likely to appear in the following type of problem.

```
 258
x103
```

where one is undecided about how to handle the term 0. Multiplication by 0 yields zero and, while mathematicians would cry a protest, one convenient way to keep the columns in proper order is as follows:

```
  258
 x103
  774
 000
258
26574
```

The important rule is to move the result of each multiplication one column to the left of the preceeding multiplication before adding.

The final point to be covered on multiplication concerns multiplication of decimals. Several cases must be covered here. The first case is illustrated by the problem

```
 1.3
x2.6
```

Now neglecting the question of decimals for a moment, we carry out the actual multiplication and obtain

[redacted]

1624

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

```
 1.3
x2.6
----
  78
 26
----
 338
```

Obviously 338 is not the actual answer since we multiplied a number of less than 2 by a number less than 3. 2 x 3 is 6 and so our answer must be less than 6. The answer is actually 3.38, a figure obtained by counting the total number of significant figures to the right of the decimal points in the two numbers multiplied, thus

```
 1.3 (1)
x2.6 (2)
```

giving two figures. Now we go to the answer obtained, count off two places from right to left

```
3    3    8
  (2)  (1)
```

and place our decimal

3.38

Another typical problem would be

```
 3.24
 x1.7
-----
 2268
 324
-----
5.508
```

The second case involving decimals looks like this

```
 3.24
 x.03
-----
  972
 000
-----
.0972
```

and is handled in exactly the same manner.

A final case of decimals often shows up as

```
  .038
  x.21
------
   038
  076
------
.00798
```

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

and turns out as indicated. A word of advice is in order here. The last illustrated problem came out with five decimal places to be marked off in the answer but with only the three significant numbers. This is handled by placing as many zeros to the LEFT as necessary - in this case, two - and then placing our decimal point so

.00798

It might be well to point out what is meant by significant figures. If we take the number 2 as an example it is correctly written as

2.
or
2
or
00002.
or
2.00000000000

but the zeros are not significant. If we write 2 without the decimal immediately following and add a string of zeros, so

200000000

then the zeros are significant and the number is not 2 but 200 million. Specifically zeros added to the left of whole numbers are not significant and zeros added to the right of decimals are not significant.

Example 00002. and 2.13000000

Zeros added between the decimal point and the numbers of a decimal are significant.

Example .0013
.00 (00) 13 Significant
.0013 (00) Not significant

Zeros which are not significant should be dropped.

d. Division: Division is the process of finding how many times one number is contained in another. Division takes two forms; short division and long division.

Short division is the simple case where one figure is divided into any number. An example is

2 / 44
22

and another

2 / 4572

[redacted]

[redacted]

which is handled as

```
2/ 4      2/ 5           2/(1)7          2/ (1) 2
   2        2(plus 1)       8(plus 1)           6
```

and our answer is 2286.

To handle decimals in short division, it is only necessary to inspect the numbers involved and the answer is apparent

Example 6/343.8

```
6/ 34     6/ (4)3     6/ (1)8
    5           7           3
```

or 573 which is obviously 57.3. Since the answer when multiplied by 6 must yield 343.8.

Long Division is usually the stumbling block for most persons so it will be considered in some detail by means of numerical problems.

Example 1. Exactly divisible.

```
18/23526
```

Step 1. Estimate number of times 18 can be divided into 2. Answer is zero.

Step 2. Estimate number of times 18 can be divided into 23. Answer is 1. Mark up, Multiply 18 by 1, mark result down under 23 and subtract.

```
     1
18/ 23 ---
    18
     5
```

Step 3. Mark down next number to right

```
     1
18/ 23526
    18
    55
```

Step 4. Estimate number of times 18 can be divided into 55. Answer is 3. Mark up 3, Multiply 18 by 3, mark down result under 55 and subtract.

```
     13
18/ 235 - -
    18
     55
     54
      1
```

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

Step 5. Mark down next number to right.

```
       13
  18/ 23526
      18
       55
       54
        12
```

Step 6. Estimate number of times 18 can be divided into 12. Answer is zero so mark up zero and then mark down final number to the right.

```
       130
  18/ 23526
      18
       55
       54
        126
```

Step 7. Estimate number of times 18 can be divided into 126. Answer is 7. Mark up 7, multiply 18 by 7, mark down result under 126 and subtract.

```
      1307
  18/23526
     18
      55
      54
       126
       126
         0
```

Answer is 1307.
To check multiply 1307 x 18 and obtain 23526, the original number.

Example 2. Divisible with a remainder

```
      3 8 9 8
  12/46 7 6 2
     36
     107
      96
      116
      106
       102
        96
         6
```

Answer 3898 6/12
= 3898 1/2
or 3898.5

The method whereby 1/2 (a common fraction) was changed to 0.5 (a decimal) will be used as the next example.

[redacted]

Example 3. Division with decimal answer.

```
2/1
```

Step 1. Place decimal after 1 and add a zero. Now ignore decimal until later

```
2/1.0
```

Step 2. Estimate number of times 1 can be divided by 2. Answer is 0. Mark up 0 and estimate number of times 10 can be divided by 2. Answer is 5. Mark up 5, multiply 2 by 5, mark down result under 10 and subtract.

```
   0 5
 2/1.0
   1 0
     0
```

Answer is 05 but this is not the final answer since the decimal point must be located. To do this we count the number of places to the left of the decimal in the number divided, in this case one and then count off this same number from the right in our answer giving us

0.5 or simply .5

the final answer.

Example 4. Division with decimals.

```
          093.50          300/304
 3.04/ 284.2700
       2736
        1067
         912
         1550
         1520
          300
```

One additional point about determining decimal point location in the answer. In making the initial trial for a dividing number the trial should be made of the same amount of numbers as are in the dividing number.

Example 18.2/ 32715.003

Try dividing 182 into 327. If it will go (in this case, yes) put down the number (in this case, 1) and continue. If it will not go, as in the following case

18.2/ 108715.003

mark up a zero and then try dividing 182 into 1087.

Are there any questions?

TRAINING OUTLINE NO:	9
CLASS EXERCISE:	Practice on Assigned Mathematical Problems.
TIME:	Fifty (50) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	None.
STUDENTS' REFERENCES:	None. Students may use notes.
TRAINING AIDS REQUIRED:	Mimeographed problems, pencils, scratch paper.

1. Instructor will have the attached set of problems reproduced and will have each student work out the problems as a classroom exercise.

2. Problems should require about 35 minutes to complete, following which the papers should be collected and questions answered. Papers should be graded and returned to students.

3. Additional paper should be distributed for student to solve problems involving multiplication and division.

4. Answers from division problems involving decimals should be worked out to the second figure, other than zeros, after the decimal point.

[redacted]

TRAINING OUTLINE NO:	10
LECTURE:	Logarithms and Calculation of Multiple Half -life Decay.
TIME:	Fifty (50) minutes.
PLACE:	Classroom
INSTRUCTORS' REFERENCES:	Any available Algebra text.
STUDENTS' REFERENCES:	Any available Algebra text - Section dealing with logarithms.
TRAINING AIDS REQUIRED:	Mimeographed copies of Chart 10-3, pencils, scratch pads.

1. The existence of widespread radioactive contamination in the vicinity of an atomic explosion has been previously discussed. The fact that this contamination consists of a mixture of fission products, unfissioned bomb material and neutron induced isotopes has also been discussed. The fact that dozens of different isotopes decay simultaneously but each with a different half-like may be recalled from our discussion of radioactivity. Finally we now know that any person entering an area where he receives a dose of radiation greater than 100 milliroentgens per day may suffer harmful physiological effects. All of these points contribute to a problem encountered in radiological defense work that may be stated as follows:

a. "How rapidly will radioactive contamination decay to a point where personnel may safely reenter the effected areas for extended periods of time?"

b. A specific general answer cannot be given since no two atomic explosions are ever exactly alike; there is a general mathematical relationship, however, which is of value.

2. Assume that the data below have been taken at a point in the contaminated areas after two separate atomic explosions. This might well be the case if one explosion were underwater and the other near the surface of a land mass.

[redacted]

1633

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

EXPLOSION NO. 1

Time after Explosion	Measured Intensity
1 day	100,000 mr/day
2 days	35,300 mr/day
4 days	12,500 mr/day
10 days	3,170 mr/day
15 days	1,730 mr/day
20 days	1,130 mr/day

EXPLOSION NO. 2

Time after Explosion	Measured Intensity
1 day	400,000 mr/day
2 days	100,000 mr/day
4 days	25,000 mr/day
10 days	4,000 mr/day
20 days	1,000 mr/day

3. A glance at these data shows that after Explosion No. 2 the residual radiation, due to radioactive contamination, was more intense initially but that it decayed more rapidly than was the case for Explosion No. 1. When plotted as curves however we see that each curve has the same shape.

(INSTRUCTOR - REPRODUCE CHART 10-1)

Without going into involved mathematics it may be stated simply that because these curves have the same general shape, and because a general mathematical relationship holds for all such curves, that a general mathematical relationship exists for decay of radioactive contamination. This general mathematical relationship is

$$It^n = K$$

where:

I is the radiation intensity at time t

t is the time since the explosion

n and K are constants as determined by each explosion. These are different for each explosion.

4. This equation is quite simple but to use it for calculations requires a slight knowledge of exponents and logarithms.

a. Starting with the procedure for squaring and cubing numbers, if we want to square 2, the expression is written as

$$2^2 = 4$$

and if we wish to cube 2, the expression is written as

$$2^3 = 8$$

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

In other words, when we square a number, a, we raise the number a to the second power and when we cube a number, a, we raise the number a to the third power. The general form for raising any number, a, to any power x, is given by the term

$$a^x$$

which means merely that a is to be multiplied by itself x times, and this expression is mathematically the same as the term

$$t^n$$

in our decay equation. Now when the power, to which we wish to raise a number is an exact figure the process is quite simple - we simply multiply the number by itself as many times as the power indicates - as for example

$$2^6 = 2 \times 2 \times 2 \times 2 \times 2 \times 2$$
$$= 64$$

or

$$3^4 = 3 \times 3 \times 3 \times 3$$
$$= 81$$

but the case of

$$2^{2.61}$$

is something more complicated. Without mathematical derivation, let us say that this expression must be written as

$$2.61 \log 2$$

to get our answer. And that brings us to the matter of logarithms.

b. For our purposes, logarithms will be considered as auxiliary numbers: one auxiliary number existing for each real number and each auxiliary number being the sum of a number and a decimal fraction.

$$\text{Log N} = (\text{a number}) + (\text{a decimal fraction})$$
$$= \text{characteristic} + \text{mantissa}$$

The characteristic indicates the order of magnitude of the numbers involved. These characteristics are as follows for positive numbers:

No.	Characteristic
1 - 9	0
10 - 99	1
100 - 999	2
1000 - 9999	3
10,000 - 99,999	4

We will not consider the case of negative numbers in this course.

[redacted]

[redacted]

c. Mantissas are determined by use of Chart 10-2

(INSTRUCTOR - PASS OUT CHART 10-2)

To find the mantissa of a number, say 283, locate the first two figures of the number, 28, in the left hand column; then go horizontally right until the third figure of the number, 3, is lined up vertically. The answer, 451, is read at the intersection.

Examples of the logarithms of several numbers are:

			Characteristic		Mantissa
log 300	= 2.477	=	2	+	.477
log 23	= 1.361	=	1	+	.361
log 8745	= 3.941	=	3	+	.941
log 100	= 2.000	=	2	+	.000

Conversely, when dealing with these auxiliary numbers, it is necessary to transpose them back to actual numbers. Thus if we have the logarithm

1.426

it is necessary to obtain the number which it represents. To obtain the number we take the mantissa, 426, and look it up in the table, obtaining 267 - which is our number. The characteristic of 1 indicates that the number is of magnitude between 10 and 99, which immediately shows that the number is

26.7

This number we call the anti-log.

Now let us work out a problem wherein we make use of these logarithms. Reference is made to the original example of

$2^{2.61}$ or (a^x)

which was rewritten as

x log a
or
2.61 log 2
now log 2 = 0.301
and (2.61) (0.301) = 0.301

```
  0.301
   2.61
  -----
   0301
  1806
 0602
 ------
0.78561
```

or 0.785

which when converted back to the actual number - or as we say "take the

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

antilog" - gives

6.1

as the actual number or antilog and this is the method with which we calculate our term

$$t^n$$

in the decay equation.

With these new tools at our disposal, the multiple decay equation

$$It^n = K$$

becomes quite simple to handle. To facilitate our work a form worksheet

(CHART 10-3)

will be used. By carefully performing, in numerical order, the indicated steps no difficulties should be encountered.

5. To use this equation the following steps are performed:

(INSTRUCTOR - WORK ILLUSTRATIVE PROBLEM USING NO. 1 SET OF DATA)

a. As soon as possible after the explosion, obtain a reading with a survey instrument. Record the intensity in R/Day and the time since zero hours in days. Example, if it is 36 hours since zero hour, record the time as 1.5 days.

b. At a later time when there has been an appreciable reduction in intensity (minimum reduction of approximately 5 R/Day) take a second reading, record intensity and time in days SINCE ZERO HOUR.

c. Carry out calculations on worksheet down to Item 14.

d. Now the decay equation may be used to answer the question, "when will the contamination decay to a certain safe value?" We take the value that we want to know (normally 0.1 R/Day) and enter it as Item 14.

e. Calculations are carried out and Item 18 gives the time in days since Zero Hour when the intensity desired will be reached.

(INSTRUCTOR - When this has been completed, the students should be required to work out a problem utilizing data from Explosion No. 2.)

TRAINING OUTLINE NO:	11
LECTURE:	Preparation of Instrument Calibration Curves.
TIME:	Fifty (50) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	Any Algebra text; Paragraph 9.12, Radiological Defense Manual, Volume 1. (See Footnote*)
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Charts appended hereto.

1. It should be apparent by this time that the presence of high energy radiation can not be felt, tasted, smelled or heard by an individual. To detect the presence of and measure the intensity of radiation, we must rely on radiation detection instruments.

2. The types, operation, calibration and use of these instruments will be covered during later phases of instruction. Without going into a discussion of the "why" at this time, it is a fact that these instruments do not read, directly, the true intensity of the radiation which they measure. Because of this fact we must determine the true value of the readings observed on an instrument and this process is called instrument calibration. The need for instrument calibration may be illustrated by the following example.

(INSTRUCTOR - REPRODUCE CHART 11-1)

A properly functioning instrument placed at Point A will read, say, 7.5 R/Day, and if the same instrument is placed at Point B, it probably will read about 1.8 R/Day. If we take a different instrument and place it at the same two points, A and B, the readings obtained will be different from both the true values and the values obtained with the first instrument.

3. This situation is undesirable since we want to be able to take any instrument, go to Point A and obtain the correct reading of 8.0 R/Day. To calibrate instruments, we compare their observed readings against a source of radiation; the intensity of which radiation is always constant

*A Victoreen 263A G-M Survey Meter should be demonstrated to aid the students in understanding how calibration curves fit into the general picture of radiological defense work.

[redacted]

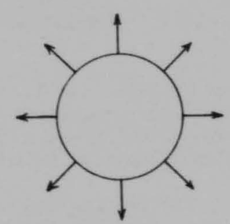
1641

[redacted]

and reproducable. The difference between the observed instrument values and the true values can then be determined and thereafter applied as a correction factor to that particular instrument.

4. To find a source of radiation, the intensity of whose radiation is always constant and reproducable, is not difficult. Gamma radiation from the element Radium has been chosen as a standard for instrument calibration work. Some discussion of the behavior of radiation from a radioactive source must be given, however, before an intelligent discussion of calibration curves can be undertaken.

5. Radiation from a radioactive source travels in all directions from that source in this manner:



6. The intensity of this radiation at any point is found to be related to

a. The quantity of radioactive material present.

b. The distance away from the point at which the radioactive material is located. We find also that as we get farther away from a source, the intensity of radiation falls off very rapidly to an insignificant value. The mathematics of this relationship is best illustrated by means of a chart.

(INSTRUCTOR - REPRODUCE CHART 11-2)

7. The equation

$$I = \frac{CM}{D^2}$$

is a formula which we use for calibration work to calculate the true value of radiation intensity. Each term in the formula is defined as follows:

a. I is the radiation intensity at any point A and is (Refer to Chart 11-2) expressed in any units which we choose. These units are normally R/Day.

b. C is a constant the numerical value of which depends on the units in which we wish our answer expressed. If I is in R/Day the value

[redacted]

1642

THIS PAGE IS DECLASSIFIED IAW EO 13526

of C will usually be 0.024. Pertinent values of C are shown in Chart 11-3.

c. M is the weight of the radium source which we use as a standard. This weight is expressed in milligrams, to the nearest hundredth of a milligram. A typical source would be 57.38 mg. in weight. The larger this source, the greater is the intensity of radiation therefrom.

d. D is the distance between the radium source and point A. This distance is normally expressed in yards but other units may be used if C is changed accordingly. It is of interest to note how radiation intensity vaires with distance since distance is our best protection against radiation hazards from an atomic bomb. The following chart will illustrate the point clearly.

(INSTRUCTOR - REPRODUCE CHART 11-4)

Thus we see that by increasing the distance between a source and ourselves from 1 yard to 4 yards causes a decrease in the radiation intensity to 1/16 of its value at 1 yard.

8. Actual instrument calibration work is carried out on a "calibration course" with a radium source whose size is known. This chart indicates how typical calibration course might look.

(INSTRUCTOR - REPRODUCE CHART 11-5)

9. Instrument calibration procedure is carried out in the following manner:

a. A data sheet similar to the following is prepared.

(INSTRUCTOR - PASS OUT CHART 11-6)

b. The radium source is placed at zero point and its weight, in milligrams (mg), recorded.

c. Instrument is placed in operation and, beginning at the marking most distant from the source and working toward the source, readings are obtained. We start at the outer edge because the radiation intensity is low and there is no danger of damaging the meter by running the needle off scale.

d. Readings are obtained for each scale of the instrument. There should be a minimum of six readings per scale; these readings to be spread evenly over the scale. The scale is normally a 1-20 scale.

e. Each reading, with the distance from the source at which the reading was obtained, is recorded.

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

f. The actual radiation intensity at each point where readings were obtained is calculated by means of our formula

$$I = \frac{CM}{D^2}$$

g. Finally we come up with a set of data which might look like these

(INSTRUCTOR - REPRODUCE FOLLOWING TABLE)

SIZE OF SOURCE - 256.00 Mg

No. 1 Scale Reading	No. 2 Scale Reading	Yards From Source	Calculated Intensity (R/D)
18.25		1.0	0.59
14.80		1.25	0.38
11.90		1.5	0.26
9.50		1.75	0.19
7.75		2.0	0.15
4.30		3.0	0.07
2.30	17.30	4.0	0.04
1.50	12.50	5.0	0.02
	9.50	6.0	0.016
	7.80	7.0	0.012
	6.50	8.0	.009
	5.00	9.0	.007
	4.10	10.0	.005
	3.20	11.0	.004
	2.80	12.0	.003

C = .024

and we are ready to produce a calibration curve.

10. A detailed mathematical investigation of curves will not be made. Let us consider a curve as an unbroken line composed of a very large number of individual points and each point having some definite value with respect to two perpendicular axes.

(INSTRUCTOR - REPRODUCE CHART 11-7)

11. On the chart we see that Point A has a definite value with respect to the X-axis and with respect to the Y-axis. Point B has definite values also. If we obtain several points and plot them in proper relation to the X and Y axes we may simply draw a smooth continuous curve through all points since all the points are related to one another, and say that this curve represents the relationship between all points.

(INSTRUCTOR - MODIFY CHART 11-7 TO LOOK LIKE CHART 11-8. DO NOT INCLUDE THE DOTTED PORTIONS AT THIS TIME)

[redacted]

1644

[redacted]

Specifically, this means, as shown by Chart 11-8, that all points on the curve satisfy the general mathematical relationship which points A, B, C, D, and E do. We can use this type of curve when we know the y value of a point, to determine what the x value of the point is. This

(INSTRUCTOR - ADD DOTTED LINES TO CHART 11-8)

is what we need for our calibration curves.

12. Since these curves are to be our aids in the matter we may assign values to the axes as suits our inclination. It is customary to assign the horizontal (x) axis for measuring true radiation intensity values while the vertical (y) axis is used for instrument readings, with convenient values assigned thereto. Graph paper is used to plot the curve. It is well to point out here that several curves may be plotted on one piece of paper with two or three scales for one axis. This will be the case with our sample data. Now, referring to these data, we see that the one vertical scale for instrument readings will have to cover a range from somewhere around 1.0 to somewhere over 18.25. 0 to 20 is a convenient choice. For the horizontal scales, true radiation intensity, two selections must be made; one for each instrument scale. For Scale No. 1 a choice of 0-0.6 R/Day is obvious, while Scale No. 2 will nicely fit a 0-0.05 R/Day subdivision. These scales are marked in and each point plotted from the data. When all the points from one scale have been plotted a smooth curve should be drawn and titled. This procedure is then repeated for the second scale.

(INSTRUCTOR - WORK OUT PROCEDURE FROM DATA AND DRAW CURVES TO ROUGH SCALE ON BOARD)

13. These curves are used to tell us the true value of an instrument reading. For example - if we have an instrument set on the No. 1 scale and obtain a reading of 10, we refer to the proper curve; locate 10 on the vertical axis, go horizontally right until the curve for No. 1 scale is intercepted, drop vertically to the x axis and read our answer as 0.36 R/Day. This figure is the true radiation intensity.

Are there any questions?

TYPICAL CURVE

[redacted]

TRAINING OUTLINE NO:	12
CLASS EXERCISE:	Student Preparation of Instrument Calibration Curves.
TIME:	Fifty (50) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	Training Outline #11. (See Footnote*)
STUDENTS' REFERENCES:	Notes from Training Outline #11 period.
TRAINING AIDS REQUIRED:	Scratch paper, graph paper, colored pencils, mimeographed data sheets (Chart 11-6 from Training Outline #11) and rulers.

1. This period is devoted to a class exercise wherein each student will plot a typical calibration curve for a 263A Geiger meter. The following procedure will be followed:

a. Pass out scratch pads, graph paper, colored pencils and data sheets to the students.

b. Instructor will make one sample intensity calculation and have students make all others. Use the equation

$$I = \frac{CM}{D^2}$$

with C = 1, M = 53.5 mg and D in yards so that I will be in units of mr/hr

Ex. I at 2 yds

$$I = \frac{(1)\ (53.5)}{(2)^2} = 13.4 \text{ mr/hr}$$

*This period should be conducted as a group performance exercise. The instructor should outline the steps to be followed and have each student complete one step before proceeding to the next. Each student should be provided with a straight edge, 3 colored pencils, one or two sheets of rectangular coordinate paper, scratch paper and two or three drawing curves should be available for use by the class. The calibration course data should be presented in tabular form on the blackboard, a chart or a mimeographed sheet. Attached as Chart No. 12-1 is the calibration curve plotted from these data, and is for use by the instructor in grading student work.

[redacted]

1654

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

2. When the students have completed the calculations, the instructor will call off the correct values as shown in Chart No. 12-2.

3. Instructor will then have students rule off graph paper with the y-axis as the scale readings and with the x-axis as the radiation intensity. Three scales will be used for the x-axis. These scales should be numbered as shown on Chart No. 12-1.

4. The students should then be instructed to plot the points for each scale, using a different colored pencil for each scale, and draw a smooth curve through each.

5. Finally the calibration curve should be labeled, turned in and graded for accuracy and neatness.

TRAINING OUTLINE NO: 13

LECTURE: Principles of Radiation Detection Instruments.

TIME: One (1) hour.

PLACE: Classroom

INSTRUCTORS REFERENCES: "All Hands", 1 July 1946, Navy Department; Paragraphs 9.01-9.12, Radiological Defense Manual, Volume 1; Chemical School Memo 202, 22 June 1948; Chapter 17, AFRTC Manual 52-355-1, Dept of the Air Force, May 1949; "Medical Aspects of Nuclear Energy", AFSWP, NME, 1949.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Charts appended hereto.

1. The detection and measurement of high energy radiation depends entirely upon the proper use of suitable instruments. Without instruments even intense radiation fields will not be discovered and irreparable injury to personnel may result. It is, therefore, of utmost importance that all persons making radiation measurements have a thorough understanding of the principles of operation and of the limitations of the available instruments. Furthermore, an individual must interpret meter readings in terms of the specific instrument used. Dangerous errors can easily be made by an individual ignorant of the principles incorporated into the instrument design.

2. Excepting photographic film all detecting devices function by measuring the ionization produced in gases by high energy radiation passing through the gases. It is well, here, to repeat that ionization is a process wherein orbital electrons of the gaseous atoms are ejected from the neutral atoms by high energy radiation passing through their orbits, whereupon these ejected electrons fly over and arbitrarily attach themselves to other neutral atoms. As a result we have two electrically charged atoms where there were two electrically neutral atoms to begin with. The atom from which the electron was ejected, is left with a positive electrical charge since one of its positively charged protons no longer has a negatively charged electron to balance it. The atom to which the ejected electron arbitrarily attached itself becomes negative since it now has one excess negatively charged electron. The importance of this situation lies in the fact that electrically charged atoms are affected by magnetic and electrical fields whereas neutral atoms are not.

3. In the case of the horseshoe magnet, one pole of the magnet is called the positive pole while the other pole is known as the negative

[redacted]

1658

pole. Now is two horseshoe magnets have their poles touching, a curious thing happens. If positive poles of the two magnets are placed together there is a strong repulsive force exerted between the two poles, whereas if a positive pole of one magnet is placed to a negative pole of the other magnet there is a strong attractive force exerted between the two poles. This illustrates the fact that like charges repel and unlike charges attract. The concept of electrical fields is not so apparent as that of magnetic fields but both act in the same manner.

4. These facts are of interest to us because electrical fields can be used to make ionized (charged) atoms move in any desired direction or with any desired velocity. When the ionized atoms, formed in a gas by high energy radiation, are subjected to an electrical field, they will move apart in opposite directions. The negatively charged atoms will move toward the positively charged anode (positive plate) and the positively charged atoms will move twoard the negatively charged cathode (negative plate).

(INSTRUCTOR - REPRODUCE CHART 13-1)

When these ions reach the plates each negatively charged atom will give up its spare attached electron. These spare electrons go into the anode (positive plate). The positively charged atoms simply pile up at the cathode, however.

(INSTRUCTOR - REPRODUCE CHART 13-2)

From the plate the spare electrons are made to travel through a circuit to the cathode (negative plate) where they recombine with the positively charged atoms to become neutral atoms once more. The flow of electrons in a circuit generates an electric current which may be measured with a meter. The rate of flow of the electrons in the circuit determines how large an electrical current is generated. Likewise the rate of flow of the electrons in the circuit is determined by the intensity of the high energy radiation which ionized the atoms in the first place. Therefore, it may be seen that there is a definite relationship between the intensity of radiation and the amount of ionization which it produces. This relationship is the basis of all radiation detection instruments.

5. One type of instrument we call the Geiger-Mueller or Geiger Counter Instrument.

6. A Geiger counter is constructed essentially in the manner shown on the following chart.

(INSTRUCTOR - REPRODUCE CHART 13-3)

The counter consists of two plates; the cathode which is a metal cylinder and the anode which is a fine metal wire inside the cylinder. These two plates are separated and surrounded by an inert gas under low pressure; the entire assembly being enclosed by a sealed glass envelope. By means of a high voltage battery the plates are kept charged and a very strong electrical field exists between the two plates. When high energy radiation penetrates the glass envelope and ionizes the gas therein, negative ions flow to the anode and for a fraction of a second the circuit is complete. The source of high voltage causes an instant surge of heavy current, the mechanical register indicates a pulse and a click is heard in the speaker. The large resistor in the circuit then cuts the current flow to such a small value that the gasious ions are no longer attracted to the plates. The circuit is then broken, the instrument goes dead for a very short instant while the electrical field between the two plates is reestablished and then the process is repeated. Each time this cycle occurs we get appulse or click on the indicating portion of the meter, and the meter is said to have "fired".

7. The greater the intensity of the radiation, the closer together these ionizing "bursts" occur and the greater will be the number of pulses or clicks obtained. We can approximate the intensity of the incident radiation by the meter reading obtained or the number of clicks counted. Further, we can place screens around the thin glass envelope and filter out beta particles so that only gamma radiation will be measured. Alpha particles are not normally measured since they will not penetrate even the thinnest of glass envelopes. Geiger counters are therefore used to measure only Beta and/or Gamma radiation of fairly low intensity.

8. Only low intensity beta and gamma radiation may be measured with Geiger counters because of the "dead instrument time" previously mentioned. With high intensity radiation so many counts are missed (while the instrument is "dead") compared to the number of counts counted (while the instrument is "alive") that the results become meaningless. Therefore, Geiger counters are not satisfactory for measuring radiation intensities greater than about 20 mr/hour (0.4 R/day).

9. Measurement of extremely high energy radiation is accomplished by means of ionization chamber instruments. These instruments make use of cylindrical containers (or chambers) in which the ionized atoms are collected on a plate and manipulated to set up a current in a circuit.

(INSTRUCTOR - REPRODUCE CHART 13-4)

10. Without delving into electronic circuits the principle of operation may be explained as follows:

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

a. The meter circuit is fixed so that, when no ionization is occurring, the current passing through the vacuum tube is constant and the meter indicates zero.

b. Radiation causes ionization in the ionization chamber and negative ions go to the plate (anode).

c. These negative ions cause a current flow in the ionization current circuit. This flow affects the vacuum tube in the meter circuit.

d. The vacuum tube allows the meter circuit to become unbalanced and the meter registers the degree of unbalance.

e. By proper adjustment of all factors the meter can be made to measure the intensity of radiation passing through the ionization chamber.

11. It should be understood that there are no pulses in an ion chamber instrument and clicks cannot be heard. The readings are not, therefore, dependent on counting of pulses and these instruments have no "dead time". For this reason they are very accurate for measuring high intensities of radiation. Due to certain characteristics, however, they <u>are not</u> used to measure <u>alpha or beta</u> radiation but only <u>for gamma radiation</u>.

12. It is possible to measure up to several hundred R/Day with these ionization chamber instruments.

Are there any questions?

INSTRUCTOR'S QUESTIONS:

1. Geiger counters may be used to measure what two types of radiation?

2. What is the highest radiation intensity that can be measured with a Geiger counter?

3. What general principle do all detection instruments, except photo film, work on?

4. Ionization chambers may be used to measure what type of radiation?

5. Is a Geiger counter or ion chamber more accurate for measuring gamma radiation?

6. How high a radiation intensity may be measured with an ion chamber?

TRAINING OUTLINE NO:	14
CLASS EXERCISE:	Operation of 263A G-M Survey Meter.
TIME:	One Hundred (100) minutes.
PLACE:	Classroom and outdoor area.
INSTRUCTORS' REFERENCES:	Technical Manual on 263A Survey Meter, Victoreen Instrument Company. (See Footnote*)
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Charts appended hereto, 263A G-M Survey Meters, radium source.

1. The 263A G-M Survey Meter is a portable instrument for measuring the intensity of beta and gamma radiation. The detecting device is a 900 volt Geiger tube. This tube is of thin wall glass construction to permit the measurement of beta particles.

2. Physical characteristics of the instruments are as follows:

(INSTRUCTOR DEMONSTRATE INSTRUMENT)

- a. Height - 10 inches.
- b. Width - 3 1/4 inches.
- c. Length - Exclusive of probe, 12 inches.
- d. Probe Opening - 2 x 2 1/2 inches.
- e. Beta Shield - 1/32 inch brass.
- f. Weight - 12 pounds.
- g. Finish - Gray enamel.
- h. Indicating Meter - 3 inch scale.
- i. Probe - 1 1/2 inches in diameter by 9 inches long and connected to the instrument by a four foot cable. Normally clamped to the front of the instrument case.

3. The principal parts of the meter are the case,

(INSTRUCTOR REPRODUCE CHART 14-1)

*This period is to be used to familiarize the student with the operation of a Victoreen 263A G-M Survey Meter. After each student has had an opportunity to operate the instrument under the supervision of an instructor, the second period should be devoted to obtaining average background counts and practicing an audio survey. Meter readings will be assumed correct for this period.

[redacted]

[redacted]

containing the batteries and wiring; a probe, containing the Geiger tube; an indicating meter, which is mounted in the case and indicates radiation intensities; a range switch which turns the meter on and allows selection from one of three intensity ranges (Range 0.2 is from 0 to 0.2 mr/hr, Range 2 is from 0 to 2 mr/hr and Range 20 is from 0 to 20 mr/hr; a phone jack which allows use of headphones, and an instrument calibration control adjustment screw which will not be tampered with. The probe has a beta shield which is closed when only gamma intensity is to be measured. Headphones are used to obtain background counts and to detect small changes in intensity which the meter will not differentiate. These instruments are quite sensitive and register the cosmic radiation which is continually bombarding all of us. This cosmic radiation causes a "count" or clicking noise to be heard in the headphones when no other radiation is present. This count is known as the background count and is fairly constant in any one area **THAT IS NOT CONTAMINATED WITH RADIOACTIVITY.**

4. Like all instruments, these meters are subject to ailments and should be checked before being used or calibrated. This check is very simple and is as follows:

a. Plug in earphones.

b. Turn range switch to the 20 scale, then to the 2 scale and then to the 0.2 scale. If the needle on the indicating meter swings to the 20 mark and stays there on any scale the instrument is defective and should be shut off at once.

c. If on the 0.2 scale an irregular clicking noise is heard and the needle on the indicating meter fluctuates between 0 and 5 the instrument may be satisfactory.

d. Readings of over 5 may indicate either the presence of radioactivity, instrument contamination or moisture in the instrument. This does not necessarily render the instrument useless but does indicate low sensitivity and therefore poor accuracy.

e. The beta shield should next be opened and the probe exposed to a source of strong light (i.e., sunlight if possible). A sharp increase in background count indicates that the Geiger tube is light sensitive and the instrument can only be used to measure gamma (with beta shield closed).

f. Constant needle fluctuation should not be taken as a sign of malfunctioning.

g. Following these checks one spot calibration check should

[redacted]

[redacted]

be made against some known source such as a luminous wrist watch which has previously been calibrated. Serious deviation indicates the recalibration of the instrument must be carried out.

5. Operating procedure is carried out in the following manner:

a. Background Measurement.

(1) Switch to 0.2 range. Meter should indicate less than 25% full scale.

(2) Plug in headphones.

(3) Observe a stop watch or wrist watch with sweep second hand. If a watch with luminous dial is used the body should be used as a shield between the watch and probe.

(4) Count the number of "clicks" in the phones for a one minute period. Repeat several times. The scale reading should be noted also for future reference.

b. Gamma Measurement.

(1) Close beta shield on probe and plug in earphones.

(2) Turn range switch to 20.

(3) Place instrument with probe in the location to be measured.

(4) If reading is less than 10% of full scale, switch to 2.0.

(5) If reading is still less than 10% of full scale, switcheto 0.2.

(6) Watch indicating meter for about 30 seconds to determine the average reading. This is very important on the 0.2 scale.

(7) Read the meter and record data.

c. Beta Measurement.

(1) Remove the probe from its brackets and place it in the desired location. This is very important in beta measurement.

(2) Repeat gamma measurement procedure outlined above but with beta shield open. Record reading. (This is beta

[redacted]

[redacted]

plus gamma reading.)

(3) Close beta shield and take gamma measurement with probe in the same location. Record reading. (This is gamma only reading).

(4) Beta intensity is obtained by subtracting reading (3) from reading (2).

d. Audio Survey.

(1) Decide upon the level of intensity above which a careful measurement should be made. It is recommended that 0.1 mr/hr be used.

(2) Plug in earphones.

(3) Switch to 0.2 range.

(4) Place a radium sample or other source of radiation at a distance to give the level of intensity selected in (1) above.

(5) Listen to the signal to become accustomed to the noise level and pulse repetition rate.

(6) Move the probe back and forth toward and away from the sample. Notice carefully the difference in the audio signal as the intensity is increased or decreased.

(7) Close your eyes and have someone move the sample a short distance.

(8) Try to reproduce the distance (4) above between the sample and the probe, within 10%, using only the audio signal as a guide.

(9) When (8) can be accomplished easily, audio surveys can be made with a degree of confidence and in much less time than in any other manner. Attempts have been made to cover a wide range of intensities in audio surveying but the one point comparison method is the only satisfactory one.

e. Recording Data. Many operations involving the measurement of radiation have been hampered by loss of information due to incomplete and improper recording of data. If data sheets are not provided, a monitor should make up his own before starting a survey. The following information must be recorded on each data sheet:

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(1) Date.
(2) Time.
(3) Place.
(4) Instrument model and serial no.
(5) Identification of source.
(6) Position of probe with respect to source.
(7) Position of beta shield.
(8) Position of range switch.
(9) Meter reading.
(10) Units of measurement.
(11) Background reading.
(12) Comparison standard reading.
(13) Identification of standard sample.

6. Those items which are the same for all measurements can be incorporated in the data sheet heading. The other items can be listed as column headings.

Are there any questions?

INSTRUCTOR'S QUESTIONS:

1. What types of radiation does the 263A Survey Meter detect?

2. What radiation intensity does the 0.2 Range of the 263A measure? The 2.0 Range? The 20 Range?

3. What is background count?

4. How is a Geiger tube checked for light sensitivity?

5. How do we differentiate between beta and gamma radiation with the 263A?

6. What is the procedure for making an audio survey?

The balance of the period will be devoted to obtaining background counts.

The second period will be devoted to practice audio surveys.

[redacted]

TRAINING OUTLINE NO:	15
EXAMINATION:	I
TIME:	One Hundred (100) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	Training Outlines 2 to 14, all previous references, Instructor's Answer Guide. (See Footnote*)
STUDENTS' REFERENCES:	Lecture notes from Training Outlines 2 to 14.
TRAINING AIDS REQUIRED:	Copies of Examination I, Copies of Chart 10-2.

<u>INSTRUCTIONS</u>:

1. Use of students' notes is permissible.

2. All questions can be answered in one short sentence or less.

3. Check your paper for completeness - there are <u>25</u> questions in this examination.

<u>QUESTIONS</u>:

1. What are isotopes?

____

____

2. All atoms (except Hydrogen 1) contain three kinds of particles. What are these three kinds of particles?

a.______________ b.______________ c.______________

3. The chemical nature of an atom is determined by one factor. What is this factor?

____

*Students should be permitted to use their notes. At completion of examination, the questions should be reviewed and the correct answers given.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

4. The necleus of an atom weighs about 1% less than it should. Why is this of interest to us?

____

____

5. The term "high energy radiation" is useful to us. Define this term.

____

____

6. There are many types of electro-magnetic radiation such as infra-red, ultra-violet and X-rays. In what one way are these types of radiation different?

____

7. Name four kinds of "high energy radiation". (Do not confuse with types of electro-magnetic radiation)

a.______________ b.______________

c.______________ d.______________

8. Radioactive isotopes spontaneously liberate energy. What is this process called?

____

9. Define the term "ionization".

____

____

10. What do nuclear reactions represent?

____

____

11. Three distinct things happen when a U-235 atom is struck by a neutron "bullet". What are these three happenings?

a.______________________________

b.______________________________

c.______________________________

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

12. There are two types of neutron induced reactions. What are these two types?

a. ____________________

b. ____________________

13. What is meant by the term "critical mass"?

____

____

14. Following an atomic explosion, there is lasting radioactive contamination. This contamination comes from three sources. What are these three sources?

a. ____________________

b. ____________________

c. ____________________

15. What is meant by the term "fall-out"?

____

____

16. When an atomic bomb explodes there are three instantaneous effects. What are these three effects?

a. ____________________

b. ____________________

c. ____________________

17. What is the daily permissible tolerance dose of radiation?

____________________ R/Day

18. What is the equation

$$It^n = K$$

useful for?

____

____

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

19. Why is it necessary to calibrate radiation detection instruments?

____

____

20. Calculate the radiation intensity at a point which is 10 yards from a 256.00 mg Radium source. C = .024

____

21. What two kinds of high energy radiation may be measured with a Geiger counter?

a. ____

b. ____

22. What is the highest radiation intensity that can be measured with a Geiger counter?

___________________________ mr/hr (approximate)

23. With the exception of film badges, all radiation detection instruments operate on one principle. What is this principle?

____

____

24. What kinds of high energy radiation can be measured with an ion-chamber instrument?

____

____

25. An atomic bomb explodes at 1200 hours on 15 July. Exactly 24 hours later a reading of 200 R/Day is obtained in one affected area. This same area reads 9 R/Day at 1200 hours on 27 July. When will this area read 0.3 R/Day? (Use attached worksheet)

[redacted]

TRAINING OUTLINE NO:	16
CLASS EXERCISE:	Student Calibration of 263A Survey Meters.
TIME:	One hundred and fifty (150) minutes.
PLACE:	Classroom and Instrument Calibration Course.
INSTRUCTORS' REFERENCES:	Paragraph 9.12, Radiological Defense Manual, Volume 1. (See Footnote*)
STUDENTS' REFERENCES:	Notes from Training Outlines No. 11, 12 and 14 periods.
TRAINING AIDS REQUIRED:	Data sheets, clip-boards, 263A Survey Meters, headphones, radium source, graph paper, rulers, colored pencils and scratch paper.

1. Students will draw equipment and assemble in the classroom. They will be briefed on the general procedure for obtaining data as outlined in Training Outline #11. The size of the radium source will be given. Data sheets should be passed out or drawn up. The following points on technique should be covered:

a. Calibration is done with the beta shield closed.

b. The instrument should be placed on the floor with the probe directly facing the source.

c. The center of the probe should be placed directly over the distance marker.

d. Each meter reading recorded should be the average reading obtained over a 30 second period.

*This exercise is based on the assumption that a gamma radium source is available and that a calibration course has been marked off prior to the start of the period. The size of the source available will determine the amount and sub-divisions of distance required. Too much emphasis cannot be placed on prior preparation for this period. Students should be able to draw instruments, proceed to the calibration course and begin obtaining readings at once. They should not be hampered by lack of distance markers or by poor placement of these markers. Specifically, markers should be so placed that one is available for each point at which a scale reading is desirable. Data should be taken for each of the three ranges and a set of three calibration curves prepared on the spot. These curves should be checked by the instructor for accuracy and graded.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

e. Care should be exercised that personnel do not come between the source and the probe. Likewise, luminous wrist watches should not be worn.

f. Readings obtained less than one inch from a source are meaningless.

g. Readings on the extreme ends of the scale are not accurate.

2. Following this, students should proceed to the calibration course, obtain readings and record data.

3. Finally, students should return to the classroom and prepare a calibration curve. This should be done as outlined in UGRD-14 with the plot being made of actual intensity vs scale reading and a smooth curve drawn, using a different color for each meter scale. This curve will be turned in for grading.

Any questions from students should be answered.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO:	17
CLASS EXERCISE:	Operation of 247A Ion Chamber Survey Meter.
TIME:	Fifty (50) minutes.
PLACE:	Classroom and Outdoor area.
INSTRUCTORS' REFERENCES:	Instruction Manual on Model 247A Survey Meter, (Victoreen Instrument Company. (See Footnote*)
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Chart appended hereto; 247A Survey Meters, Radium Source.

1. The 247A Ion Chamber Survey Meter is a portable instrument for measuring the intensity of gamma radiation. The detecting device is a hermetically sealed ionization chamber which measures only gamma radiation.

2. Physical characteristics of the instrument are as follows:

(INSTRUCTOR - DEMONSTRATE INSTRUMENT)

a. Height - 13 inches.
b. Length - 10 1/3 inches.
c. Width - 5 1/3 inches.
d. Weight - 1.2 pounds.
e. Finish - Gray enamel.
f. Indicating Meter - 3 inch scale with 25 divisions.

3. The principal parts of the instrument are a case, containing the ion chamber, batteries and wiring; an indicating meter, mounted in the case; and controls which include a battery switch, a zero adjustment, and a range switch that allows selection of one of four intensity ranges as follows:

x1	-	0 to 2.5 mr/hr
x10	-	0 to 25 mr/hr
x100	-	0 to 250 mr/hr
x1000	-	0 to 2500 mr/hr

*This period is to be used to familiarize the student with the operation of a Victoreen 247A Ion Chamber Instrument. Each student should be "checked out" on its operation under the direct supervision of an instructor.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

4. Headphones are not used nor is it possible to measure beta with this instrument. The gamma sensitivity of the x1 range is comparable to the 2 range of the 263A G-M meter. Background count will not, normally, register on this instrument.

5. The 247A instrument is a fairly rugged device and little trouble should be encountered in its use. The most undesirable feature of the 247A lies in the fact that the needle must be rezeroed very frequently. Erratic fluctuations of the needle may be taken as a sign of malfunctioning. Prior to use a spot calibration check should be made.

6. Operating procedure is carried out in the following manner:

(INSTRUCTOR - REPRODUCE CHART 17-1)

a. Turn battery switch to "CHECK" position. Indicating meter should show a reading of 1.9 or greater. If lower than 1.8 batteries should be replaced.

b. Turn battery switch to "ON" position.

c. Turn range switch to "SENSITIVITY CHECK" position. The indicating meter should show a reading of 1.9 or greater If lower than 1.8 the instrument needs adjustment by a qualified technician.

d. Turn range switch to "ZERO CHECK". Indicating meter should show reading in the vicinity of zero.

e. Turn the zero adjustment knob until the meter reading is exactly zero.

f. Turn the range switch to the x1000 range. Place instrument in location to be measured.

g. If reading is less than 10% of full scale, switch to x100 range and on down until a reading is obtained. Wait 10-15 seconds and obtain the average reading.

h. Record the data.

7. These instruments should be handled with care and the switches turned gently. The battery switch has stop pins which limit its travel in both directions. If a battery switch is forced, these pins will shear off and the instrument rendered inoperative.

Are there any questions?

[redacted]

[redacted]

INSTRUCTOR'S QUESTIONS:

1. What types of radiation does the 247A survey meter detect?

2. What radiation intensity does the x1000 Range of the 247A survey meter measure? The x10 Range? The x1 Range? The x100 Range?

3. What range of the 247A survey meter is comparable to the 2 range of the 263A survey meter?

4. How is background count obtained with a 247A survey meter?

5. What adjustment must be frequently made when using the 247A survey meter?

6. Why must the battery switch of a 247A survey meter not be forced?

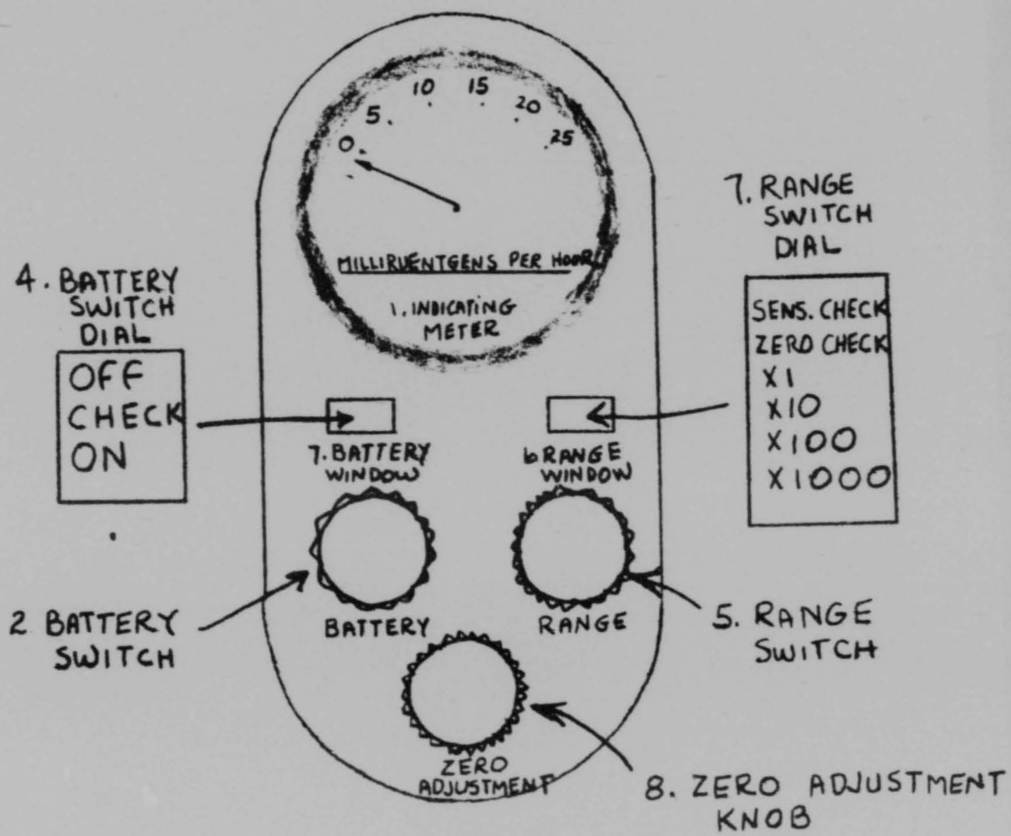
Balance of period is devoted to "checking out" students on the operation of the 247A.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

247A ION-CHAMBER SURVEY METER

CHART 17-1



THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO:	18
CLASS EXERCISE:	Student Calibration of 247A Survey Meters.
TIME:	One hundred and fifty (150) minutes.
PLACE:	Classroom and Instrument Calibration Course.
INSTRUCTORS' REFERENCES:	Paragraph 9.12, Radiological Defense Manual, Volume 1. (See Footnote*)
STUDENTS' REFERENCES:	Notes from Training Outlines No. 11, 12, 14 and 16 periods.
TRAINING AIDS REQUIRED:	Data Sheets, clip-boards, 247A Survey Meters, radium source, graph paper, rulers, colored pencils and scratch paper.

1. Students will draw equipment and assemble in the classroom. They will be briefed on the general procedure for obtaining data as outlined in Training Outline No. 11 and 16. The size of the radium source is given and data sheets are prepared. The following points on technique should be covered:

a. The importance of constantly checking the zero of the instrument. Before any reading is recorded the zero should be checked.

b. The importance of placing the center of the indicating meter over the distance marker. Failure to do so will result in inaccurate readings since the ion chamber is directly beneath the meter.

c. The fact that the ion chamber has a diameter of over two inches and therefore readings taken a short distance apart are valueless. No two readings should be taken closer together than 2 inches.

2. Following this, students should proceed to the calibration course, obtain readings and record data.

3. Finally, students should return to the classroom and prepare a calibration curve as outlined in Course Outlines 12 and 16. This curve will be turned in for grading.

*This exercise is conducted in exactly the same manner as Training Outline No. 16. Two additional factors must be considered however; first that a 100 mg source is necessary to calibrate even 40% of the X1000 range (if a smaller sample is used no attempt should be made to calibrate the X1000 scale) and, second that the center of the dial should be placed over the distance marker in order that accurate results are obtained. It is essential that the instructor "dry run" this exercise prior to presentation to insure that distance markers are at satisfactory locations.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO:	19
LECTURE:	Radiation Dosimetry.
TIME:	Fifty (50) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	Paragraphs 9.04-9.05, 9.12, 9.15-9.17, Radiological Defense Manual, Volume 1.
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Charts Appended hereto; pocket dosimeters, dosimeter charge box, film badges.

1. This period is devoted to a study of the equipment and methods used to determine the dose of external radiation which an individual receives in an area contaminated with radioactivity.

2. During a previous period the effect of radiation on the body was discussed and it was pointed out that 0.1 R/Day is the maximum allowable dose for personnel to receive at the present time. The question then arises as to how an individual knows when he has received 0.1 R/Day. To answer this question it is best to clarify and review the difference between "Radiation Intensity" and "Radiation Dosage".

3. "Radiation Intensity" may be compared to the velocity with which an automobile is traveling at any particular moment. In other words how fast or intense something is "right now". However, just because we may be going 60 miles per hour "right now" does not mean that we will cover 60 miles in the next hour. We may only drive 1 mile at 60 miles per hour and then stop. The distance which we cover may be compared to "Radiation Dosage". Thus, just as the distance which we travel in an automobile is a summation of all the small distances which we cover at various rates of speed so the radiation dose is a summation of all the small quantities of radiation which an individual absorbs in moving through areas of varying radiation intensity.

4. The Geiger meter and the ion-chamber meter which we have previously studied are rate or intensity meters. They tell what the radiation intensity at a point is right now. If we stay in that spot for a definite period of time it is possible to determine about what dose we will receive, (for example - a person in an area where a Geiger meter showed the radiation intensity to be 50 mr/hr would know that if he remained in that area for 2 hours he would receive a dose of about 100 mr), but in practice this is not the case since we move around continually through areas of greatly varying intensity. It is necessary to find some device which will act as

[redacted]

1683

[redacted]

a totalizer or adding machine to keep a running total of our dose. In practice two devices are used side by side to accomplish this task; the film badge and the pocket dosimeter. Each will be discussed.

5. The pocket dosimeter is a small ionization chamber which is contained in a case resembling a fountain pen. This dosimeter contains a charged metal fiber which becomes neutralized when ions are formed inside the case by radiation. The amount of radiation received by the instrument is proportional to the amount of neutralization of charge. The measuring portion of this instrument utilizes the principle of electricity wherein like charges repel each other. The ionization within the chamber neutralizes these charges so that the metal foil or fiber returns to its uncharged position. The pocket dosimeter does not require continuous external voltage for operation but, when discharged, must be recharged from an external source. One form of this instrument is shown on the following chart.

(INSTRUCTOR - REPRODUCE CHART 19-1)

The instrument is about the size of a large fountain pen. The conducting system in the dosimeter consists of two metal coated quartz fibers, each of which is bent into a U (C and D in the illustration). These two fibers are fused together at the end of the U and a simple optical lens system is focused at the end of one fiber (D in the illustration). Contained within the lens system is a transparent scale, graduated in milliroentgens, so that the movement of the movable fiber gives direct readings of radiation dosage received. A positive charge is placed on the fiber system and causes the fibers to diverge by mutual repulsion. Radiation causes ionization within the chamber which neutralizes this positive charge and allows the fibers to move back together. The protective cap on one end of the dosimeter has a glass window to allow light for illuminating the fiber and scale. When this cap is removed, a contact is exposed for charging the fiber system from a charging box. At the present time, dosimeters are built with several different ranges but the one which we will normally use has a range of 0 to 200 mr. These dosimeters are sufficiently strong to withstand the shock of normal human activity and are small enough to be worn comfortably for direct reading. Each individual entering a radioactive area wears a pocket dosimeter and periodically checks it to determine how closely he is approaching a tolerance dose (100 mr). Two additional points should be noted in connection with dosimeters:

a. Insulator Soak-In. When pocket dosimeters have not been used for some length of time (3-4 days) and are initially charged, the charge will leak away quite rapidly. After two or three rechargings this leak-away rate will decrease to a normal value of 1-20 mr per 24 hour period.

b. Calibration of Dosimeters. All dosimeters are slowly discharged by cosmic radiation. This leakage rate must be determined by charging a dosimeter, letting it sit for a 24 hour period and then determining the leakage rate. Dosimeters in good condition should not have a leakage rate in excess of 1-2 mr per hour. Finally it is wise to calibrate dosimeters periodically (say every two weeks) against a standard

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

source. If a dosimeter is given a very hard blow (i.e. dropped on a concrete floor) it should be immediately recalibrated.

6. The film badge is a small piece of X-Ray film with a lead foil cross wrapped around it so that only the corners of the film are exposed and the entire unit wrapped in several layers of waterproof, lightproof paper. This is illustrated by the following chart.

(INSTRUCTOR - REPRODUCE CHART 19-2)

Upon exposure to radiation, the silver salt contained in the photographic film is converted to developable metallic silver. When the film is developed, the degree of darkness caused by the deposit of silver is proportional to the dosage of radiation received. By comparison with standard films (i.e. those which have been exposed to a known dosage) it is possible to determine the total dosage received. Most of the gamma radiation will pass completely through the uncovered portion of the film so that this uncovered portion of the film will record only the beta radiation. On the other hand the lead cross will stop all beta radiation and will deenergize the gamma radiation to such an extent that all the gamma radiation (and only gamma) will be recorded under the cross. Each person entering a radioactive area wears a film badge along with a pocket dosimeter. The reason for carrying a film badge is the fact that it is more accurate than a dosimeter, it differentiates between beta and gamma radiation, and it provides a permanent legal record to protect the government against fraudulent medical claims at some later date. It has the disadvantages that it is not direct reading and requires several hours for development and reading. For this reason it is necessary that an individual carry a pocket dosimeter in order that he may determine his dosage on the spot. Care must be exercised in the storage of unexposed film badges since they deteriorate with time and unfavorable condition of temperature and humidity. Personnel film badges are normally made to cover a dosage range of 50-4000 mr although it is possible to produce films which will measure much greater doses.

Are there any questions?

<u>INSTRUCTOR'S QUESTIONS</u>:

1. What is the difference between radiation intensity and radiation dosage?

2. What are two devices for measuring radiation dosage?

3. Essentially, what is a pocket dosimeter?

4. What source of power does a dosimeter require?

[redacted]

5. What is the leakage rate of a good dosimeter?
6. Why do we use film badges?
7. Why do we use pocket dosimeters?
8. What is the purpose of the lead cross on a film badge?

Note to Instructor:

The balance of the period should be devoted to instructing students in the use of the dosimeter charge box.

TRAINING OUTLINE NO: 20

LECTURE: Monitoring Techniques.

TIME: One (1) hour.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Chapter 13, Chemical School Memo 393 (1 July 1949) (500) (WSW); Chapter 16, "AFRTC Manual 52-355-1", Dept of the Air Force, May 1949.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Charts appended hereto.

1. Monitoring is defined as a continued check of the surroundings of an individual or unit in order to detect the presence of radioactivity. This definition is not broad enough, however, to cover all the phases of monitoring. These phases include determination of the type and intensity of radioactive contamination existing at any point, evaluation of the personnel hazards resulting therefrom and supervision of personnel entering contaminated areas.

2. In many respects monitoring can be compared to reconnaissance work. We must be looking for something specific, we must have the proper equipment, we must be able to immediately evaluate what we find and determine the course of tactical action to be taken. The long range effect or strategic results of radioactive contamination are the concern of Radiological Defense Engineers.

3. The reasons for monitoring are because of some overt act of war and sabotage by a foreign nation. These acts may be the explosion of an atomic bomb or some less obvious method such as radioactive dusts dropped during a conventional bombing attack, and acts of sabotage by foreign agents. In time of war, any area within 50 miles of such an attack should be considered suspect until proven otherwise by complete monitoring of all such areas. Therefore, preliminary plans for systematic monitoring of all USAF installations should be on hand and automatic warning devices be operational at all times.

4. The problem is threefold:

a. To determine the intensity of contamination present in critical areas and/or materiel.

b. To determine the general extent and degree of contamination existing in general areas.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

c. To prevent personnel entering contaminated areas from overexposing themselves through either ignorance, carelessness, or misguided enthusiasm for their mission. This does not mean that certain people on missions of vital importance should be denied access to contaminated areas.

5. The successful accomplishment of these tasks demands intelligent application of the material presented in previous lectures, tact, and occasionally, downright stubbornness.

6. Monitoring, to be successful and effective, should be carried out by teams. While a general rule cannot be drawn, each team should consist of at least two men. These men should be equipped with: Geiger and ion chamber instruments film badges, pocket dosimeters, gas masks, work clothing and a map or sketch on which to record data. They should, prior to making a survey, lay out a rough survey plan of the area and/or materiel to be covered in order that no time is lost while in the radioactive area. This plan should be based on the mission of the unit to which they belong. In general, preliminary monitoring is for the purpose of determining how soon an area can be reentered and how soon certain undamaged equipment in that area can be utilized. The first survey is normally a rapid one to gain information in the shortest possible time. In some cases, however, damage control and evacuation of wounded will be the primary aim.

7. To determine how soon areas may be safely reentered or equipment reused depends on the tolerance dose of radiation which personnel are allowed. We will assume 0.1 R/Day. Hasty initial surveys are limited to critical and essential areas or material necessary for use as soon as possible. Therefore, the monitors go to these points as rapidly as possible and obtain specific readings. General contamination is measured only as an approximation. The following procedure is outlined as typical:

a. As the suspected area is approached the Geiger counter is placed in operation with the beta window open. Pocket dosimeters are checked to insure that they read zero. Boots, gloves and clothing are checked for adjustment.

b. As the count picks up on the Geiger counter the team leader watches the meter closely and begins to estimate where dangerous radiation will begin. A rough estimate of the ratio of beta to gamma should be obtained. If the ratio of beta to gamma is high it generally indicates that:

(1) Alpha emitters are probably present as a definite hazard.

(2) Overall intensity will probably decay fairly rapidly.

c. When the count indicates 4-5 mr/hour (0.1 R/Day) this position should be marked on the map and some sort of ground marker put up.

[redacted]

1690

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

d. The monitors should proceed at a fast steady walk toward the desired objectives. An overall evaluation of the general contamination should be made rather than many spot readings. When the 12-15 mr/hr (0.3 R/Day) position is reached, this point should likewise be recorded on the map and marked on the ground since, up to here, personnel may remain for up to eight hours. At this point it is well to close the beta window and proceed with the survey, based only on gamma radiation.

e. When the 20 mr/hr position is reached it is necessary to change to an ion chamber instrument. Beyond this point the intensity will tend to increase at a more rapid rate if the monitor is proceeding toward the center of contamination. If at any point the readings start to decrease slowly but definitely it is an indication that the center of contamination has either been passed or does not lie in the direction of progress. A sudden sharp decrease in intensity generally indicates a small uncontaminated spot in the midst of a large contaminated area.

(INSTRUCTOR - REPRODUCE CHART 20-1 AND USE IT TO ILLUSTRATE THE ABOVE POINTS)

f. Above intensities of 100 mr/hr (2.4 R/Day) each monitor should check his pocket dosimeter every five minutes in order to determine how rapidly he is approaching his tolerance dose. Sufficient reserve should be maintained to allow leaving the area.

g. Within the limits of allowable dosage all critical points should be monitored and their intensity recorded. Monitors then leave the area as rapidly as possible. If buildings, rubble-covered holes or other confined spaces must be entered, gas masks may be needed for protection against the alpha hazards.

h. After leaving the contaminated area, monitors return to a central control point and report. Following this they turn in film badges and dosimeters, check themselves for contamination, bathe and, if possible, change into clean clothes.

i. Based on the findings of this survey, certain areas and/or material is either cleared for unrestricted use, cleared for use within certain working times or denied for access by personnel. When cleared for use for specified working times a monitor should accompany all working parties to enforce safety precautions.

8. If the object of an initial survey is damage control or evacuation of wounded, the monitor should accompany the working party as it progresses toward its objective.

9. As more time becomes available detailed surveys are made. These surveys are to determine the extent of and degree of contamination existing in contaminated areas. The procedure is similar to that used for hasty

[redacted]

1691

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

surveys except that all contaminated areas are located and their intensities determined. This information is plotted on a master chart in the form of isodose lines. Isodose lines are lines connecting points of identical radiation intensity. Thus any area outside a 0.1 R/Day isodose line would have an intensity of less than 0.1 R/Day and be safe for unrestricted use. As decay and/or decontamination progresses, remonitoring is accomplished and the chart altered accordingly. The decay equation $It^n = K$ is used to predict future decay.

10. Finally monitoring is reduced to a routine basis where the main task is monitoring of personnel working parties and supervision of working parties to see that time limits are not exceeded.

11. Air monitoring is the reconnaissance of air, land and water areas by airborne personnel for the purpose of detecting and avoiding, or of detecting, measuring and reporting the presence of radioactivity. The two general types of air monitoring work performed are:

a. Evasive monitoring which is an approach to the fringes of a contaminated area with the objective of locating these boundaries. Care is taken to avoid entering these areas and, based on data obtained, other aircraft can avoid contamination by passing around the area.

b. Survey monitoring is the type wherein survey aircraft enter contaminated areas to determine the location, extent and intensity of these areas.

12. Typical airborne monitors are equipped with the same instruments that are common to ground monitor personnel. Instrument calibration and operating skill are very important in air monitoring due to the time element. Typical procedure for air monitoring would be somewhat as follows:

a. Pilot and monitor would plan mission prior to take-off.

b. Monitor would brief crew on radiological safety procedures prior to take-off.

c. On evasive monitoring missions, continuous "in-flight" monitoring would be accomplished from time of take-off. The position location of each contact with contamination would be determined by the navigator and this information recorded. If time were important these data would be radioed back to a control center. The monitor would keep the pilot informed of the general radiological situation over the inter-communications system and advise when evasive action became necessary.

d. On survey missions this same general procedure would be followed. The monitor would notify the pilot when to proceed to additional areas or altitudes.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

e. Upon completion of the mission the monitor would monitor all flight personnel and the aircraft for contamination. Appropriate action would be taken if contamination were found.

MONITORING TECHNIQUES

13. Monitoring techniques are purely arbitrary rules which have been evolved to guide personnel in making surveys. They are based on practical experience obtained during past atomic energy tests, however, and should not be deviated from by non-technical personnel. It is assumed that each student is now fairly proficient in the operation of radiation detection instruments.

a. General.

(1) Care must be taken in monitoring to see that instruments do not become contaminated due to touching contaminated surfaces. Contaminated instruments give false readings and cannot be satisfactorily decontaminated. To prevent instrument contamination, due to accidents, a cellophane instrument cover should always be used.

(2) Accurate records should be kept of instrument battery life in order that replacement may be properly effected. Exhausted batteries result in erroneous readings.

(3) An instrument should be handled by only one man if possible. If not, a minimum of personnel should be allowed to handle instruments.

(4) Any malfunctioning or hard knocks on instruments should be reported.

(5) All readings should be taken at a uniform distance from the object being monitored. A one inch variation when using an instrument at close intervals may cause a large variation in observed intensities.

(6) Provision must be made to monitor and decontaminate all personnel working in contaminated area.

(7) Smoking, drinking, eating and gum chewing are specifically prohibited in contaminated areas.

b. Area Monitoring.

(1) Readings should be taken at belt height. While this

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

reading is considerably lower than the actual intensity on the ground it is a fair indication of the average radiation intensity to which an individual's body is subjected. Also variations in height of the instrument from the ground due to monitor's height is minimized.

(2) Generally gamma readings only are obtained.

(3) Only rough average intensities over large areas are obtained. The monitor should average the general readings in his mind and arrive at an overall figure. Local "hot spots", however, should be traced down and marked.

(4) The intensity of areas which cannot be entered may be estimated through use of the $I = \frac{CM}{D^2}$ relationship. For example, if in circling a very hot spot the monitor obtains a reading of 0.1 R/Day around the edge of a rough circle 9 feet in radius, he may assume an intensity of 8-10 R/Day near the center of the circle. This is only a rough approximation and must be considered as such.

(5) Special attention must be given to wood, concrete, bituminous and other porous surfaces since these tend to absorb and retain contamination.

c. Equipment Monitoring

(1) Readings should be taken one inch from the surface. This is facilitated by mounting an improvised guage on the instrument.

(2) Items such as rope, canvas, rough or rusted surfaces, greasy and oily surfaces, bituminous coverings, pumps, drains, wood, air intakes and water systems should be closely checked.

(3) Care must be exercised to obtain readings which represent only contamination existing on equipment. In some cases localized "hot spots" on the ground may give distorted values to readings obtained on equipment in that area.

d. Personnel Monitoring.

(1) All readings should be taken as close to the body surface as possible without actual contact.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(2) Personnel returning from a contaminated area should first remove all expendable protective devices such as boots and turn in equipment. Then, one man at a time, each individual should be taken to an area with low background count and monitored with his clothing on. Any reading over 0.2 mr/hr, beta plus gamma, indicates contamination and decontamination measures should be accomplished.

e. Airborne Monitoring.

(1) Calibration of instruments is necessary at the altitude which they are to be used.

(2) Only gamma readings have any significance.

(3) Coordination is necessary between the monitor and navigator to determine position locations.

(4) Aircraft oxygen systems should be used in contaminated areas with the regulator in the 100% position. Cabin heater systems should be turned off.

(5) Aircraft should not enter areas where the intensity is high, since, due to instrument lag and the inability of aircraft to instantly reverse direction, highly dangerous areas may be entered almost without warning. In addition high intensity areas will contaminate an aircraft rapidly.

(6) Aircraft must be monitored after landing. Most likely sources of contamination are air intakes, turbo-superchargers, engines and leading wing surfaces.

(7) Monitors should be located in forward nose compartments.

Are there any questions?

INSTRUCTOR'S QUESTIONS:

1. What is monitoring?

2. What are isodose lines?

3. What is the significance of the 4-5mr/hr isodose line? The 12-15 mr/hr isodose line?

4. What must a survey team do when they reach a 20 mr/hr intensity?

[redacted]

1695

[redacted]

5. What is the significance of a high beta to gamma radiation ratio?

6. How can future radioactive decay be estimated?

7. What are two types of air monitoring?

8. What are three things that are always prohibited in contaminated areas?

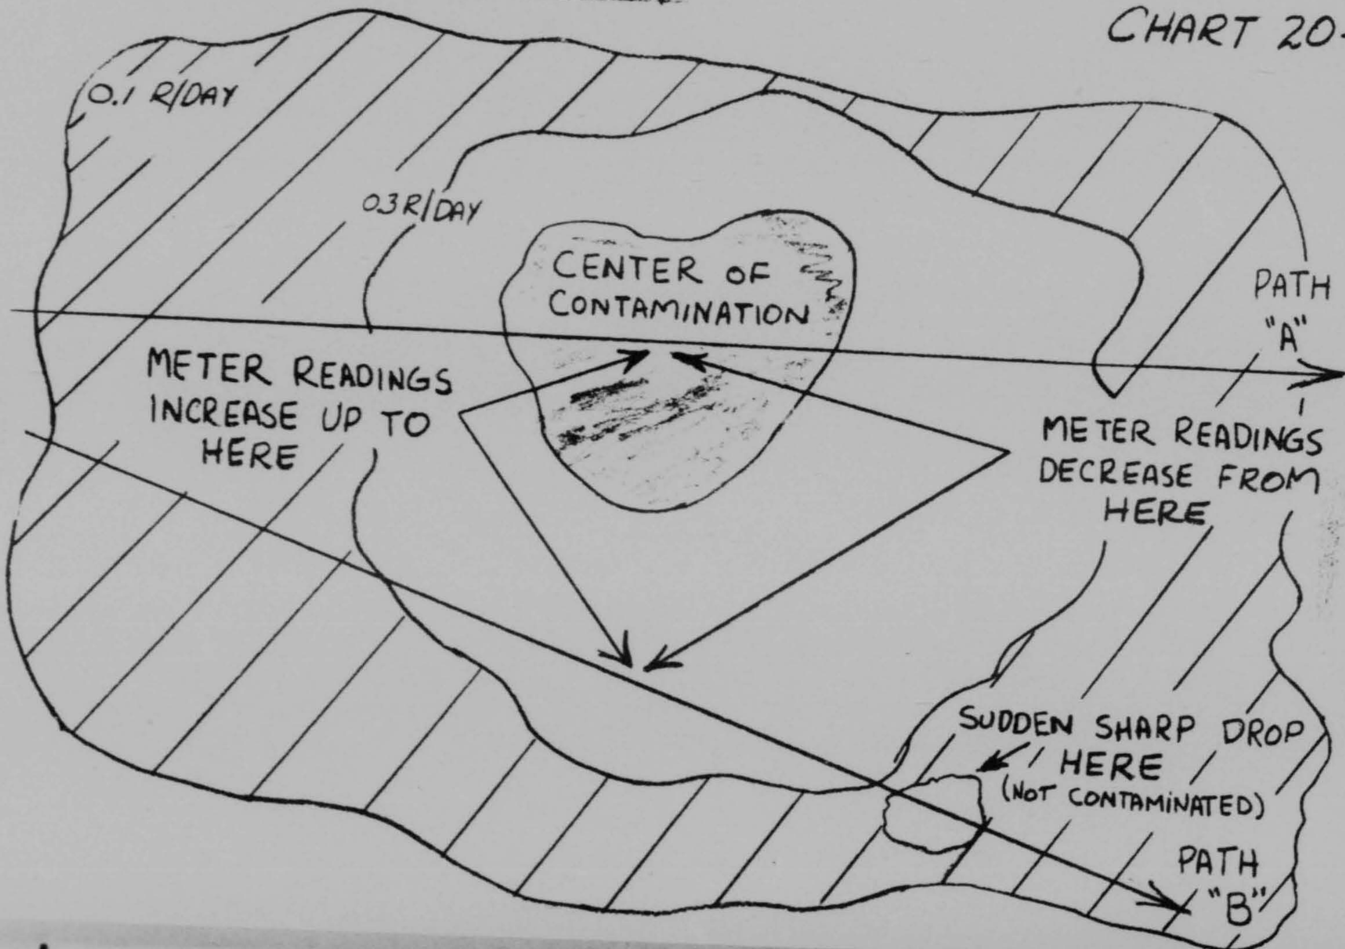
9. What radiation intensity indicates personnel contamination? Is the gamma or gamma plus beta?

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

CONTAMINATED AREA

CHART 20-1



THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO:	21
LECTURE:	Individual and Collective Protection.
TIME:	One (1) hour.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	All previous references.
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Charts appended hereto.

1. This hour is devoted to individual and collective protection against the atom bomb and associated radiological hazards.

2. These hazards are illustrated by Charts 21-1, 21-2. From the original neutron striking the fissionable material, and the resulting explosion, in addition to immense blast, there are fission products, most of them radioactive, prompt radiation consisting of the neutron flux and gamma rays, heat of sunlike intensity, blinding glare, and one or two other phenomena.

3. What can the individual do - acting as an individual? At the sounding of the alert, take the best shelter available. The few people who were in deep earth tunnel shelters at Hiroshima and Nagasaki were not harmed when the bomb was detonated. Even a foxhole would be enough, providing the bomb was not detonated directly or nearly overhead. If it is off to one side, the penetrating radiation has to go through several feet of earth to reach you.

(INSTRUCTOR - REPRODUCE CHART 21-3)

If an earth covered or concrete air raid shelter is available, use it.

4. One thing <u>not</u> to do. DO NOT stay out of the shelter to watch the flak bursts as the enemy planes come in. DON'T look up during any raid. Wear your helmet. Cover your face and keep it turned toward the ground.

5. It has never been announced, as to just what thickness of earth, brick, concrete or other material will provide protection from prompt radiation. Neutrons, however, are very penetrating, and a minimum of four feet of reinforced concrete should be required in shelters.

6. Shelter doors should be closed, or if in a foxhole, a cover should be used. People in deep tunnel shelters in the Hiroshima blast

[redacted]

[redacted]

were slightly burned in some cases where the heat wave struck the open shelter entrance directly.

7. Try to select a shelter that won't come down or burn if it does collapse. It is known than many of the thousands who died at Hiroshima and Nagasaki were trapped in the burning debris of collapsed houses. Never take shelter under a vehicle except as a very last resort.

8. If caught in the open a mile or so away from the blast, the chances of survival are better if white or light colored clothing is worn. It reflects the heat, and thus protects the body, whereas dark clothing absorbs the heat radiation, and the body beneath is burned badly.

9. Assuming that you are uninjured after the bomb has burst, you, as monitors, will have a very definite job, and would carry out the duties assigned under the unit defense plan. Other personnel will also have assigned duties such as fire fighting, or rescue work. Fires will be burning all around the place, both spontaneous fires caused by the heat of the bomb burst, and secondary fires caused by short circuits, overturned stoves, burst gasoline tanks and other sources.

10. It would be best to put on a gas mask until a check shows whether the area is free of contamination or not. And most important, DON'T eat, drink, or smoke in a possibly contaminated area until the degree of contamination or its absence is established, then abide by instructions from higher headquarters.

11. If you suspect or know that your person or clothing is contaminated, get to a personnel decontamination station immediately. If you were within a mile of the blast, and especially if you feel nauseated or have been wounded, get medical attention promptly, if possible.

12. If you are away from your unit and away from the instruments required for detecting and measuring dangerous radioactivity, always keep in mind the possibility of fall-out even from an atomic explosion, many miles away. Stay inside, and avoid food and water where any possibility of contamination exists, until authorities anounce the district as clear.

13. On the question of collective protection, there is one fact which should be understood before any discussion is undertaken. We may be reasonably sure that no atomic bombs will be used on purely tactical targets. They cost too much, and it is fairly certain that no nation will ever have large quantities of atomic bombs. It is considered that the bomb would be used only on a tactical objective where its use would be decisive to the outcome of a war. Therefore, a bomb probably would not be used on an airbase, or against troops in the field.

14. More likely is the enemy use of large capacity bombs, gliders,

[redacted]

1699

[redacted]

or guided missiles loaded with radioactive dusts. These are relatively cheap, and a comparatively small amount can force evacuation of an area.

15. Considering the above possibilities, it is highly probable that USAF policy will be against the construction of elaborate deep shelters, which are very expensive, and that any construction effort will be directed toward simpler surface or semi-sub surface shelters, capable of holding all the personnel of a given installation. Such shelters may be gas proofed and equipped with collective protectors, may have non-combustible tight sealing doors, include sanitary facilities, may have storage space for food and water, and, since many would be area defense centers, may have telephone and/or radio communication with other shelters in the same vicinity. Whether they are made of brick or concrete, such shelters should be banked and covered with earth to provide additional shielding for the occupants.

16. Dispersion of personnel and equipment over a wide area is an obvious and effective method of collective protection, and dispersion should be utilized to the utmost at all times, and practiced in peacetime so that dispersion becomes an established habit for times of war. It must apply to key personnel, medical facilities, vehicles, planes, ammunition, fuels - to all the components which go to make up a unit able to perform its mission.

17. Most of the considerations applicable to collective protection should be covered by unit and base defense plans. These will be discussed at a later period.

18. Such defense plans must be simple, practical and kept up to date, for there will be little time for improvisation in the event of an emergency. Personnel concerned must know their jobs beforehand and set to work immediately after the attack. Such plans must include a SOP for all individuals, including the unit radiological defense group.

19. Other facilities required for collective protection include personnel decontamination centers. These are emergency bathing facilities which have a clean and dirty side as in personnel gas decontamination centers. Normally, first aid personnel should be stationed here, and also a monitor to check personnel going through.

20. Instrument storage facilities for delicate detection instruments will be required. Space may be set aside in shelters for this purpose, and here again, the principle of dispersion used, since all instruments should never be concentrated in one spot.

21. A Damage Control Organization of fire fighters, rescue teams, and first aid personnel will be essential. This should be organized on a unit basis, so that teams from an unaffected area can go to heavily hit areas. Equipment for these units should be dispersed.

[redacted]

[redacted]

22. Every installation should have a designated Evacuation Area or Assembly Point to which personnel could proceed in the event that area evacuation is required. Such areas can be stocked with emergency supplies of food and water and medical facilities. An evacuation area should be chosen after consideration is given to the probable fall-out (prevailing winds being known) from an atom bomb on any local potential target.

23. Prevention of panic will be a major factor in collective protection. This can be accomplished only by thorough training of all personnel in all echelons and by an effective working organization for defense.

24. It is unlikely that Air Force units will have any direct concern with civilian defense, but the use of Air Force personnel in disaster control to assist the Civil Defense authorities is always possible. Should that occur, personnel with specialized training as monitors will have an important function.

Are there any questions?

TRAINING OUTLINE NO: 22

LECTURE: Decontamination Procedures.

TIME: One (1) hour.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Chemical School Memo 202, 22 June 1948; Chapter 10, Chemical School Memo 393 (1 July 49) (500) (WSW); Page 14-5 and 14-6, "AFRTC Manual 52-355-1", Dept of the Air Force, May 1949.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Charts appended hereto.

1. Decontamination is the removal of radioactive contamination from personnel, materiel and areas.

2. Inasmuch as there is no practical way to destroy radioactivity, decontamination must be accomplished by physical removal of the radioactive material. This material is in the form of sub-microscopic particles scattered over large areas some of which is firmly imbedded in surface areas. For that reason, and because by decontamination we merely transfer the radioactivity to another place, it is normal procedure to let radioactive decay take care of decontamination. With one exception, therefore, decontamination is normally limited to a few critical areas and/or items of materiel. That one exception is personnel decontamination.

3. While it is not the scope of this course to teach tactical doctrines on decontamination, a few general principles should be outlined. This is felt to be of particular importance since commanders, staff officers and operating agencies, almost without exception, often misunderstand what it is possible to accomplish with decontamination measures. The points which should be understood are:

a. Decontamination, except for personnel decontamination, should never be attempted except for critical items of equipment and very small areas. This is because decontamination is a process which consumes large amounts of supplies and man-hours of work. In almost every case dangerously contaminated equipment should be allowed to age and contaminated areas abandoned.

b. Decontamination is a slow process which in many cases, depending on the type of material and conditions of contamination, is only partially successful.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

c. It is very difficult to evaluate the success of decontamination measures since such factors as natural decay and weathering often a are actually responsible for supposed decontamination.

d. Personnel decontamination, by contrast, is simple and a relatively minor but important problem.

4. The bulk of the information in the remainder of this lecture will be devoted to personnel decontamination techniques since this is well within the province of a monitor. Other types of decontamination, while discussed briefly, should not be undertaken in the absence of a qualified Radiological Defense Officer.

PERSONNEL DECONTAMINATION

5. Personnel working in a contaminated area or persons who may be in an area over which contamination is spread will require decontamination. Because both their clothing and parts of their bodies may pick up radioactive particles, it is necessary to monitor these personnel and establish decontamination centers.

6. All clothing is subject to the hazards of contamination but gloves and shoes are usually the more heavily contaminated. Canvas booties, if available and worn, will protect shoes completely, and can be discarded after use. When shoes are not protected, however, they will pick up dangerous amounts of contamination on the top, edge and bottom of the soles. Cord-rubber and rubber soles are much worse in this respect than leather soles. Canvas gloves are highly desirable to protect the hands against contamination but are very clumsy if precise work must be done. Despite some opinions to the contrary, it has been proven that monitors can operate instruments quite satisfactorily while wearing gloves.

7. The fact that work clothing has been used once in a radioactive area does not mean that it should be promptly discarded even if slightly contaminated. On the contrary, as long as clothing reads below 3 mr/hr, beta plus gamma, it may be worn for work periods of 4 to 6 hours quite safely.

8. On the body, special attention should be given to the hair, face and hands as probable locations of contamination. If gloves are not worn, it will be found that grime beneath the fingernails is always contaminated. The entire body must be checked, however, after all clothing is removed.

9. A diagrammatic sketch of a personnel decontamination center is shown on the following chart;

(INSTRUCTOR - REPRODUCE CHART 22-1)

Emphasis must be placed on the fact that almost any type of facility

[redacted]

[redacted]

which has a source of running water can be used for decontamination. The cardinal rule is to keep contaminated personnel and equipment out of "clean" areas. Procedure is as follows:

a. Personnel assemble in an area and turn in equipment. Gloves and booties are then discarded.

b. One man at a time, each individual is monitored with his clothing on. Remainder of personnel should remain 30-40 feet away to keep a low background count.

c. Readings should be taken as close to the clothing as possible, and should be beta plus gamma readings.

d. Any clothing reading higher than 3.0 mr/hr, beta plus gamma, should be discarded. Only those articles of clothing so reading should be discarded. Replacement items should be issued at time of discard.

e. Clothing reading 3.0 mr/hr, beta plus gamma, or less should be stowed away for future use.

f. One man at a time, each individual should then be monitored without any clothing on. Any appreciable increase in background count shows some degree of contamination and, unless shortage of water is a factor, the man should be decontaminated. If water shortage is a factor, only men reading over 0.2 mr/hr, beta plus gamma, need be decontaminated.

g. Decontamination is accomplished by scrubbing down with soap, water and a GI brush. Several applications may be necessary.

h. Men are then checked by a monitor and, if clean, are given a towel. If necessary, men are sent back to the showers until free of radioactivity.

i. Men are then cleared to dress and are released.

10. Certain modifications may be necessary in this procedure with respect to issuing clean or replacement clothing. There is little objection to how this is done as long as contaminated personnel do not handle dress clothing. By dress clothing is meant clothes which will be worn after release from a monitor's supervision. It should not be confused with clean or slightly contaminated work clothing which will be worn under a monitor's supervision only - there is little objection to contaminated personnel handling this work clothing.

11. The major requirements for operating personnel decontamination

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

centers are running water, soap, brushes, towels, a supply of clothing and a place for work parties to stow or hang two sets of clothes. These two sets of clothing as pointed out above, are dress clothing and work clothing. In connection with work clothing, it is well to point out that personnel working in radioactive areas should be furnished a minimum of clothing. A cap, a shirt, a pair of trousers, a piece of heavy twine for a belt, and a pair of shoes is all that is needed. To this should be added a pair of canvas gloves and a pair of canvas booties as expendable items for each mission. Underwear and socks are not normally necessary and complicate supply problems. In winter weather, however, they might be required. Towels are not a problem if care is used to insure that they do not become contaminated. Clothing which has become contaminated should not be arbitrarily destroyed but stored so that radioactive decay may render it useable again.

12. Personnel requirements for operation of a decontamination center will range from 4 to 6 persons, if men are to be processed rapidly. At least three monitors are necessary to handle a continuous flow of personnel.

13. Finally,-it is necessary to exercise strict supervision over all personnel entering radioactive areas to insure that they are properly decontaminated before release. It is a proven fact that personnel get careless after working on a dangerous job for some time. One of the biggest jobs will be to combat such carelessness.

<u>MATERIEL DECONTAMINATION</u>

14. Materiel decontamination should be carried out in an area which is uninhabited and where contamination of the ground by run-off of decontaminating solutions is not objectionable. Care must be taken that:

a. Men work upwind of the object being decontaminated.

b. Washing down must begin at the highest levels and work down.

c. All portions of the object being decontaminated are equally washed down.

15. Specific procedures for decontamination are as follows:

a. <u>Aircraft</u>: Aircraft may be decontaminated by spraying with a mixture of kerosene and "gunk" (Compound, cleaning, aircraft, Specification No. 20015). This mixture can be sprayed on by use of a 400 gallon power driven decontaminating apparatus (M3A2 or M4) which delivers a working pressure of about 400 lbs., per sq., in. An additional decontamination apparatus, utilizing water, or a steam cleaner should be used to wash down the gunk mixture. Suitable fire precautions will be taken.

[redacted]

1708

THIS PAGE IS DECLASSIFIED IAW EO 13526

b. Metal Surfaces (Corrosion not permissible): Use the gunk solution outlined above.

c. Metal Surfaces (Corrosion permissible):

(1) Swab surface with a weak acid solution and follow by washing down with a stream of high pressure water.

(2) On painted surfaces, it is very effective to remove the paint. This may be done by use of a solution consisting of:

5 lbs lye (Na OH)
5 lbs boiler compound
1 lb cornstarch
10 gallons water

which is allowed to remain on the paint for two hours before removal with a high pressure water stream.

d. Wood Surfaces: Decontamination of wooden surfaces is impractical beyond a hosing down with water.

e. Canvas and Fabrics: Washing with soap and water is the most that can be done. Except for clothing, this type of material should be destroyed.

AREA DECONTAMINATION

16. There are three possible methods whereby areas may be decontaminated, none of which are satisfactory. They are:

a. Wash down with high pressure hoses and transfer contamination to another area.

b. Cover the area with a layer of uncontaminated material, (i.e., dirt, duckboards, steel matting, etc.)

c. Remove a layer of the topsoil with power equipment. Some disposal area must be utilized.

Are there any questions?

INSTRUCTOR'S QUESTIONS

1. What are booties? Why should they be used, if available?

2. Below what intensity can contaminated clothing be used for work periods of 4-6 hours? Is this gamma only or gamma plus beta intensity?

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

3. What parts of the human body are more likely to pick up contamination in contaminated areas?

4. What is a cardinal rule to follow in the operation of a personnel decontamination center?

5. If water is scarce, what is the maximum intensity of radioactive body contamination that a person may have without requiring decontamination? Is this gamma only or gamma plus beta intensity?

6. How are personnel decontaminated?

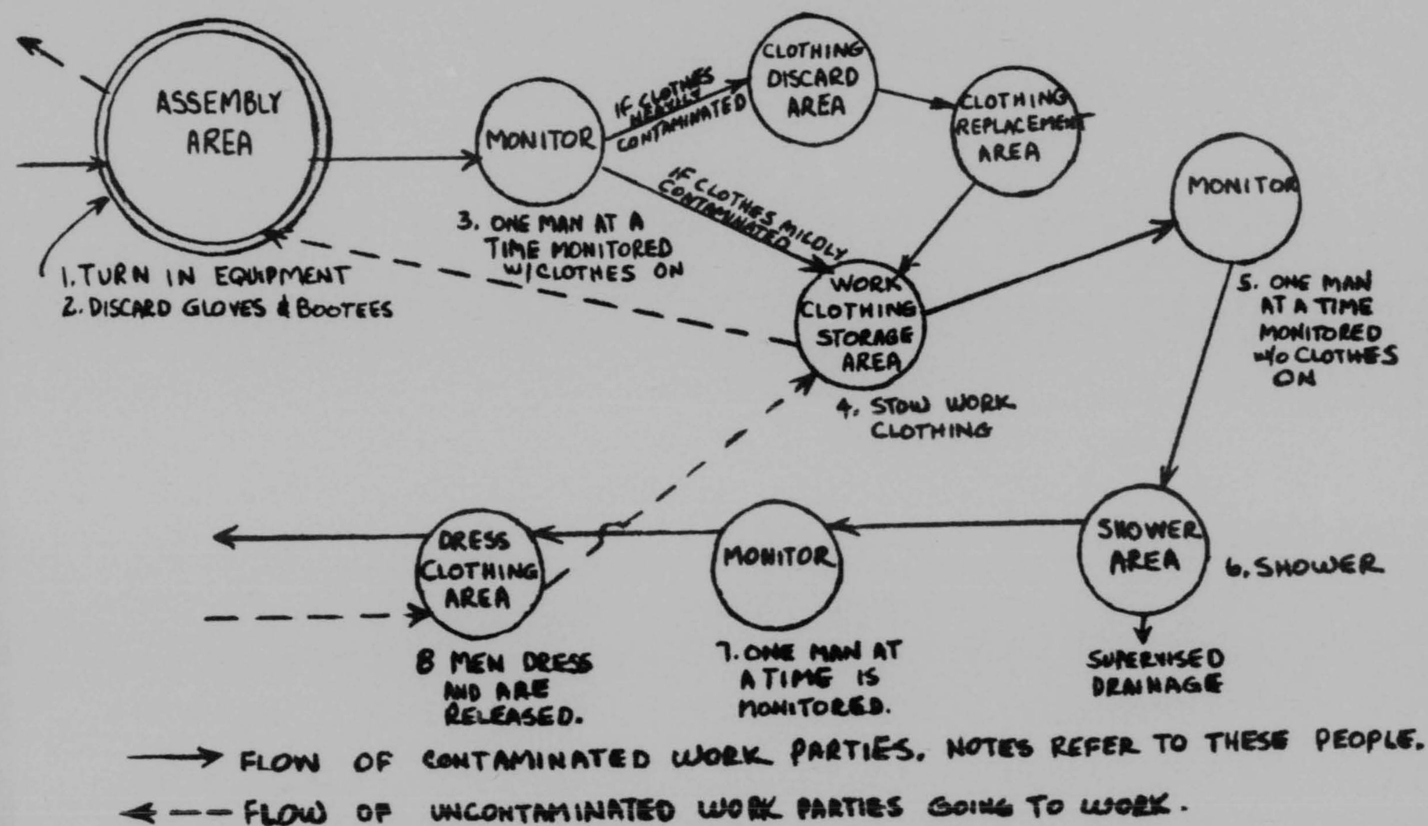
7. What decontaminating agent may be used for cleaning aircraft? What type of decontaimnating apparatus is best suited to this job? What precautions must be taken?

8. Can wooden surfaces be decontaminated? How?

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

PERSONNEL DECONTAMINATION CENTER CHART 22-1



[redacted]

TRAINING OUTLINE NO: 23

CLASS EXERCISE: Monitoring Field Problem - 263A Survey Meter.

TIME: Two hundred (200) minutes.

PLACE: Outdoor Area.

INSTRUCTORS' REFERENCES: None. (See Footnote*)

STUDENTS' REFERENCES: Notes from previous periods.

TRAINING AIDS REQUIRED: 263A Survey Meters. Radium Source, pocket dosimeters, dosimeter charge box, film badges, data sheets, maps or sketches, clipboards.

1. Objectives:

a. To have students check 263A meters and pocket dosimeters and prepare survey plans.

b. To have students survey an area and determine the general overall intensity thereof.

c. To have students determine the location and intensity of hot spots within a contaminated area.

d. To have students determine and roughly plot on a map the location of 0.1 R/Day and 0.3 R/Day isodose lines in a contaminated area.

e. To have each student determine his dosage for the period of exposure.

*Development of this field problem is left to the instructor since local circumstances such as size and quantities of sources available, size and types of areas available, and number of instruments available will vary. The objectives to be obtained from this field exercise are given in the subject outline below. As a result of the survey, each student or team should prepare a short report to accompany the sketch and these turned in for grading. Too much emphasis cannot be placed on the instructor "dry running" this exercise before actual presentation to a class.

[redacted]

1712

[redacted]

2. General Procedure:

a. Students will draw 263A meters and check these meters; draw pocket dosimeters and charge these dosimeters; prepare data sheets; and, based on instructor's briefing, make a rough survey plan. This survey should be made by teams, each team consisting of 2-3 students.

b. Teams should proceed to the contaminated area and, using hasty circling tactics determine the location of the 0.1 R/Day and 0.3 R/Day isodose lines. The location of these lines should be sketched on a map of the area.

c. Teams should then work in toward the center of the areas located in (b) above and determine the location and intensity of "hot spots" (i.e. sources). The location of these "hot spots" should be plotted on the survey map.

d. Upon completion of the survey, teams should determine their dosage from pocket dosimeters, turn in instruments and prepare a report on the general overall condition of the contaminated area. The survey map should accompany this report and be graded for legibility and accuracy.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO:	24
CLASS EXERCISE:	Monitoring Field Problem - 247A Survey Meter.
TIME:	Two hundred (200) minutes.
PLACE:	Outdoor Area.
INSTRUCTORS' REFERENCES:	None.
STUDENTS' REFERENCES:	Notes from previous periods.
TRAINING AIDS REQUIRED:	247A Survey Meters, Radium Source, pocket dosimeters, dosimeter charge box, film badges, data sheets, maps or sketches, clip-boards.

This field exercise is comparable in scope to Training Outline No 23 except that the 247A meter will be unsed for survey purposes. Multiplication factors may be arbitrarily assigned for the radiation intensities present. If this is done, however, care should be taken that the isodose lines, assigned to be determined, are of correspondingly higher values. For example: If a multiplication factor of 10 is used the students might be required to determine the location of the 0.3 R/Day (0.1R in 8 hours) and the 0.6 R/Day (0.1R in 4 hours) isodose lines.

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO:	25
LECTURE:	Radiological Defense Organization.
TIME:	Two (2) hours.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	Pertinent AF Directives. All previous material. Chapter 15 and 16, "AFRTC Manual 52-355-1", Dept of the Air Force, May 1949; Chapter 7 and 8, Chemical School Memo 202, 22 June 1948; Medical Aspects of Nuclear Energy AFSWP, NME 1949.
STUDENTS' REFERENCES:	All previous material.
TRAINING AIDS REQUIRED:	Copies of AF Regulation 20-28, 3 May 1948 and copies of Air Base Radiological Defense Plans included with these notes. Copies to be issued to all students for retention. Blackboard map of Air Base.

Note to Instructor:

Policy decisions are still lacking on many of the matters discussed in this lecture. For that reason, no material should be presented as representing USAF policy unless covered now by existing directives such as AF Regulation 20-28.

1. The entire subject of radiological defense organization has not yet crystallized, and a firm policy is not as yet available. It is believed that this condition will be corrected in the very near future, however, and that organization will proceed on the following principles.

2. The fundamental USAF policy directive is AF Regulation 20-28, 3 May 1948, of which you all have copies.

3. In practice, responsibility is divided as follows:

a. The Atomic Energy Commission has general control over all phases of atomic energy and its applications, and over all specialized training in that field. Through its Military Liaison Committee, it works with the Armed

[redacted]

[redacted]

Forces Special Weapons Project, and the Air Force. In Headquarters USAF there is an Assistant Deputy Chief of Staff, Operations for Atomic Energy, but actual training for defense is supervised by the Radiological Defense Branch in the Office of the Director of Armament, USAF, which oversees all matters pertaining to Radiological Defense in the Air Force. At a lower level, in Air Force Commands, the Command Armament Office is also the Radiological Defense Office. The same is true at Air Force and Wing level.

b. At Group and Squadron level, student of this course will assume radiological defense duties for units, in addition to chemical duties in most cases.

4. What special training is necessary in radiological defense work? There are several categories, and we will note them briefly.

a. There is a three year course given to selected officers from which they emerge as Radiological Defense Engineers. It is contemplated that these officers will be assigned to Command or possibly Air Force level.

b. The six weeks course qualifies an officer as a Radiological Defense Officer. Three schools are currently being conducted for this course at the following installations: Treasure Island at San Francisco, The Army Chemical Center, Maryland, and Keesler Air Force Base, Mississippi.

c. Additional courses are contemplated to qualify selected officers and airmen as survey officers and instrument maintenance specialists respectively. The training given here is considered as the basic course for survey officers and as an adequate course for the qualification of radiological monitors.

5. No formal organization has been set up for Wing Radiological defense, though several tentative suggestions have been made. An organization of the tentative type will be considered in discussing Radiological Defense plans.

6. The plan for the protection of an organization, or an installation, against atomic explosion or other form of radiological attack may take a variety of forms. It is probably not too important what form is used, as long as the plan is a workable one. However, the individual formulating the plan should have a definite form in mind and follow that form. Otherwise, it is almost certain that details which are important will be overlooked. Possibly the best answer here is that the same form should be followed as has been followed by the organization in the past in preparing its defense plans.

7. Once a decision has been made as to what form the plan will take, it must be decided what amount of detail will be included in the plan. No set rule applies here. A poorly trained and relatively inexperienced

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

organization must have a plan which is more detailed than would be necessary for a well organized and trained organization. Too, the type and mission of a unit will have much to do with the type of plan and the detail with which duties and responsibilities are outlined.

8. The following check list is presented as a guide only. In some plans, all of the details mentioned need not be considered. In others, it may be necessary to include details not mentioned in the check list. However, it is believed that this list is complete enough to serve as a guide for relatively inexperienced personnel in writing up their first plans.

a. Responsibilities. Who is charged with directing radiological defense? What is his status with respect to the Commanding Officer? Other staff officers? Are all interested staff agencies coordinated in a single plan?

b. Organization. What base organizations will have Radiological Defense Officers? Which will have only monitors? Will they be enlisted or officer personnel? Will any civilians be utilized here?

c. Training. What special training is necessary? Do all personnel get the same training? Who is responsible for general indoctrination type of training? Who is responsible for special training and the development of special skills?

d. Warning System. Are any special warning systems needed? Who is responsible? Any special signal for evacuation of the installation?

e. Dispersion. To what degree? Materiel, personnel, or both? Are duplicate command posts necessary? Evacuation areas designated? Stocked?

f. Shelters. For all personnel? For any type of materiel? For medical and special equipment? What type will be constructed? Who will design? Are there any useful types of hasty field shelters?

g. Monitoring. Who directs and supervises? Who does the work? Who monitors materiel? Personnel? Areas? Will there be a fast survey made first and then a detailed survey? What types of instruments will monitor use? Should provision be made for continuous monitoring? Will monitoring be done to detect radioactive dusts, radioactive war gases, and isotopes which may

[redacted]

1717

be spread without an explosion? Who monitors food and water supplies? Do firefighters enter the area after an explosion without monitors? Who must make the decision as to whether firefighters and medical personnel enter a contaminated area? Will the monitor be delegated authority to say who goes in? Will monitoring priorities be necessary?

h. Communications. Is it necessary to set up any sort of special service to use after an explosion? Any restrictions on use of communications after an explosion? Who is to be responsible for special communications?

i. Supply. Who supplies and services the radiation detection instruments? The film badges? Who develops film badges? Who furnishes chemicals and special tools for decontamination work?

j. Fall-out Areas. Who will estimate and advise the commander as to area or areas which will be contaminated by fall-out particles? Should this estimate be made after an explosion, or should it be a continuing estimate so that the commander may be informed of the expected area of fall-out immediately after an explosion?

k. Plans for Civilians. Is it necessary to make any special plans for civilian employees? If so, who is responsible?

l. Personnel Decontamination. Where will personnel decontamination centers be established? Who is responsible? Who will operate? What special equipment will be necessary? Can existing bathing facilities be used, with or without alteration?

m. Materiel Decontamination. Who is to be responsible for decontaminating areas? Buildings and other installations? Equipment?

n. Special Instructions. Are any special instructions necessary for general and specialist personnel?

o. Medical. Are policies established on casualty procedure? What plans for evacuation and treatment of personnel? Allowable radiation dosage for monitors? Other individuals?

9. All the above points must at least be considered in writing an adequate defense plan.

10. The defense plan of a large air base, occupied as it is by many and various units having different functions, is bound to be complex. It is not likely that with your present status of training

[redacted]

in radiological defense that you will ever be called upon to write such a plan - that is a job for a fully trained Radiological Defense Officer - but a summary will illustrate the many problems involved in such a plan.

NOTE TO INSTRUCTOR:

1. Read and explain attached plan with cover letter. It will be found helpful to draw a map of a representative large air base on blackboard to aid in explanation. It will be stated that this plan is tentative, and is not final USAF policy, but that it does offer one solution. There is, of course, no Composite Air Command, and students will be so informed.

2. The attached plan for "Defense of a Small Air Force Unit" will be read and explained to students. They will be told that such a plan will be within their scope of activitiy in their unit radiological defense.

[redacted]

[redacted]

SAMPLE COPY

Headquarters
Air Composite Command
Pittsford Air Force Base
New York

7 April 1948

Subject: Radiological Defense of Air Composite Command Installations.

To: Commanding General, Twenty-second, Twenty-fourth, Twenty-seventh, and Twenty-ninth Air Forces.

1. The attached "Installation Radiological Defense Plan" is forwarded for information and guidance of commanding officers in all echelons of this Command.

2. Effective immediately, a radiological defense plan based upon this supplied model will be implemented and maintained for all Composite Air Command installations.

3. The atom bomb and associated radiological weapons represent new modes of warfare, many aspects of which are of necessity unfamiliar. In order that full advantage may be taken of known principles of radiological defense, and to insure desirable uniformaty of procedures throughout this Command, the provisions of the attached plan will be considered as representing Command policy, until further notice.

4. It is realized that certain installations notably Air Force Headquarters, detached organizations, and others present defense problems varying widely from that of an air base. Commanding Officers of such units will formulate suitable defense plans, stressing dispersion and the ability to continue operations under battle conditions. Such plans will be forwarded through channels to this Headquarters for approval, but meanwhile, will be made operative.

5. It is anticipated that qualified Radiological Defense Officers will be assigned to major organizations of this Command, down to and including Wings, in the near future; these officers will advise unit commanders in all matters pertaining to Radiological Defense.

BY COMMAND OF LIEUTENANT GENERAL O'SHEA:

ANNEX 1

[redacted]

1720

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

SAMPLE COPY

Headquarters
Air Composite Command
Pittsford Air Force Base
New York.

Installation Radiological Defense Plan

1. Introduction

a. The following plan provides for the defense of a typical Wing Base of this command against atomic bomb or associated radiological attack. It will be integrated with, and will extend existing plans against chemical and biological attack.

b. Radiological, biological, and chemical defense will be coordinated and supervised at all echelons by the Armament organization, but can only be successful with the full cooperation of all personnal and staff sections as required.

2. Responsibility and Organization

a. The Commanding Officer of the Wing is responsible for the defense of the base. He will be advised and assisted in the radiological defense of the base by the Radiological Defense Officer (RDO) who will coordinate all measures to be taken by the Radiological Defense Organization and associated specialists before, during, and after any attack in which radiological munitions may be involved.

b. The Radiological Defense Organization will consist of (See Chart A, attached):

(1) The RDO, in Wing Headquarters, and commissioned and enlisted assistants.

(2) Survey Officers (SO), one in each unit of the Wing. These are qualified monitors who have received required training in radiological defense. SO's are assisted by enlisted Radiological Monitors (RM) varying in numbers in each unit according to its function. Unit Gas personnel will be designated for this duty.

(3) Each unit of squadron size will maintain 20-man squads trained in decontamination, rescue, and fire fighting, to operate under the unit SO. These squads will function as Unit Damage Control Groups.

Inclosure 1 to Annex 1

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(4) A Photodosimetry Laboratory (Hospital).

(5) Instrument specialists in Maintenance Squadrons.

c. Each unit will be responsible for radiological defense measures in its own area under direction of the unit SO, and under general direction by the RDO. Chain of command will be observed in wing defense organization, thus the RDO under battle conditions will receive reports from and direct action of Group SO's, who will in turn receive reports from and direct Squadron SO's.

3. Defense Facilities

a. Shelters

(1) USAF policy does not allow heavy construction as would be required for elaborate bomb proof shelters. Consideration will be given to improvement of existing shelter facilities, or careful improvisation where necessary.

(2) One centrally located shelter will be designated for the Commanding General of the Wing. It will house the Central Control Point, and will be the action station for the RDO during any enemy attack on the base or vicinity. From this point he will direct activities of the base Radiological Defense Organization.

(3) In addition, shelters for necessary unit functions and personnel will be dispersed throughout each unit area.

(4) These shelters will be gasproofed where possible. They will be stocked with emergency food and water supplies, and will also house unit radiation detection instruments in at least one shelter per unit.

(5) Shelter housing the Central Control Point will have emergency radio and telephone communication with unit commander shelters.

(6) Slit trenches, covered with planks and banked with earth, and with blast walls protecting entrances will be provided near working and living sites for the accommodation of personnel unable to reach or use main shelters in event of attack.

b. Decontamination Centers. The normal bathing facilities of each unit will be used for personal decontamination. A monitor will

[redacted]

[redacted]

be assigned to each such point to check personnel for radioactive contamination, should use of such facilities be necessary.

c. Dispersion.

(1) The Base Commanders will arrange through local Civil Defense Organizations for storage facilities at some point at least five miles from the base, and away from any industrial concentration. Upon direction from higher headquarters, these facilities will be used for storage of three days rations (packaged), water, emergency medical supplies, and tentage.

(2) This point will be designated as Emergency Evacuation Rendezvous, should evacuation of the base be necessary. Prevailing winds will be taken into consideration in selection of this point to insure, as far as possible that fall-out from an atomic bomb on any local potential target or on the base itself will not endanger the Evacuation Rendezvous.

4. Current Operation of Radiological Defense

a. Unit commanders will institute radiological defense training programs, including continuing indoctrination and training of new personnel. Unit commanders will maintain continuing check on defense measures within their units.

b. Each unit will prepare and maintain a list of priorities for evacuation of equipment in event such action becomes necessary.

c. Provisions will be made for an alternate field to be used by Wing aircraft should contamination or damage to runways render the base unusable.

d. Each unit will have one SO and two RM's trained at schools to be established at Wing level. These in turn, will train additional necessary monitor personnel within their units. In accordance with USAF policy, unit gas personnel will be detailed for such assignments in most instances.

e. Duties of the RDO

(1) The RDO will conduct initial training, and such additional training as may be necessary to maintain proficiency of SO's, RM's and general personnel in Radiological Defense.

Inclosure 1 to Annex 1

[redacted]

1723

[redacted]

(2) The RDO will conduct monthly inspection of the state of radiological defense training, equipment, organization, supplies, and facilities of Wing units.

(3) The RDO will conduct a monthly CPX in which the Radiological Defense Organization will participate. Emergency communications system will be used exclusively. Problems will be set, and the solutions thereto worked out by the Radiological Defense Organization. Every effort will be made to make these exercises as realistic as possible.

(4) The RDO will advise the Commanding Officer on exercises to be held quarterly, with all personnel participating, to test operations of defense measures.

(5) The RDO will maintain liaison with local Civil Defense authorities, for such mutual assistance as may be required. It will be understood that in event of attack the base can furnish no assistance to the local civilian population until all operation requirements have been made.

5. Warning System

a. Telephone warning of impending or possible attack will be given key personnel (Unit CO's, SO's, RM's, and leaders of Damage Control Groups) as far in advance of attack as possible ("Warning yellow" for possible, "warning red" for impending attack).

b. Attack alarm will be the prolonged rising and falling note of the base siren.

c. Radiological Attack Alarm will be a series of three short blasts on the siren, repeated at intervals. (This signal will also be used for chemical and biological attack.)

d. Evacuate Base will be signalled by a series of five short blasts on the siren, repeated at intervals, or by repeated firing of two green flares should the siren be inoperative.

e. All Clear Signal will be a prolonged single note on the siren. (Personnel will be warned not to leave shelters until rapid survey of the area is made, and unit SO's give the order.)

6. Measures to be Taken in Event of Outbreak of War

a. Gas masks and other available protective equipment (individual flash-burn protective covers, for example) will be issued to troops, and will be carried or kept at hand at all times.

Inclosure 1 to Annex 1

[redacted]

[redacted]

Installation Radiological Defense Plan (Cont'd)

b. Maximum dispersion of planes will be maintained at all times. Available foliage cover will be utilized. Revetments will be constructed for single engine and other small planes. An emergency two-mission supply of gasoline and ammunition will be kept in the vicinity of each plane as a reserve, but normal stocks will be utilized for daily operation.

c. Stocks of bombs and ammunition will be dispersed as widely as available area of the base will allow Wooded areas will be utilized where possible.

d. The Transportation Squadron will disperse vehicles as directed; no concentration will be allowed at any time. Any reserve vehicles will be pooled at the Evacuation Rendezvous. The Transportation Officer will maintain a plan for control of his dispersed personnel and vechicles.

e. The Food Service Squadron will disperse food supplies in two or more locations on the base.

f. Supplies of gasoline on the base will be kept at a reasonable minimum, depending upon local circumstances. Since outbreak of war will almost certainly mean gasoline rationing, local civilian storage facilities may be made available where their location renders them suitable for their use.

g. The Wing Surgeon will designate a school, church, or other public building near the Evacuation Rendezvous as an emergency hospital, and it will be stocked with such supplies as might be required for treatment of radiation sickness along with other standard items.

h. The Wing Surgeon will coordinate duty requirements of base medical personnel, to the end that only those actually needed on duty will remain on the base. This is to insure that no single attack can wipe out all base medical personnel.

i. The Air Installations Officer will disperse a reserve of fire fighting personnel and apparatus to some point away from the base.

j. In event of enemy action within a fifty mile radius, the duty RM in each unit will make a quarter hourly check for radioactivity for the following eight hours. Any positive reading will be communicated direct to the RDO immediately.

k. If, an atomic bomb is dropped within a fifty mile radius, duty RM's will maintain this check until notified by the RDO that no fall-out can endanger the station.

Inclosure 1 to Annex 1

[redacted]

1725

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

l. The RDO will make a daily check with the Weather Officer to determine whether fall-out from an atomic bomb on any local potential target would affect the base itself or the Evacuation Rendezvous.

m. Film badges are issued to SO's and RM's and stocks readied for general issue.

7. In Event of Attack on Base or in Vicinity

a. All personnel not directly engaged in getting planes into the air will take shelter at the Attack Alarm. They will take with them gas masks, helmets, canteens (filled), arms and first aid packets.

b. Personnel of the Radiological Defense Organization will proceed to duty stations. (Command or other shelters as designated.)

c. The RDO will proceed immediately to the Central Control Point, and report to the CO or his representative. He will then establish communication with the unit command Control Points, and receive any preliminary reports. He will make a check with the Weather Officer on fall-out possibilities from a bomb or any local target. If dangerous contamination is anticipated, the CO will be so notified.

d. The SO's in each unit, immediately the attack has passed, will send out monitors and assistants (as runners, recorders, etc.) to each sub area of the unit area. A quick reconnaissance will be made, and results of this reconnaissance, including radiation danger areas and physical damage, communicated back to the SO and through him to the RDO.

e. Unit Area Damage Control Groups will go into action immediately after the attack has passed, each group accompanied by one or more monitors. Group leaders will report situations as soon as possible to the SO who will transmit reports to the RDO.

f. The RDO will assess reports, and as soon as possible present a report to the CO, with recommendations for action. He will divert assistance from unaffected areas, if any, to those requiring it.

g. Should preliminary survey reports indicate necessity for evacuation of the base, the CO is so advised, and necessary steps taken upon his decision.

Inclosure 1 to Annex 1

[redacted]

Installation Radiological Defense Plan (Cont'd)

h. Monitors, meanwhile, if preliminary check has shown only mild or spotted contamination, will make a thorough survey of the unit areas, and direct the isolation and suitable marking of those areas found to be dangerous. Detailed information will be transmitted to SO's who plot readings on unit area maps, and transmit to the RDO. If highly dangerous contamination exists over a large part of the unit area, the fact is reported.

i. The RDO reports final state of the base to the CO as soon as full information is available, listing areas that are dangerous, the time men can work in them, and physical damage done. Should continued operation of the station be possible, the RDO then makes a personal inspection of each unit area to assist SO's as necessary.

j. Photodosimetry Laboratory begins operation, keeping necessary records under medical jurisdiction.

Inclosure 1 to Annex 1

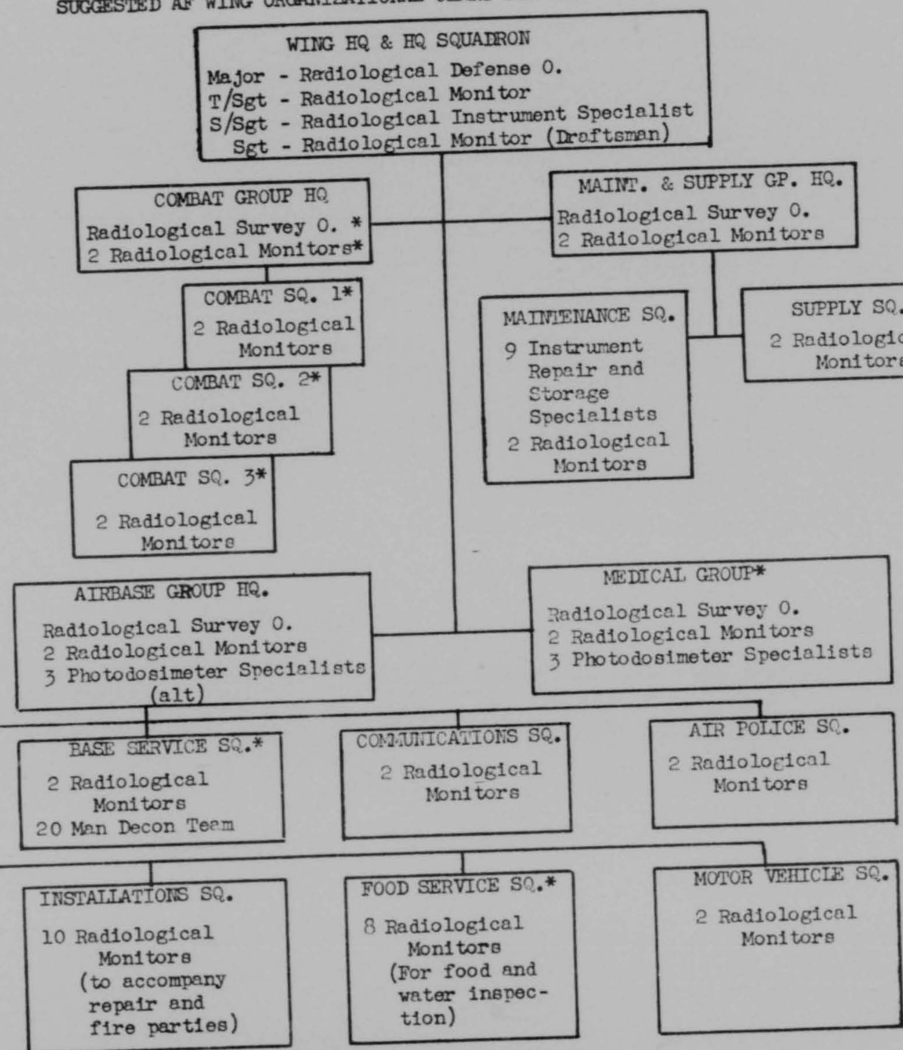
SUGGESTED AF WING ORGANIZATIONAL CHART FOR RADIOLOGICAL DEFENSE



Wing Hq. -Radiological Defense O. is his sole duty
Combat Hq. -Rad. Survey O. is additional duty for UGO & UGNCO's

CHART A (Inclosure 2 to Annex 1

[redacted]

[redacted]

HEADQUARTERS
225th AIR COMPOSITE SQUADRON
Gamma Air Force Base, New York

UNIT RADIOLOGICAL DEFENSE PLAN

1. Radiological Defense Unit.

Lt. A, Survey Officer
T/Sgt B, Radiological Monitor
S/Sgt C, Radiological Monitor
Sgt D, Decon Squad Leader (10 designated EM)
Sgt E, Damage Control Squad Leader (10 designated EM)
Cpl F, Medical Non-com

2. Mission.

a. The unit CO is responsible for the radiological defense of this unit.

b. The Radiological Defense Unit is responsible for the co-ordination of the squadron activities in event of an atomic explosion or radiological attack. It will fulfill all of its responsibilities to the Base Radiological Defense Organization, and endeavor by all means possible to minimize casualties and damage in event of atomic attack.

c. It is responsible under direction of the CO for training and indoctrination of squadron personnel to insure accomplishment of the provisions of this directive.

3. Organization. The Survey Officer is responsible to the Squadron CO, and will advise him or direct activities upon approval of the CO. The Survey Officer will be guided by directions from the Base Radiological Defense Officer.

4. Warning System.

a. Provisions for defense will go into immediate effect with the signal for chemical or radiological attack (repeated series of short blasts on siren).

b. Crash alarm telephone system and any other method of communication possible will be used to further warn personnel.

5. Standard Operating Procedure.

ANNEX 2

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

Unit Radiological Defense Plan (Cont'd)

a. Unit Radiological Defense Center.

(1) Upon sounding of alert, all radiological defense personnel will report to the Radiological Defense CP.

(2) All other personnel will take shelter unless engaged in activities immediately vital to the defense of the unit area against impending attack. Personnel taking shelter will have with them gas mask, proper protective clothing, weapons, and filled canteens.

(3) Instruments will be issued to monitors and final check will be made of this operating condition.

(4) Monitors will move out immediately after the attack has passed, and make a rapid survey of their areas of responsibility, reporting back to the Survey Officer as soon as possible. Survey Officer will transmit report of condition of his area to the Base Radiological Defense Officer as soon as possible. Monitors will then undertake detailed survey providing area is not too contaminated.

(5) Damage control and medical personnel will move out as soon as possible after the attack has passed and begin assigned operations, if this can be done without exceeding accepted tolerance dose.

(6) Necessary protective devices (film badges and pocket dosimeters) will be worn when required, and readings recorded.

(7) Continuing check of areas will be maintained and the CO notified of any changes of situation.

b. Further Duties of Monitors.

(1) Check food and water for possible contamination.

(2) Monitor equipment necessary in rescue and salvage operations.

(3) Monitor personnel requiring decontamination

c. Squadron Section Heads. Collect all personnel of sections:

Annex 2

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

Unit Radiological Defense Plan (Cont'd)

(1) If within a contaminated area, remove to safe ground. See that men perform personal decontamination.

(2) If outside contaminated area, have men report to CP for assignment to any necessary special duty (i.e., to assist in evacuation, salvage, decontamination of equipment and supplies).

(3) Report to CO and/or Survey Officer for further assignment and special instructions.

d. Fire and Crash Crews.

(1) Follow Radiological Defense SOP.

(2) Fight fires as required.

(3) Assist in rescue and evacuation as necessary.

Annex 2

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO: 26

LECTURE: Tactical and Strategic Use of Atomic Weapons.

TIME: One hundred (100) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: USSBS Report on Hiroshima and Nagasaki. (See Footnote*)

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: None.

1. Introduction. Before we can arrive at a logical decision as to the significance of any new weapon, and atomic weapons in particular, we must be able to answer all six basic questions: who, what, when, where, why, and how? More specifically we must know the answers to the following questions about atomic weapons, viz:

a. What types of munitions are available now and in the immediate future?

b. What materiel and personnel effects will these munitions produce under a variety of possible conditions of use?

c. What psychological and political effects will this weapon produce?

d. What quantity and quality of munitions may be available?

e. What means are available now, or may be available in the near future, for launching this weapon, or placing radioactive materal on the target?

*Students should be informed that due to high classification of subject matter, this discussion must be in generalities.

[redacted]

[redacted]

f. What are the actual and comparative costs of this weapon and other possible substitutes for accomplishing the same end-result?

g. What are the possibilities and influence of various protective and active defensive measures that can be taken on the target area before, during, and after an attack?

h. In view of the various possibilities and limitations of this weapon, what targets are likely to be selected for this weapon and how will the weapon be launched?

i. Much of the precise data we would like is not available. For instance, we do not know the precise intensity of nuclear radiation at 400 yards from an atomic bomb burst but we do know that this radiation is lethal to exposed personnel at one mile and may produce some effect at 3,000 yards when there is not shielding, and that shielding is proportional to the mass of material between the man and the source of radiations.

2. Explanation.

a. Types of munitions available and likely to be Used: The potency of the atom bomb has been demonstrated in controlled proving ground tests, as well as in war. We know that this munition is available to the United States at the present time. We doubt if it is available to any other nation in the world; but we can be certain that such a weapon will become available at some time in the future, perhaps five years or perhaps 25 years hence, but more likely within the next 10 years. We know also that one of the major steps in the manufacture of fissionable material for the atom bomb takes place in the so-called "chain reacting pile." Under the conditions existing in this device relatively large quantities of highly potent radioactive material are produced which cannot be used in the atom bomb.. The most potent of these by-products have a relatively short half-life, yet others of real potency have half lives of weeks and months. Therefore, it is entirely probable that highly effective radioactive dusts produced as by-products from the chain reacting pile are now available to a number of countries, and that such material will more than likely be available to all combatants in any future war. There is also a possibility that certain toxic gases containing arsenic and/or phosphorus, such as Lewisite or the so-called German nerve gases, might be made radioactive in a chain reacting pile and thereby produce a highly radioactive toxic gas. Such a material would be more difficult to produce than radioactive dust but it might offer some advantages in tactical use and the supply would be easier and much cheaper than atom bombs. These piles could operate near the combat zone to simplify supply.

[redacted]

[redacted]

b. Effects of Atomic Munitions:

(1) The atom bomb really does not explode in the same sense as we speak of the functioning of a high explosive bomb. We normally think of an explosive as a sudden conversion of a solid occupying a relatively small space into an equal weight of gas at a very high temperature and high pressure tending to expand to occupy a very much larger space than that of the parent solid substance. Practically no gas is produced from the atom bomb but heat energy at the enormous temperature of several million degrees is produced in vast quantities. Much of this heat is dissipated from the point of reaction by radiation so that the surrounding air, ground, or water is heated to a very high temperature and functions in much the same way as the incandescent gas produced by the chemical reaction we normally associate with explosive phenomena but is more powerful because of the great quantity of energy released.

(2) The explosive wave set up by heating the surrounding gas or water is of longer duration in the air than is a corresponding true high explosive wave. Therefore the blast in air from an atomic bomb has more of the effect of a wind at super-tornado force, say 1,000 miles per hour, instead of a standard shock effect of very short duration which we associate with the high explosive bomb. There is a very material shock wave, however, when either the surrounding air or the surrounding water is heated suddenly to an enormous temperature.

(3) Whether or not the explosive wave would be of great significance if the atom bomb were caused to function in bone dry sand devoid of air is a matter of very interesting speculation. However, there is no question that a powerful underground explosion in ordinary earth would occur because of the enormous expansion of the moisture in the ground in the vicintiy of the bomb burst. Since no one has ever seen such a reaction this phenomenon of an underground burst will have to remain one of the unknown factors for some time to come, but it is safe to assume that a crater of extremely large proportions would be created and that the material within this crater would be atomized, rendered highly radioactive, and blown high into the sky as a dust cloud

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

mixed with unfissioned matter. The heat produced would cause strong ascending air currents for a much longer period of time than would be the case with an air or water burst. The radioactive dust would fall out in an area downwind equal to several square miles of area and would render that area uninhabitable for some weeks and would be lethal to the inhabitants of the area unless they were promptly evacuated.

(4) The heating effect of an air burst atomic bomb is great and the radiant heat falling on combustible material or individuals within a range of about one mile will cause instantaneous fires in highly combustible materiel and may cause heat burns of a fatal nature to exposed personnel. The fires caused by radiant heat striking upon combustible material in the surrounding area and the fire wind associated with a huge fire will be the principal causes of materiel destruction from an air burst atom bomb. Buildings knocked down by the explosive wave may cause many secondary fires in the area. The air burst atomic bomb may be expected to destroy about three to four square miles of American urban area, but there would be little radioactive after-effect. You lose the radioactive after-effect if you get the instantaneous electromagnetic radiation effect of the air burst bomb.

(5) In addition to the heating effect, the prompt electromagnetic radiations produced by air bursts may be fatal to men through air at distances up to one mile if personnel are unshielded. When shielded by ten feet of earth this danger is reduced considerably.

(6) A perfectly enormous number of high velocity neutrons are shot out in all directions during an atomic explosion. Neutrons have a range of about one mile through air and are little affected by ordinary thicknesses of steel, lead, or concrete walls. Only massive thicknesses of earth would slow down and finally stop these neutrons. The effect of the neutrons is to induce radioactivity in calcium, phosphorus, salt, and other minerals in the human body and thus kill the individual by self-generated radiation. Beyond one mile the neutrons would be ineffective

[redacted]

[redacted]

through air and their effective range through water and through the soil would be enormously decreased compared to their air range.

(7) Thus for all practical purposes we can say that the atom bomb produces:

(a) A powerful shock wave regardless of where or how it is exploded.

(b) Enormous heating of the surrounding medium, whether it be air or water, is produced by the atom bomb.

(c) In an air burst, powerful radiation effects are produced; but these radiation effects are considerably less on individuals beyond the immediate vicinity of the burst when the bomb is exploded underwater.

(d) An enormous quantity of radioactive materials are produced and blown into the surrounding medium. This radioactive material will fall out downwind for several miles, creating a definite fall-out hazard. This fall-out hazard, is minimized when the bomb burst is in the air because the radioactive cloud is dissipated into the upper atmosphere and the concentration of particles at points downwind is correspondingly reduced.

(8) Spraying an area with war gases such as mustard containing radioactive dusts or simply dusting the area with the by-products of a chain reacting pile would produce much the same effect as occurs in a fall-out.

c. Psychological and Political Effects of this Weapon: The atomic bomb, or radioactive dusts when properly used, would create an immediate local disaster which would necessitate hospitalization of large numbers of people for a prolonged period of time. Relatively few people would know initially the degree of radiation damage which they had sustained. This would tend to produce a mass hysteria. The psychological and political effect of the use of this weapon on a people would depend to a large degree on the people themselves and upon the propaganda countermeasures used to offset the effects of this weapon. In other words, the use of this weapon would make weak-kneed

[redacted]

1736

[redacted]

people surrender quickly without further effort, but it would spur a resolute people to far greater efforts. It will take very close study by highly competent experts in the subject to arrive at an evaluation of the psychological and political effects of atomic weapons on the people inhabiting a target area.

d. Number and Quality of Munitions Available: The production of atomic weapons is an extremely complicated and expensive process. In the future it may be possible to develop new methods for producing fissionable material from other than uranium ore. However we are limited, at present, to using these ores as raw material. These ores are scarce and in out of the way places other nations unfortunately have an appreciable portion of the known deposits within their jurisdiction. Fortunately certain countries, friendly to this nation, have very rich deposits of ore and these are our primary source of raw ore. At best, however, the total known amount of uranium ore is small. Therefore for the immediate and foreseeable future, the number of atom bombs available to any country for military purposes is going to be relatively small and these bombs are going to be exceedingly expensive. On the other hand, the amount of radioactive material produced in a chain reacting pile will be very much greater (probably in weight thousands of times greater than the actual fissionable material usable in atomic bombs) and such radioactive material can be produced by simply subjecting such things as table salt to neutron bombardment in a chain reacting pile. When, and if, this method is demonstrated it undoubtedly will be utilized to a much wider extent than the atomic bomb. Furthermore it is a very simple technical problem to operate a chain reacting pile compared to the production of fissionable material suitable for atomic bombs.

e. Suitable Targets for the Atomic Weapon:

(1) Any target to be worth the expenditure of an atomic bomb must have within a one mile radius of the point of detonation, large numbers of people, or national industrial installations of great strategic value. If an atomic bomb cannot be expected to kill or permanently disable and remove from the war several thousand people and destroy at least 100 million dollars worth of vital war materiel: or destroy industrial capacity that is vital to the war effort and which cannot be replaced in a reasonable time, then that target is not suitable for the expenditure of an atomic bomb. The one exception would be in a tactical situation of probable strategic importance.

[redacted]

1737

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(2) An area consisting of a high density of population, expecially one of vital importance in producing war material, would be an ideal target for dissemination of radioactive dust or radioactive toxic gases because such an attack, even against a community having an ideal area damage control organization, would certainly disrupt production for a prolonged period of time and a large percentage of the people would absolutely refuse to return to their homes within the alleged danger area. Furthermore, a large city could be covered with patchwork contaminated areas, thereby increasing the effectiveness of this weapon. Therefore, dust or liquids containing radioactive material would be used mainly for their effect on personnel, whereas the explosive and incendiary effect of the atomic bomb would be used primarily against materiel targets with the anti-personnel effects as an added factor.

(3) Again we must state that targets might be selected which are of great military, political, or economical value. For instance, the portable harbor set up by Allied Invasion Forces on the coast in France was the life line of General Eisenhower's forces in France for a considerable period of time. One atom bomb dropped into this harbor would have destroyed it and rendered the shore and all shore installations, as well as large quantities of materiel on the shore, totally unfit for further use and highly dangerous to personnel in the area. By cutting the vital life line link at this point a single atomic bomb might have changed the course of the history of World War II in Europe. The Allied Invasion Forces for Southern France of the Seventh Army could have been eliminated by one atomic bomb in the Naples harbor at any time for a three-day period. However, for tactical purposes the atomic weapon must always be reserved for such special cases where there is an all-important bottleneck or all-important operation which, if destroyed, would enable the force of the nation using the atomic bomb to gain a distinct advantage.

(4) Atomic weapons therefore are essentially strategic weapons for the destruction of the economic heart of the enemy.

[redacted]

[redacted]

f. Means and Weapons Available for Launching Atomic Weapons:

(1) A very large aircraft (B-29 or larger) is required to lift one atomic bomb. Therefore, such an aircraft, either piloted or pilotless, is required to drop an atomic bomb. No rocket or guided missile yet known to exist has the pay-load needed to take an explodable atomic weapon to the target. For instance, the pay-load of a V-2 German rocket is only 10 percent of that required to lift an atomic bomb. No doubt guided missiles can and will be developed capable of carrying an atomic warhead but this has not been accomplished.

(2) A ship could be used to place an exploding type atomic bomb in a harbor and such a weapon could be exploded later by radio waves or by a suitable delayed action mechanism, of which there are two or three suitable types. A submarine could be built to fire a torpedo carrying an atomic bomb in the warhead but torpedoes of such size are not made nor are submarines capable of firing such weapons in existance today without a major redesign.

(3) An atomic bomb could be constructed in place by saboteurs from material purchased commercially, except the relatively small weight of fissionable material and the trigger mechanism used in the heart of the bomb. Such material might be smuggled ashore from a foreign country.

(4) For scattering radioactive dusts and toxic gases we would need suitable bombs designed for air bursts. Actually such bombs would be gigantic M25 exploding hand grenades Such munitions would be loaded in special gliders and dropped from the glider by remote control. A thousand foot towline and shielding provided by ordinary bomb cases would provide safety for the crew.

(5) We can see from the foregoing discussion that the actual methods available for delivery of atomic weapons on suitable targets is somewhat limited at the present time, yet the variety is sufficiently great to make defense most difficult.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

g. Comparative Cost of Atomic Weapons and Other Munitions: It is not possible to state categorically the cost of destroying one square mile of area by means of the atomic bomb as compared with similar action by high explosive or by incendiary bombs. However, a very careful study of the area destroyed in Japan by various weapons indicates that one atom bomb (requiring one B-29 to carry it) produced destruction equivalent to 221 B-29s loaded with incendiaries or about 1,000 such planes loaded with high explosives. The cost of 220 B-29s and crews, of course, must be included in the cost of the incendiary attack while the cost of the larger number of planes and crews loaded with high explosives would have to be figured in this computation as well as the actual cost of the munitions used in each case. However, in all probability a lone plane can never again get to its target with an atom bomb because under such conditions jet fighters and rocket propelled defensive munitions would undoubtedly be concentrated in all areas likely to be attacked by atom bombs, and in order for the plane carrying the bomb to reach its target it would have to be guarded by an exceedingly strong escort of fighters and fighter bombers. Therefore, it would be futile at this stage to set down in dollars or man-hours or man-lives the comparative cost of destroying one square mile of urban area by the various weapons. However, it is sufficient to say that, regardless of the actual cost in dollars, the scarcity of fissionable material with which to make these munitions will, for a good many years, prevent their use on targets that can be erased effectively by other means.

h. Possibilities of Various Protective Measures That Can Be Taken:

(1) Before, During and After an Atomic Attack. A good survey, warning, and evacuation plan, with proper means for its implementation, will reduce the expected damage of an atomic attack on a target area by an appreciable amount. Therefore, the better the area damage control plan and organization the less successful an attack will be.

(2) If disaster control units, communication centers, medical facilities and command posts have been adequately dispersed under suitable shelters and have a sound defensive plan to guide trained personnel, then such targets will be much less helpless in the first hour following an atomic attack and appropriate damage control measures can be initiated at once.

(3) Target areas which are well protected by extremely fast interceptor aircraft, and antiaircraft units assisted by an adequate radar net are much less

[redacted]

likely to be struck effectively by atomic attack. This type of active air defense will only by available to highly critical areas and is not effective against saboteurs.

(4) It is thus apparent that the defense of an area can be divided into two phases of equal importance, viz:

(a) Active defense measures.

(b) Passive defense measures.

i. Final Selection of Targets: In making a final selection of a target for atomic attack, due consideration will be given to the following factors:

(1) Chance of a successful attack.

(2) Casualties inflicted by an attack.

(3) Type and extent of physical damage.

(4) Psychological and political effects achieved.

(5) Effect on the industrial potential of a nation.

(6) Disruption of important military operations.

j. General Conclusions:

(1) Atom bombs are going to be few in number for some time to come.

(2) Radioactive dusts are likely to be available on a relatively large scale.

(3) Atomic attacks will be so expensive to launch that only targets of major tactical or strategical importance can be engaged and then only when the chance of success is very great.

(4) The decision to use atomic weapons AT ALL must be considered carefully by the highest military and political authorities: as must each target so engaged.

3. Summary.

[redacted]

QUESTIONS FOR USE IN CONFERENCE FOLLOWING LECTURE:

a. What would be the difference in time required on a dusted area compared to an atom bombed area for casualties to appear?

b. What specific military operations carried out in World War II (other than those cited in the text) might have justified the expenditure of an atomic bomb for tactical purposes?

c. What reasons might cause an enemy to concentrate on radioactive agents rather than atomic bombs for military weapons?

d. What are the major logistical problems in supplying

(1) Atomic bombs?

(2) Powerful radioactive dust and liquids?

e. What types of targets would be selected for

(1) Air burst atomic bombs?

(2) Shallow water bursts of atom bombs?

(3) Dusting an area with radioactive material?

f. How can a knowledge of possible tactical and strategic uses of atomic warfare be used to plan both active and passive means of defense (Area Damage Control)?

g. Select five target in the U.S.A. in order of priority which you think an enemy might try to tom bomb or neutralize on outbreak of war. Consider: (1) the chance of the attack reaching the target, (2) the effects of the bomb: (a) materially, (b) psychologically, (c) politically, (d) militarily.

h. What psychological and political effect might be produced in the U.S.A. by ten (10) atomic bombs at the outbreak of war followed by one such bomb per month thereafter?

[redacted]

[redacted]

TRAINING OUTLINE: 27

LECTURE: Training Programs.

TIME: Fifty (50) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: None.

STUDENTS' REFERENCES: None.

TRAINING AIDS REQUIRED: Copies of Training Outlines No 6, 7, 14, 17, 19, 21, and 27.

1. It has been stated in previous lectures that many policy decisions in the field of radiological defense have not been made firm. Irrespective of this, it can be clearly appreciated that every individual within the National Military Establishment should receive indoctrination training in this field at the earliest practicable time. Individual unit instructors should be qualified now to conduct this indoctrination training.

2. The minimum amount of training mandatory is that amount which indoctrinates each individual to an understanding of explosion phenomena, radiological hazards and the defensive measures possible. All additional training is highly desirable and should be limited only by lack of equipment. Even this situation is being corrected and within one year each active Air Force base should have radiation detection instruments.

3. Many of the lectures which have been presented in this course can be used for indoctrination training. Copies of these lectures will be issued for permanent retention.

4. A suggested six hour indoctrination course for all officer and enlisted personnel is outlined below:

[redacted]

1743

ANNEX 1

GENERAL NATURE OF ATOMIC STRUCTURE

1. Introduction. Until the blast of the first atomic bomb tested fused the sand of the New Mexican desert into a glass-like substance, man had depended on the sun for all of his energy. Man used fire of one kind or another to warm himself, to cook his food, and run his engines. Fire derives its heat, its energy, from the sun. When we burn wood, some of the solar energy is liberated -- energy stored up by the tree from the sun's heat while it was growing. In burning coal and oil and gasoline we do the same thing, because coal and oil and the gasoline made from oil are, like wood, vegetable matter which stored energy from the sun during growth and then decayed or petrified millions of years ago to lie dormant under the earth's surface with stored-up energy until man discovered that they could be burned and their energy released as heat. Even when we eat plants, our bodies transform the solar energy in the plants into human energy and tissue. Meat brings us such energy second-hand, for the animals whose meat we use ate vegetable matter. Also, the power we get from wind and water comes indirectly from the sun, for, without the sun's heat, water would freeze and never evaporate to form rain and rivers and waterpower, and air unwarmed by the sun contains no currents of shifting cool and warm air which we know as wind. But there is another vast source of energy in the universe which does not originate in the sun. Scientists learned many, many years ago that the energy existed but they did not know how to release it. The solving of this problem and its potential uses have become a matter of utmost importance to the world.

2. The New Source of Power.

a. From the day of President Truman's dramatic announcement on 6 August 1945 that a bomb of unprecedented violence had all but obliterated the city of Hiroshima in Japan we have heard more and more about atomic bombs, atomic energy, fissionable materials, and the Atomic Age. The development of atomic energy was a discovery that is certain to affect not only the future development of the Air Force and the other armed services but also the course of our own lives and the lives of those who follow us.

b. Atomic power has already added many new words to our vocabularies. But not yet have we reached the point where a basic understanding of atomic energy is common knowledge. What is an atom? How is it constructed? Exactly why has the unlocking of the secret of the atom brought into the world tremendous possibilities for future good or evil? These things must become more commonly understood if we as Americans are to make correct decisions on the uses in which atomic energy may be put, and if we as members of the armed

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

forces are to gain an understanding of what the atom can mean in possible future warfare.

c. The structure of the atom and the sources of atomic power are somewhat complicated but not impossible to understand. Comprehension of the fundamentals does not require a high degree of education.

d. This new source of energy is in matter itself. In order to understand it we must first learn how matter - all matter - is constructed. We must also change some of the ideas about matter and energy that have been believed for hundreds of years - ideas that have been taught, for example, in high school physics.

e. Two supposed rules on the behavior of matter are now changed - the laws of conservation of mass and conservation of energy. The law of conservation of mass held that matter could neither be created nor destroyed, that it can only be altered in form. Thus when we burn a piece of coal, we do not destroy the matter that forms the coal; we only convert it from coal into gases and ash. The law of conservation of energy likewise holds that energy can neither be created nor destroyed but can only be changed in form. Thus, when we burn the piece of coal we merely set free in the form of heat and light the energy that the coal soaked up from the sun millions of years ago.

f. But in 1896 a French physicist, Becquerel, discovered that an element called uranium gave off energy by itself. Two years later the Curies, French scientists, discovered the same properties in radium. The energy given off by these and similar heavy elements of matter is called radioactivity.

g. It was this discovery of radioactivity that led to our tapping the energy bound up in matter, which up to the present time has been released in practical form only in the atomic bomb. We now know that matter and energy are but two manifestations of the same thing, and that under certain conditions matter can now be converted directly into energy and vice versa.

3. The Amount of Energy or Power in Matter.

a. When an atomic bomb explodes a certain amount of matter, as such, disappears. It is transformed into energy. After each explosion there is a little less matter in the world. Thus the old separate laws of conservation of mass and energy no longer hold true. Neither matter nor energy can be completely destroyed. But one can be transformed into the other.

[redacted]

[redacted]

ANNEX 1 (Cont'd)

b. To comprehend this, we must also revise our ideas about what happens to matter and energy even in ordinary chemical reactions, or changes in matter, such as the burning of coal or the explosion of TNT. It was long believed that when a piece of coal is burned the total of the weights of the gases and the ash produced were exactly equal to the ori-nal weight of the coal.

c. For all practical purposes this is still true, because the percentage of the weight of the coal transformed into heat and light, or energy, is so extremely small that it cannot be measured with any instruments now at our disposal. But what the scientists have learned about the transformation of matter into energy has made it possible to calculate with some accuracy the very small amounts of matter turned into energy by ordinary fire. Professor Albert Einstein, in his famous theory of relativity, devised a formula to determine the amount of energy contained in a given amount of matter. By comparing the amount of energy derived from the burning of a given quantity of coal with the greater amounts of heat given off by a given quantity of radium we can tell exactly how much of the coal actually turns into energy. In all normal chemical processes the percentage is infinitesimally small.

d. The Einstein formula in brief form is this: One pound of matter, any kind of matter inanimate or living, equals 11,400,000,000 kilowatt-hours of energy. The correctness of this method of calculation has been proven conclusively. From it we find that if the energy contained in one lump of coal could be completely liberated it would be about three billion times the energy obtained by burning the coal. The total energy of some twenty-five pounds of matter is equal to all the power produced in the United States in a year's time.

4. How Matter is Constructed.

a. Long ago the early Greek philosophers believed that all matter was composed of tiny indivisible particles to which they gave the name of "atoms". Their arguments were based only upon shrewd observation and were not confirmed by scientific experimentation. It was not until the eighteenth century that scientists found concrete scientific evidence to prove the "atomic hypothesis." The proof was found that all of the several hundred thousand substances found in nature are made up of very small particles called molecules.

b. The molecule is the smallest division of matter that allows a given substance to retain its identity and characteristic properties. For example, a molecule of sugar is the smallest particle into which sugar can be separated and still be sugar. There are several hundred thousand different molecules that occur naturally. Chemists have made hundreds of thousands more.

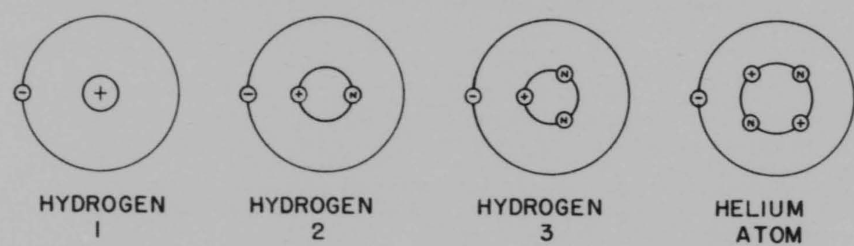
[redacted]

[redacted]

ANNEX 1 (Cont'd)

c. But although there are hundreds of thousands of molecules, all of them are combinations of only 92 simpler "elements" and several hundred "isotopes" of these elements, plus a few more recently discovered unstable elements. Elements are materials which cannot be broken down into simpler substances by chemical means. Water, for example, can be divided by chemical process into two elements, oxygen and hydrogen.

DIAGRAM OF HYDROGEN ISOTOPES COMPARED WITH HELIUM ATOM



d. The smallest unit of an element -- that is, the unit which cannot be subdivided without becoming something else -- is called the atom of that element. Some common examples of elements are hydrogen, carbon, nitrogen, oxygen, iron, copper, silver, gold, platinum, mercury, and many others. We can talk about atoms of these elements. But sugar, for example, is not an element, because a molecule of sugar contains many atoms of carbon, many of oxygen, and many of hydrogen. A molecule of water actually consists of two hydrogen atoms (H is the chemical abbreviation for hydrogen) and one oxygen atom (O), and is represented by the familiar chemical formula H_2O. Salt is not an element but a combination of two elements -- one sodium atom (Na) and one chlorine atom (Cl) and is represented by the formula NaCl.

e. But even after atoms and molecules had been discovered, it was not clear why, for example, the two atoms of hydrogen would combine with one of oxygen to form a molecule of water. The reason for this combination into molecules was discovered in the second decade of the present century, when it was found that atoms were divisible and had complicated structures of their own.

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

f. Atoms might be compared with minute solar systems, with a heavy central core, or "sun" called the nucleus. This central nucleus consists of one or more "protons". Around the nucleus, at relatively great distances from it, revolve much lighter particles, called "electrons". A proton weighs 1836 times as much as an electron.

g. This whole atomic "solar system" is very tiny; about one billion atoms could be lined up on a one-foot rule. Yet the size of the atom is enormous compared with the size of the electron. The average distance of the electron from the nucleus is about one hundred thousand times as great as the diameter of the nucleus. Hence every atom consists mostly of empty space.

h. The central nucleus of the atom is from two thousand to five thousand times heavier than its surrounding electrons. Actually, more than 99.9 percent of all the matter in the world is concentrated in the central nucleus of the atoms of the 92 basic elements.

i. In addition to size and weight, an electric charge is a very important quality of the electrons and nucleus of an atom. There are two kinds of electric charge -- positive and negative. Electric charges of the same kind -- either positive and positive or negative and negative -- repel each other. Charges of opposite kinds -- positive and negative -- attract each other.

j. An electron carries the smallest unit of negative electricity that has ever been observed. The unit of measure of the flow of electricity (electric current) as we ordinarily know it and use it for light, heat, and power is the ampere. One ampere is a small current. But the charge of an electron is so much smaller that it takes the flow of more then six million million million million electrons per second to make one ampere. This tiny electric charge of one electron is used as the unit of measurement to state the electrical properties of atoms.

k. The element hydrogen has the simplest atom. The hydrogen atom has one electron revolving around its nucleus. Its nucleus consists of one proton. The proton carries a positive charge of electricity which exactly balances the negative charge of the electron so that, electrically speaking, the atom as a whole is neutral.

l. The nature of each of the 92 elements is determined by the number of protons in the nucleus of its atom. Thus, the hydrogen nucleus has one proton, the helium atom two, the lithium atom three, and so on up the atomic scale until we arrive at the nenety-second element, uranium, which has 92 protons in its nucleus.

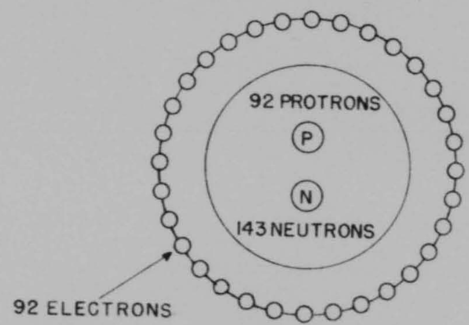
m. Since each proton contains one charge-unit of positive electricity, the number of protons in the nucleus determines the number of electrons which revolve around the nucleus. The number of revolving electrons always balances exactly the number of protons in the nucleus.

[redacted]

[redacted]

ANNEX 1 (Cont'd)

n. The number of protons in the nucleus also determines the atomic number of the element. Thus hydrogen, with one proton in its nucleus, has the atomic number 1, helium has number 2, and so on up to uranium again, which has the atomic number 92.



o. If we can picture to ourselves the structure of the atom with its central nucleus of one or more heavy protons, and one or more much lighter electrons revolving about the nucleus, we can understand nearly all of the physical and chemical properties of matter.

p. But it is not quite as simple as that. Nature has departed from consistency in certain elements. With the discovery of radioactive elements, such as radium and uranium, it was found that such types of matter had surprising properties that could not be explained on the simple basis of balanced nuclei and electrons. The ability of uranium and radium to give off energy in the form of rays (some of which were identified as fast-flying nuclei of an entirely different element, helium) indicated that the atoms of radium and uranium and similar elements were actually undergoing changes deep within their nuclei. These changes are known as radioactive decay, which is really the emission of various forms of excess energy. Alpha radiation, beta radiation and gamma radiation are the three forms in which this energy is emitted.

q. An even more surprising property of matter was discovered in 1919. It was found that the collision of helium atoms with nitrogen atoms led to the formation of two entirely different atoms -- oxygen and hydrogen. This actual change of one element into another, which was as startling and remarkable as changing iron into copper or lead or silver, could only be explained by assuming that the nucleus of an atom could be divided and other elements thus formed.

RESTRICTED

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

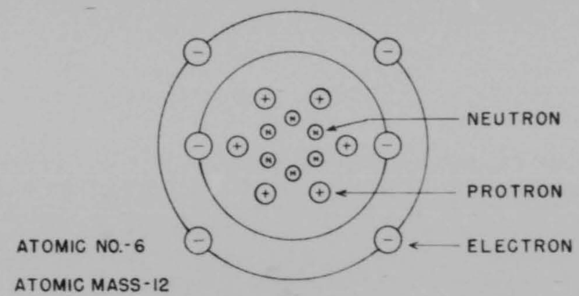
ANNEX 1 (Cont'd)

r. In 1932, a new particle, the neutron, was discovered within the nucleus of the atom by Professor Chadwick, of Cambridge University. The neutron is electrically neutral. It possesses a tremendous amount of energy.

s. The protons and neutrons which form the nucleus of an atom differ markedly in electrical properties, but they have nearly the same weight. The weight of a neutron like that of a proton is about two thousand times that of an electron. Since the weights of the proton and neutron are about the same, and the weight of the electron much less, the weight of the atom is very close to that of the total number of neutrons and protons in the nucleus.

t. The total number of protons and neutrons in the nucleus of any atom is called the atomic mass, or mass number, of the particular element. For example, carbon has six protons in its nucleus, giving it the atomic number 6. In addition the carbon nucleus contains six neutrons, so we say that carbon has the atomic mass, or mass number, of 12. To determine the number of neutrons in the nucleus of each element, we subtract the atomic number (that is, the number of protons) from the atomic mass number.

u. It has also been discovered that most elements may consist of mixed atoms of more than one form -- called "isotopes" -- in the sense that the number of protons in the nucleus is always the same, but the number of neutrons may be different. These isotopes have the same atomic number but different atomic weights. For example, there are three kinds of hydrogen, all called isotopes, all containing one proton in the nucleus of the atom; hence, all three have the atomic number 1. The first hydrogen isotope has no neutrons (the only element of its kind), and thus it has an atomic mass of 1. The second hydrogen isotope has one proton and one neutron and thus an atomic mass of 2; the third, with two neutrons, has an atomic mass of 3. (see diagram of hydrogen isotopes, page 5).



CARBON ATOM

[redacted]

[redacted]

ANNEX 1 (Cont'd)

v. Likewise the uranium atom always has 92 protons; but uranium is found in nature in three isotopes, the nuclei of which have either 142, 143 or 146 neutrons (in addition to the 92 protons in each kind). Thus the three uranium isotopes have atomic masses of 234, 235, and 238 respectively.

5. The Forces Within the Atom.

a. We have seen that the nuclei of atoms are built of protons and neutrons. Before the discovery of the complex structure of the atomic nucleus it was believed that two general types of force could account for all natural phenomena; electrical forces, which account for lighting, radio, and television; and gravitational forces, which cause objects to fall to the earth and govern the motion of the planets around the sun.

b. The forces that hold together the particles in an atomic nucleus are due neither to electricity nor to gravity. For one thing, although neutrons have no electrical charge and protons do have an electrical charge, the holding force between two neutrons or between a neutron and a proton in the nucleus of an atom is the same as between two protons.

c. The exact nature of these nuclear forces is not yet clearly understood, but it is known that when protons and neutrons are at distances smaller than a million millionth of an inch -- the diameter of an atomic nucleus -- extremely strong forces of attraction between them come into play. The force that holds a proton or neutron inside the nucleus of an atom is more than a million times stronger than the electric force that holds an electron inside the atom itself, and this force in turn is much stronger than any gravitational force.

d. The strength of this nuclear force is best shown by comparing the weight of an atomic nucleus with the total weight of its separated protons and neutrons. The whole nucleus actually weight slightly less than its parts; it has about 99 percent of their weight. But from Professor Einstein we know that weight (or mass) and energy are equivalent and can be transformed into each other. Hence in a nucleus a small part of the weight of the protons and neutrons appears to become energy holding the nucleus together.

e. A tiny bit of matter is equivalent to an enormous amount of energy. Therefore the one percent difference between the weight of the nucleus and that of its separated neutrons and protons indicates that a tremendous amount of energy is stored in the nucleus. This is "atomic energy". The scientific problem, partly solved in developing the atomic bomb, was how to get some of this energy out of the atomic nucleus -- how to get it released -- in a practical, usable form.

6. Releasing the Energy of the Atom.

[redacted]

[redacted]

ANNEX 1 (Cont'd)

a. According to the nuclear physicists, atomic energy can be obtained either by splitting the nuclei of heavy atoms into almost equal parts, or by building up heavier nuclei out of the nuclei of light atoms. So far it has been possible to obtain atomic energy only by "atom splitting". The building-up process, which accounts for the energy in the sun, requires such high temperatures that it is considered impossible for man to accomplish it on earth.

b. During the 1930's many investigators "split" the nuclei of atoms by building special scientific instruments and bombarding them with protons or neutrons. A separate proton directed or "shot" at an atomic nucleus tends to be repelled by the nucleus because the outside proton carries the same type of electric charge as the protons in the nucleus. Hence outside protons must have tremendous speed to overcome this repelling force and come close enough to the nucleus for a proton to hit it occasionally. On the other hand, a separate neutron directed at a nucleus has no electric charge. It is therefore not repelled and can more easily strike and penetrate the nucleus.

c. This is why the discovery of the neutron was of tremendous importance. It was use of the neutron that enabled the scientists to tap the heart of the uranium atom, releasing the energy that erupted so explosively in the atomic bomb. It is the neutron that will unlock further atomic secrets for us, opening up possibilities that at present can only be imagined. In the words of one scientist, the neutron is "the sword with which to open the cosmic oyster."

d. All the cases of atom-splitting up to 1938 have one result in common -- the bombarded nucleus split into two fragments. One was always very small while in the other was left most of the original nucleus. But in 1938 it was found that a heavy nucleus would split into two almost equal parts upon a neutron bombardment. In particular it was found that the nucleus of the uranium isotope of mass number 235 would split into two large pieces of almost equal weight. This real atom-splitting is called "nuclear fission".

e. Further investigations showed that nuclear fission liberated tremendous amounts of energy. The split nucleus lost about one one-thousandth of its mass by transformation into energy. We have already noted that a small difference in mass corresponds to an enormous amount of energy.

f. Even more important was the fact that during the fission process extra neutrons were released and these multiplied the effect of the original neutron bombardment. It is these extra neutrons that make it possible to release atomic energy in practical amounts. Without the additional effect of the released neutrons which strike and break up other nuclei, thus releasing still more neutrons, nuclear fission would be a comparatively rare event and the amount of energy released each time

[redacted]

1753

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

would be of no practical value. It would be as if a ton of coal needed thousands of dollars worth of matches to keep it burning.

g. The extra neutrons released in the fission process in turn produce fission in more nuclei, and this releases more neutrons, and so on. A large number of nuclei undergoing fission release large amounts of energy, and the repeating process is called a "chain reaction".

h. In order to cause a chain reaction, quite a big lump of fissionable material, such as uranium, must be used. If only a small piece is used most of the extra neutrons will escape from the lump and not enough will remain within it to keep the reaction going. But the comparative number of neutrons that escape can be reduced by increasing the size of the lump of the material. This is because the production of neutrons is proportional to the volume, whereas the escape of neutrons is proportional to the surface area and the volume increases more rapidly with size than does the surface area.

i. As the size of the lump is increased a point is reached at which there are as many neutrons produced by fission as escape through the surface of the lump. This amount is called a critical mass. Any amount of the material smaller than a critical mass is not enough to keep a chain reaction going. On the other hand, if the amount is greater than a critical mass, more neutrons will be produced than leak out and an explosion may result.

j. Whether or not there is an explosion depends on whether the chain reaction develops in a short enough time. If the mass of active material is made strongly over-critical, the chain reaction develops very rapidly. Energy is then released at an explosive rate and the active material expands until it becomes diluted. With the dilution of the active material more neutrons escape and in time the reaction stops. But during the short time before expansion stops the chain reaction a large number of nuclei undergo fission resulting in a tremendous release of energy and a violent explosion. This is what happens when an atomic bomb is exploded.

k. If the amount of active material is only slightly over-critical the chain reaction develops slowly. Then it can be controlled and the energy can be released at a slow, even pace. It is this controlled chain reaction that offers hope for future uses of atomic energy for peace-time purposes.

TRAINING OUTLINE NO:	28
LECTURE:	Effect of the Atomic Bomb on Hiroshima Nagasaki.
TIME:	One (1) hour.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	USSB Report on Hiroshima and Nagaski; "Medical Aspects of Nuclear Energy", AFSWP, NME, 1949; Chapter 12, 13 and 14, "AFRTC Manual 52-355-1", Dept of the Air Force, May 1949.
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Charts appended hereto.

To determine the basis on which the probable effects of an atomic weapon can be predicated we can best study the effects of the weapon on Japan. Consideration of the conditions existent when the attack was delivered and an evaluation of the damage resulting therefrom will help us greatly to predict the probable effect of an atomic weapon on some strategic target within the United States. Consideration will be given to Hiroshima and Nagasaki separately and overall conclusions drawn from both.

1. HIROSHIMA

a. General. The city of Hiroshima was selected as a target for the first atomic weapon because it had received an insignificant amount of prior bomb damage, was on a flat level delta, had representative structural types of construction located over a large area, contained predominately over-crowded wooden buildings, was well equipped with public utilities and services, and was an important military center.

b. The Target. Hiroshima covered an area of approximately 26.5 square miles and had a population of about 245,000. However in the central portion of the city there was a population density of over 31,600 persons per square mile. This density is about 1¼ times the density of New York City despite the fact that Japanese dwellings are not over two stories high. The central portion of the city was devoted to residences, commercial sections and military installations but had no industrial establishments of any size. All houses were equipped with electric lighting, about 75% of the

[redacted]

1755

[redacted]

residences were supplied with gas for domestic consumption, all residences had water connections to the municipal system but there was no sewer system. The city was built on a flat delta and divided into five islands by the Inland Sea. These islands were connected by forty-five bridges and the streets were wide enough for two lanes of traffic. There were few firebreaks, those which existed were inadequate in width, the fire department was small and poorly equipped and no well organized civilian defense units were functional. There were eight major hospitals in the city.

c. Circumstances. The morning of the attack was clear with a 4 mph wind. At 0709 hours an air raid alert was sounded but only a few planes came over and at 0731 hours the "all-clear" was sounded, since the B-29s were thought to be reconnaissance planes only. Following this, people were on their way to work when planes arrived over Hiroshima at 28,000 feet and dropped the atomic bomb. As a result almost 75% of the population was in a congested 4 mile square area of the city's center at the instant of detonation. In addition there had been no rain in three weeks and the area was dry.

d. Action. At the instant of detonation there was a blinding flash more brilliant than the sun. Following this flash there was a blast of heat and wind. The large majority of people within 3,000 feet of the explosion were killed immediately. Within a radius of about 7,000 feet almost every building collasped. Beyond 7,000 and up to 15,000 feet - 20,000 feet many buildings collasped and others received serious structural damage. Persons in the open were burned on exposed surfaces, and within 3,000 - 5,000 feet many were burned to death while others received severe burns through their clothes. In many instances clothing burst into spontaneous flame. Thousands of people were pinned beneath collapsed buildings or injured by flying debris, particularly flying glass. Fires began to spring up over the city and developed into a fire storm in the center of the city. Some of these fires were caused by direct ignition of thatched roofs, curtains and rubbish but the majority resulted from secondary effects such as debris falling on kitchen fires, electrical short circuits and industrial process fires. For half an hour the fires spread in all directions, thereafter they merged, and burned out all combustible material in an area of 5 square miles. The fire department was paralyzed and survivors, becoming panicky, fled to the outskirts of the city.

e. Damages.

(1) Buildings - Of 90,000 buildings spread over an area of 9.5 square miles, some 60,000 were totally or severely damaged. Roofs and walls were stripped from other buildings 4 miles from the explosion and glass windows were broken up to 8 miles.

[redacted]

(2) Public Utilities - All utilites and services were disruptedand damaged, a great many key employees were killed, and the city was temporarily without transportation, electricity, communications, gas, water or effective authority. Thirty hours elapsed before the first rescue or relief parties entered the stricken areas.

f. Casualties. Approximately 80,000 persons were killed outright, almost another 100,000 were injured of whom some 60,000 died in the next two months and only about 50,000 remained uninjured. Deaths were due to the following causes:

(1)	Radiation disease	15 - 20%
(2)	Flash burns	20 - 30%
(3)	Secondary injuries	50 - 60%

Radiation effects were very prominent up to 6,500 feet and personnel within a radius of 3,000 feet would have been killed by radiation sickness later had they not been killed outright due to blast, burns and debris. All medical facilities and most of the medical personnel in Hiroshima were destroyed. The injured who survived did so without any appreciable medical care, however it is estimated that not more than 10% of the terminal casualties could have been saved by the best of medical care.

2. NAGASAKI

a. General. The second attack involving an atomic weapon was initially directed against an unknown city but weather closed in and Nagasaki, an industrial city, was hit. Five previous HE bomb attacks had produced negligible damage.

b. Target. Nagasaki covered an area of approximately 35 square miles, of which 4 square miles was heavily built-up, and had a population of some 230,000 persons. The city lay on a narrow coastal strip encircling a long narrow bay and extending up two river valleys which were separated by a mountain spur. One of these spurs contained the industrial zone, while the other contained the residential and commercial areas. Information on electrical, water and gas connections to residences is not available. The city was haphazardly built and the street system was poor. Firebreaks were inadequate and the fire department was inferior. Over 90% of the available hospital facilities were concentrated in two hospitals.

c. Circumstances. The day of the attack was clear with a 3 mph wind. An air raid alert was sounded at 0750 hours but was cancelled at 0830. No warning was sounded at 1102 hours when the aircraft came over and dropped the bomb.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

d. <u>Action</u>. The bomb detonated in the air and the results were generally the same as at Hiroshima. The blast was not centered over the main business area of the city but up the valley about two miles where there were industrial plants, hospitals and partially built-up residential areas. The terrain in this area was uneven with large hills which shielded certain areas. Due to the shielding factor and distance of the explosion from the city, Nagasaki was not as completely destroyed as Hiroshima. There was no fire storm and not nearly as much panic as at Hiroshima but there was greater damage within the blast area. The fire department was unable to cope with fires but bucket brigades were effective in some areas.

e. <u>Damages</u>.

(1) Buildings - Some 20,000 buildings in an area of 1.8 square miles were destroyed or severely damaged. Structural damage due to blast extended some 6,000 feet - 7,000 feet north and south of the explosion. Superficial and minor damage due to blast extended as far as 19,000 feet along the bay and extended to valleys protected from the direct blast.

(2) Public Utilities - All utilities and services were disrupted and damaged as at Hiroshima. The destruction was not so great, however, and restoration of limited service was quicker.

f. <u>Casualities</u>. About 45,000 people were killed and some 60,000 injured in about the same ratio of casualties as were noted at Hiroshima. All hospitals and almost all medical personnel were destroyed. It was several days before any organized medical care was instituted..

3. CONCLUSIONS

a. <u>General</u>. Detailed evaluation of all available data from the bombing of Japan has not been released. Certain general rules can be drawn however. These rules are summarized below.

b. <u>Effect of Explosion</u>.

(1) Blast or pressure wave similar to normal explosion except in degree of magnitude.

(2) Primary fires which are those started instantaneously by the heat radiated from the atomic explosion.

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

(3) Secondary fires which are those resulting from the collapse of buildings, damage to electrical systems, overturning of stoves and industrial process fires.

(4) Spread of primary and secondary fires to other buildings.

c. Radius of Blast. With the exception of certain reinforced concrete structures, everything within 1,000 yards from the center of the explosiion will be totally destroyed. Portions of strong concrete structures may survive the blast but will be useless. Everything up to three miles will suffer considerable damage and beyond this distance damage, although comparatively light, may extend for six to seven miles. Glass may be broken up to ten miles. Details are shown on the following chart.

(INSTRUCTOR - REPRODUCE CHART 28-1)

d. **Fire Damage.** A vast quantity of radiant energy is released at the instant of detonation. This radiation causes intense surface heating of all objects up to two miles from the center of the explosion. In some cases this surface heating will ignite readily flammable material. The majority of fires, however, are due to secondary causes. Depending on the wind, effectiveness of fire breaks and action of disaster control personnel, these fires may be contained or allowed to spread and become a conflagration which burns out areas untouched by the blast. More specific data are included on the following chart.

(INSTRUCTOR - REPRODUCE CHART 28-2)

e. Effects of Radioactivity.

(1) Prompt - All persons within about 1 mile of the center of the explosion will receive a fatal dose of gamma and neutron radiation. They will, however, most likely be killed outright by heat, blast or debris. Those in an area between 1 and 1.5 miles from the explosion will receive an appreciable dose of radiation that, while not necessarily fatal will complicate recovery from other injuries. Outside the 2 mile radius there is little effect from instantaneous radiation.

(2) Residual - A high airburst detonation will leave negligible residual radioactivity and may be confined to some neutron induced radioactivity directly under the blast. However, fall-out of radioactive particles from the cloud will occur and may do so many miles away in

[redacted]

1759

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

dangerous amounts. If detonated on the ground, small areas up to one mile in radius from the center of detonation may be heavily and semi-permanently contaminated, thereby necessitating abandonment.

f. Casualties. Unless personnel were dispersed in underground shelters a minimum of 100,000 casualties would probably result in an area such as New York City and some 25,000 - 50,000 would be killed outright. The bulk of all medical facilities would be destroyed as well as medical personnel.

4. CONCLUSION

The atomic bomb is a weapon without parallel in destructive power. Its effect on Japan was to destroy two cities and break the will of the Japanese nation to wage war. A large portion of its effectiveness was due to the overwhelming surprise of a new weapon, the inferior passive defense organization and the fact that personnel were not dispersed in air raid shelters. The effect of an atomic bomb on other cities and nations could be similar to that on Japan. However it is felt that a disciplined populace well organized and prepared for atomic attack could greatly minimize the effect of an atomic attack.

INSTRUCTOR'S QUESTIONS:

1. What percentage of atomic bomb casualties are due to radiation injury? What percent to burns? What percent to secondary injuries?

2. What will happen to every man-made structure within 1,000 yards of an atomic explosion?

3. How far does appreciable blast damage extend from an atomic explosion?

4. How far do intense surface heating effects extend from an atomic explosion?

5. How far is the prompt radiation from an atomic explosion dangerous?

TRAINING OUTLINE NO:	29
LECTURE:	Atomic Bomb Explosion - Effects on an American City.
TIME:	Fifty (50) minutes.
PLACE:	Classroom.
INSTRUCTORS' REFERENCES:	None. (See Footnote*)
STUDENTS' REFERENCES:	None.
TRAINING AIDS REQUIRED:	Charts appended hereto.

1. Introduction. It is important that one appreciate the real power of an atom bomb, and the purpose of this article is to present a realistic picture of the damage which a typical American city might suffer were an atom bomb to be detonated over it. As a typical city, "City X", is an excellent choice. Furthermore, it is strategically situated in the industrial heart of the United States so that it would certainly be selected as a target city if this country were ever to be embroiled in another war.

2. The Problem.

a. Just how would an aggressor nation go about atom-bombing "City X"? What type of bomb would it select? At what point would the bomb be detonated? To answer these questions one has to consider many factors.

b. The type of atomic bomb used would depend upon the technical ability of the aggressor to fabricate and detonate bigger and better bombs. Or perhaps they should be termed bigger and worse bombs. Assuming that

*This lecture is a copy of a document, prepared by Dr. R. E. Lapp of the War Department General Staff. It does not contain classified material. The charts appended hereto should be prepared beforehand on a blackboard and "blown up" as much as possible.

[redacted]

1763

[redacted]

the technical difficulties are surmounted and that it is possible to make A-bombs of considerably more than 20,000 tons high-explosive equivalent, than the problem of the selection of the bomb size involves a careful evaluation of the following two factors:

(1) How much of the aggressor nation's plutonium (or other fissionable material) reserve could be allocated to the target? This question brings out an interesting fact with which many may not yet be familar. The world is no longer on the gold standard; it is actually on a plutonium standard. Aggressor nations will measure their wealth in terms of the amount of fissionable material (plutonium) which they stock-pile.

(2) What is the military priority of the target? The answer to this question will involve a detailed study of the contribution which the city makes to the nation's war economy.

c. A glance at the map of "City X" shows that there are at least two areas of prime military importance. One is the "Section A" steel industry and the other is the "Section B" industrial section. Of paramount importance, but not so easily seen on a map, is the wide diversification of feeder industries which abound in the city.

3. A New Bombing Problem.

a. It will be noted that the two critical areas singled out for discussion are separated by about ten miles. In planning an ordinary bombing raid, it would be a simple problem merely to assign so many bombs to each area in the city, but in using atomic bombs, the problem is more complex. Because the A-bomb has such enormous destructive effect, one has to balance desired damage to structures against desired damage to personnel.

b. It is quite possible that in bombing "City X" it would be decided to use a detonation designed to kill off or injure the maximum number of people in the city and thus cripple the industrial capacity of the entire area. In order to knock out both "Section A" and "Section B" areas with one bomb, the bomb would have to be prohibitively large in size in comparison with the military priority of the targets. Furthermore, the use of more than one atomic bomb would not be feasible since destruction of both areas would not result in sufficient casualties in the crowded residential areas of the city.

4. Point Zero.

a. Without going into a further detailed study of the problem let it be assumed that it is decided to detonate an atomic bomb

RESTRICTED

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

of 50,000 tons high explosive equivalent at an altitude of 2500 feet at Point Zero.

b. The reason for selecting the target center at Point Zero is that this will insure that the destructive effect of the bomb will not be wasted over unpopulated or non-critical areas.

c. If "City X" is situated on the shores of a lake or is so located that its build-up area fans out radially to the northeast, as much as 50% of the bomb's destructive power could be wasted over the uninhabited south western area by exploding the bomb two miles to the south west of Point Zero.

d. If one wanted to kill off large number of the population and render the city uninhabitable, one might conceivably detonate the bomb in the nearby lake. While no blast damage would be inflicted on the city, it might happen that under proper conditions the prevailing winds would carry lethal quantities of spray-borne radioactive materials over the city, thus raining down upon it lethal quantities of invisible radioactivity.

e. Why select a bomb of 50,000 H. E. equivalent? This is done to insure that the destructive range of the explosion will be sufficient to accomplish the objective of killing or maiming the maximum number of people in the area.

f. Such a bomb would be more than twice as powerful (published value = 20,000 tons H. E. equivalent) as the type used on Nagasaki. Without violating any security regulations, it is possible to say a few things about the bomb mechanism. Despite all of its differences from an ordinary explosive, the atomic bomb has at least one similarity. Under proper conditions, an increase in the amount of charge (fissionable material such as plutonium) can result in a corresponding increase in the over-all explosive power of the bomb.

5. Possible Size Limitations.

a. However, since the trick in setting off atomic explosives is to keep the fissionable parts in a subcritical state until the time desired for detonation, it is obvious that making more powerful bombs of the Nagasaki type will require considerable development. The reason for this is, that if one assumes that two subcritical masses of plutonium are violently brought together (made critical), then using the same technique more than two such subcritical masses must likewise be brought together if a higher order explosion is desired; this is easier said than done. Furthermore there is no guarantee that when one successfully detonates such an improved atom bomb, it will have the same

[redacted]

efficiency per pound of plutonium as obtained with a smaller bomb. In view of the scarcity of this man-made element, it must be carefully rationed in peace and in war.

b. These two factors might alone limit the ultimate feasible size for atom bombs but there is another even more convincing reason why plutonium bombs may not be progressively increased in destructive power. This reason, simply stated, is that one 20,000-ton high explosive blast does not do as much direct damage as two 10,000-ton explosions. This rule holds true for all explosives.

6. Altitude of Detonation.

a. How does one decide at what altitude the bomb should be exploded and why are these bombs exploded so high in the air? The exact altitude for detonation depends upon the explosive power of the bomb, the nature of the target, and the type of damage desired over the given area. If one wants to annihilate a small but vitally-important installation, the proper procedure is to explode the bomb as close as possible to the target. But if the damage is to be extended over a much greater flat area, then one simply explodes the bomb high enough in the air so that the blast wave will extend out over the desired area and still produce destructive effects.

b. At Nagasaki, where the Japanese tell us the bomb exploded 1800 feet above the ground, there were about ten square miles of land hard hit by the blast. At Almogordo, N. M., the bomb was only 100 feet above the ground and less than three square miles were damaged to the same degree.

7. The Attack.

a. With the foregoing facts in mind, one can proceed to examine what would happen to the "City X" if it were subjected to an atom bombing of the type just described. Let us assume the attack takes place at noon when the downtown area is most heavily populated.

b. The city is enjoying a pleasant sunny day with a cooling breeze coming in. The streets are thronged with thousands of shoppers in the downtown and Point Zero areas. Then suddenly and without warning the bomb is detonated high above the city.

c. A dazzling bluish-white flash blinds those people on nearby streets and sears them at the same time with its million-degree heat. Almost within a thousandth of a second the small ball of fire shoots out to form a sphere of flame 100 yards in radius. Simultaneously the color of the ball changes going over to a varicolored seething mass which spreads outward and downward at terrifying speed. Above it all, a huge pinkish white mushroom "atomic cloud" forms and climbs toward the stratosphere.

d. Directly under the blast, the instantaneous flash of heat sears all pedestrians into unidentifiable charred and grotesque forms. Those shielded from the heat are momentarily conscious of a terrible pressure wave that topples taller buildings and crumbles others into rubble. Within a second a blast wind of near supersonic velocity rushes in and demolishes those buildings untouched by the primary blast wave. The air is thick with dust from pulverized buildings and the crashing of surrounding buildings creates a din which is soon followed by the ominous Niagara-like noise of fires ignited by the flash.

8. Secondary Damage.

a. To feed the multitude of fires, air rushes in from the surrounding area, even overcoming the prevailing breeze, and soon a firestorm of gale proportions sweeps the city. This unusual fire-storm persists for several hours and makes the entire area near the epicenter inaccessible to what fire-fighting equipment is available. Streets made impassable with debris, the failure of the water pressure, disrupted communications all prevent fire fighters from reaching the stricken area.

b. Within a three-mile radius of the epicenter, the number of dead and injured is staggering to the imagination. Those who were with-in one mile of the blash center, while still surviving, are living on borrowed time. When the brilliant flash of light occurred, those living within a mile of the blast center were exposed to a deadly dose of penetrating radiation. Unseen, unheard and unfelt these deadly rays penetrated the human tissue and left their mark. Perhaps the survivors would linger for a few days, or even a few weeks but they are doomed.

c. Much of the enormous damage is due not so much to the primary effect of the bomb but to the secondary effects. In this cat-egory, one would list fire damage, injuries due to collapse of the fire-gutted buildings, deaths from burns, suffocation and lack of med-ical care. Much of the effectiveness of the A-bomb is due to its in-stantaneous and widespread action. A modern and efficient fire depart-ment, such as "City X" has, can cope capably with a few outbreaks of fire within the city, but when hundreds of fires are simultaneously started miles apart in an impassable area, it is a hopeless task to stem the onrush of the holocaust.

9. Damage at Point Zero.

a. Suppose that the fire burns itself out within the next day and one can then re-enter the area and critically examine the smolder-ing ruins and evaluate the over-all damage to the area. To make the survey more systematic, let the examination be concerned first with blast damage.

(INSTRUCTOR - REPRODUCE CHART 29-1)

[redacted]

[redacted]

b. In the larger map, the various zones of damage due to blast are outlined. Since it is difficult to separate the individual effect of the shock wave from that of the blast wind, their combined effect is considered. From the epicenter to a distance of 1 mile there is heavy blast damage. All frame and brick buildings are demolished and only those sturdy, reinforced-concrete structures on the periphery of this zone escape complete destruction. Within the zone the interior of all buildings is subject to intensive damage.

c. Both the downtown and the Point Zero shopping centers on the periphery of this zone sustain extensive damage ranging from total destruction to heavy damage. In some cases the walls of the buildings remain standing but the roofs and floors are missing. Able street is a scene of utter desolation. From the City Hall to Baker Street it is impassable. Streetcars and automobiles, many with their occupants lying dead inside them, stand out in the rubble-strewn streets.

10. Damage 1 Mile from Point Zero.

a. Farther out from the epicenter, within the 1- to 2-mile radius, heavy damage is sustained. Included within this zone is the downtown area of the city. Here some of the larger, well-built structures seem to be intact but closer examination shows that their interiors are extensively damaged and many are gutted by fire. At the lower end of Main Street, the beautiful Memorial Auditorium is in ruins, but many of the buildings along Main Street even closer to the epicenter are almost untouched. Apparently these were shielded by other buildings or merely escaped blast damage by virtue of having been "skipped".

b. The neon beacon high atop the Charles Building has been ripped asunder and lies in the street below. The main structure remains more or less intact with greatest damage being apparent on the upper part of the building. In spite of the appearance of the exterior of the modern structure, there were many casualties in it and due to the fires which raged throughout the downtown area it was impossible to evacuate all of the occupants of the building.

c. To the east, the Central Terminal still stands, but severely damaged. Without any shielding from the blast wave, parts of the structure collapsed. The railroad yards are inoperable with twisted rails jutting up from the ground. Apparently many of the railroad ties in the bed were burned by the flash.

11. Damage at a Distance.

a. Between 2 and 3 miles distance from the epicenter moderate blast damage is evidenced among the ruins. The majority of the blast damage is concentrated on frame dwellings and plants of light construction.

[redacted]

Brick houses in this zone still stand but show some signs of interior damage.

b. More than 3 miles from the point of bomb detonation there are still signs of blast damage but for the most part they are minor and are masked by damage from fire.

c. It is possible for blast effects to be felt at as great a distance as 8 miles from the epicenter, but such damage would be slight and rare.

12. Fire Damage.

(INSTRUCTOR - REPRODUCE CHART 29-2)

a. When the bomb explodes a vast quantity of radiant energy (light) is liberated in the form of ultraviolet, visible and infra-red radiation. This radiation causes intense surface heating of all objects which it strikes within a 3-mile radius of the epicenter. In some cases, depending on the local conditions, this surface heating is sufficient to ignite the material. Thus, within a circle roughly 6 miles across, there may be hundreds or even thousands of fires started and of these several hundred will persist and spread.

b. The effect of such intense burning over such a wide area is to cause a mass influx of air from outside the region. This movement continues if it overcomes the prevailing winds and an enormously destructive firestorm results and whole areas untouched by the blast are burned out.

c. In "City X" the prevailing southwesterly wind would overcome the firestorm after a few hours and tend to sweep the blaze into the B Section of the city. To the north, Forest Lawn and Dog Park would act as natural fire breaks and to the southwest, the South Park section would be shielded by the prevailing winds.

13. Effects of Radioactivity.

a. Before continuing the discussion of the damage inflicted by the bombing, it is useful to summarize here certain facts which are known for radioactivity resulting from atomic-bomb-explosions. When Hiroshima and Nagasaki were A-bombed, there was great confusion in the nation about the effects of radioactivity resulting from these explosions. Some of this confusion persists today and the following facts may clarify the situation:

(1) Before the bomb is exploded the material gives off only alpha rays which are easily absorbed in a piece

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

of writing paper. Except for the fact that plutonium is extremely toxic one might treat this material very casually by merely wearing gloves to protect against alpha rays. After the bomb is properly exploded, what plutonium is not "burned" up or fissioned is widely scattered and will persist for many years.

(2) When the bomb explodes, an instantaneous burst of neutrons and gamma rays occurs. These penetrating rays flash through the atmosphere and many go right through concrete walls to pass through the bodies of people inside the buildings. A thick shield of lead or many feet of earth or concrete would protect against most of the gamma rays but lead, for example, would be quite transparent to the neutrons. Except for the ground directly below the point of detonation, good protection would be afforded from the deadly radiation by a fairly deep tunnel shelter.

(3) After the bomb has exploded, the only danger that persists is from the so-called fission products which fall out from the atomic cloud and from radioactivity induced in material close to where the bomb is detonated. The fall of radioactive material from the atomic cloud depends on atmospheric conditions and it may occur over the city or it may occur many miles from the city. Such radioactivity is due to burned-out atoms (fission products) and it is composed of beta and gamma rays. Beta rays are essentially high-speed electrons and they can be absorbed in a few sheets of thin aluminum. Gamma rays, on the other hand, are extremely penetrating X-rays and require several inches of lead to filter them out. Both rays are dangerous to human tissue. Perhaps the beta rays are the most insidious for they are more difficult to measure than gamma rays and therefore are sometimes overlooked even when present. No neutrons are present after the first few seconds of the blast.

(4) Should the bomb be exploded close to the ground or to tall buildings, then considerable radioactivity is produced in this material by the action of the neutrons in passing through it. Such radioactivity is said to be "induced" in the material. Certain elements such as sodium (as in table salt) are easily made radioactive. Each element so activated by neutrons thereafter "decays" by emitting beta and gamma rays; the time taken by the various elements to decay varies from elements

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

to element. Depending on the exact circumstances of the bombing, the ground below the point of detonation will be radioactive for a length of time varying up to several months' duration. For example, if an atomic bomb were smuggled into the basement of the City Hall and then detonated, it would be many weeks before that area could be safely re-entered and many months or even years before it was safe for rehabilitation.

(5) Using radioactive materials which accumulate in the manufacture of plutonium, it would be possible to make a lethal gas of finely dispersed fission-products which could be deposited on an unsuspecting city. Such a radioactive gas attack on a city would panic the entire populace unless the city were provided with radiation-measuring instruments to detect the activity. Even the rumor of such an attack would send a city's populace into flight if it were not reassured by on-the-spot instruments capable of measuring the radioactivity. Incidentally, there are very few such instruments now in "City X" and fewer still which can measure alpha rays.

(6) It should be emphasized that one cannot rely on the senses to detect the presence of radioactivity. Neutrons, beta and gamma rays can be present in lethal intensities without any immediate effect on the senses. To be sure, after a while there is a decided effect noted by the body but by that time it is too late for the victim to get away from the radiation. Scientists do not understand the ways in which penetrating radiation produces changes in human tissues, but they know what happens to such tissues after it is exposed to radiation. As a result of exposure to intense radioactivity, certain physiological changes take place in the body. Symptoms of radiation damage include nausea, vomiting, general debility, sustained fever, loss of body hair, erythema (redness of the skin from capillary congestion), loss of appetite, and a decrease in the while blood cell count. These symptoms may appear soon after the exposure or in a few weeks. For example, epilation (loss of hair) may occur within a few days or within a few weeks. Exposure to radiation accompanied by injury from burns or falling debris may result in the death of a person even though neither the radiation injury nor the burn would of itself have caused death. There is very little that medical science can do for persons suffering from radiation damage and almost nothing it can do if the victim is exposed to more than a certain critical dose of the rays.

[redacted]

[redacted]

14. Zones of Damage from Radioactivity.

a. To return to discussion of hypothetical A-bombing of "City X", the necessary facts about radioactivity have been presented and the specific radiation damage inflicted upon the populace can now be considered.

(INSTRUCTOR - REPRODUCE CHART 29-3)

b. All persons living within a radius of about 1 1/3 miles of the epicenter would be exposed to a lethal dose of radiation provided they were not shielded by thick brick or concrete walls. A wood frame wall offers little shielding from this radiation. Therefore most of the people surviving the combined effects of fire and blast in this area would probably die within a few days or weeks from the effects of the penetrating radiation.

c. Those living in the zone from 1 1/3 miles to 2 miles from the epicenter, while not receiving a lethal dose of radiation, would receive a considerable exposure that would complicate their recovery if they suffered any other injuries. Many would show obvious signs of radiation damage, such as loss of hair, but they would later recover and live apparently normal lives.

d. Outside the 2-mile radius, there would be no effect from the primary flash of radiation, but it is possible that a fall-out of radioactivity would occur. If so, varying intensities of radioactivity might be found ranging from harmless to dangerous amounts.

e. Village Y would lie directly in the favored path of the fall-out and if conditions were such that a rain storm occurred carrying down vast quantities of radioactivity with it, then the entire populace of Village Y and surrounding territory would have to be quickly evacuated.

f. It will be recalled that in the case of the New Mexico atom-bomb test, some of the atomic cloud settled out miles away from the detonation point and cattle in the path of this fall-out latter were found to have white backs where some of the radioactive particles adhered.

15. Total Casualties.

a. In summing up the supposed atom-bombing of "City X", one can most readily realize the terrific striking power of the new weapon by estimating the total casualties caused by the explosion -- about 100,000. Of these, about 50,000 would result in fatalities. The number of fatalities would run as high as this because of the lack of proper medical facilities at the time they are needed most, i. e., the day of the explosion. At Hiroshima there were only a few hospitals in usable

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

condition out of about 50. Of 1780 nurses only about 100 were available for duty after the explosion.

b. The staggering figure of 100,000 casualties would mean that every family in the city would be directly affected by the explosion. Many civic leaders, key industrialists, and thousands of skilled craftsmen would succumb to the disaster. Thus while the Section A steel plants would still be intact and outlying factories would be undamaged, the city would require many months before it could rebuild the bombed-out area, replace personnel, and repair public service throughout the striken community. "City X" would have been effectively knocked out by one bomb!

16. Defense Against Atomic Attack.

a. There are many who will ask if there is not a means of counteracting the atom bomb. The atom bomb is a new type of high explosive and as such it is the same as any other high explosive in that you can protect against it only by deflecting it from its trajectory or by blowing it apart before it reaches its object. There is no mysterious mechanism in the bomb that one can detonate prematurely by radio waves, ultrosonics, or other means.

b. The use of guided missiles may do much to enable one to seek out and explode atom bombs before they reach their objectives, but it is difficult to conceive of this process being perfected to the point where it will guarantee that no bombs will get through the defense.

c. Furthermore, since warfare of the future promises to be one of split-second timing in which the element of surprise will be of paramount importance, adequate defense would require constant on-the-trigger vigilance by every nation. In an atomic war, if even a few minutes are required for alerting defensive forces or for getting administrative decisions, the war may be over before the defense went into action.

d. The danger of insidious warfare using sabotage with radioactive materials planting atomic bombs in cities or harbors is not to be minimized.

e. This discussion is not entirely academic, for other nations will soon have atom bombs of their own. If a great world power is willing to spend enormous amounts of money, resources and manpower in an all-out effort, it may be able to produce bombs of effective design within 15 years perhaps in less than 10. This nation has already released a large amount of information about the atomic bomb which will considerably reduce the time required for another nation to make it.

f. It is true that it would require more than 10 years for another nation to duplicate our effort in atomic research on the bomb but it would profit by our experience and not try to duplicate all of it.

[redacted]

1773

[redacted]

g. There are many preventive measures a city can undertake to minimize damage from atom-bombs, for example, decentralization of vital facilities and utilities, proper city planning with adequate allowance for fire lanes and fire-breaks to minimize fire-damage. The building of strong reinforced concrete structures for vital industries, construction of tunnel shelters, and many other measures will all tend to make a target city less desirable as a target.

h. In many cases, the cost of such defensive measures would be prohibitive and in the final analysis, they are futile. In the few years which are left before other nations have atom bombs of their own, it is useless as well as economically unsound to try to convert our cities into decentralized underground strongholds. The effect that such action would have upon civilian morale cannot be estimated.

i. In spite of the enormous destructive power of the atomic bomb, the new weapon is not an absolute weapon. It remains to be seen just what place the weapon will have in military strategy. From the standpoint of this nation's defense, it is not at all certain that our military position is strengthened by the possession of atomic bombs. If one coldly analyzes the use to which these bombs can be put in time of war and one considers that other nations will have the same type of weapons, then it is apparent that our military position is actually weakened by the possession of the bomb. There is also a very real danger that we will delude ourselves into thinking that the atom bomb has given us military superiority over all other nations.

j. The purpose of this article has been to present various facts about the destructive power of the atomic bomb in realistic terms. It is hoped that on so doing, it has served to stimulate common sense thinking about the bomb. It is, of course, quite apparent that the answer to the threat of the atomic bomb must be found in the political, not military field. All the forces which we possess must be marshalled in a concerted effort to outlaw war as a means of settling international disputes.

TRAINING OUTLINE NO: 30

LECTURE: Seminar. General Review.

TIME: One (1) hour.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: All previous material.

STUDENTS' REFERENCES: All previous material.

TRAINING AIDS REQUIRED: Blackboard.

This is intended as a question and answer period, with students asking the questions. If considered advisable, all instructors may be present, each to deal with questions pertaining to his specialty.

When no more questions from the students are forthcoming, instructors may ask questions from a previously prepared list, so organized as to provide a review for the final examination. Many or most of the questions on the final can be discussed at this point, and every attempt should be made to insure that all students have an adequate grasp of all points under discussion.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

TRAINING OUTLINE NO: 31

EXAMINATION: II

TIME: One hundred (100) minutes.

PLACE: Classroom.

INSTRUCTORS' REFERENCES: Training Outlines No 16 to 30. All previous references, Instructors's Answer Guide, (See Footnote *).

STUDENTS' REFERENCES: Lecture notes from Training Outlines No 16 to 30.

TRAINING AIDS REQUIRED: Copies of Examination II.

Instructions.

1. Use of student's notes is permissible.

2. All questions can be answered in one short sentence or less.

3. Check your paper for completeness - there are 20 questions in this examination.

QUESTIONS.

1. Is the 263A survey meter calibrated with the beta shield open or shut?

____

2. There are three intensity ranges on the 263A survey meter. What is the approximate range of each?

a. ____________ mr/hr b. ______________ mr/hr

c. ____________ mr/hr

*Students should be permitted to use their notes. At completion of examination, the questions should be reviewed and the correct answers given.

[redacted]

[redacted]

1779

THIS PAGE IS DECLASSIFIED IAW EO 13526

3. The 247A survey meter has four intensity ranges. What is the range of each?

a. x1 range ________mr/hr   b. x10 range __________mr/hr

c. x100 range ______mr/hr   d. x1000 range ________mr/hr

4. How may beta radiation be measured with a 247A Survey Meter?

____

____

5. There are three checks to be made on a 247A survey meter before it is ready for operation. What are these three checks?

a. ____

b. ____

c. ____

6. Personnel entering radioactive areas wear dosimeters in addition to carrying survey meters. Why is this necessary?

____

____

7. Give two reasons why film badges are used in addition to dosimeters.

a. ____

b. ____

8. What is the significance of a 0.1 R/Day isodose line?

____

____

9. What materials are required to decontaminate personnel who have been working in radioactive areas?

____

10. Above what radiation intensity are personnel considered contaminated? __________________mr/hr. Is this gamma only or beta plus gamma? ___________________________.

RESTRICTED

11. After an atomic explosion, the affected areas are monitored. What type of survey is made first?

____

12. Does a fox-hole afford any protection against an atomic explosion (not directly overhead)?

____

____

13. List 10 factors which should be considered in preparing a unit radiological defense plan.

a. _______________ b. _______________

c. _______________ d. _______________

e. _______________ f. _______________

g. _______________ h. _______________

i. _______________ j. _______________

14. List three cases where decontamination of radioactive contamination is possible.

a. ______________________________

b. ______________________________

c. ______________________________

15. Clothing which is worn in radioactive areas becomes contaminated. Above what intensity should it be discarded for use? __________ mr/hr

16. Casualties from an atomic explosion are due to three main causes. What are these three causes?

a. ______________________________

b. ______________________________

c. ______________________________

17. The blast effect from an atomic explosion has a definite radius. What is the radius for:

[redacted]

a. Total destruction? ________________ yards

b. Considerable damage? ______________ miles

c. Negligible damage? ________________ miles

18. What causes the majority of fires following an atomic explosion?

____

____

19. Personnel within a certain distance of an atomic explosion will receive a dose of instantaneous radiation. What is the effect at:

a. Less than 1 mile? ___________________________________

____

b. Between 1 and 1.5 miles? ____________________________

____

c. Over two miles? ______________________________________

____

20. State whether you now feel qualified to act as a unit radiological defense officer. ____

Instructors' Answer Guide

This answer outline has been prepared for the instructors' convenience. It contains answers to all examinations and questions which are given in the training outlines.

It should be understood that a great many questions do not have one dogmatic answer. Judgment should be exercised, therefore, in the use of this guide, particularly on examinations.

Training Outline No 1

No questions.

Training Outline No 2

No questions.

Training Outline No 3

1. A molecule is the smallest portion of a compound which can exist and still be that compound. Atoms are the particles from which molecules are built.

2. Neutrons, protons and electrons.

3. Isotopes are atoms with the same number of protons in their nucleus but with different numbers of neutrons in their nucleus.

4. The significance of $E = mc^2$ is the fact that mass and energy are interconvertable.

5. A nucleus weighs 1% less than it should because 1% of the mass has been converted into binding energy.

6. Atomic energy is "released" binding energy.

Training Outline No 4

1. Energy is the ability to do work.

2. Wave lengths.

3 The shortness of wave length.

[redacted]

[redacted]

4. X-Rays.

5. High energy radiation is any ionizing radiation which contains enough energy to cause bodily harm.

6. Alpha, beta, gamma, and neutrons.

7. Gamma - greatest. Alpha - least.

Training Outline No 5

1. a. Nucleus splits into two parts.

   b. Three neutrons are liberated.

   c. Large amount of energy is released.

2. The scarity of raw material.

3. Plutonium must be made to conserve available uranium ore.

4. No, because of the critical mass factor.

5. A critical mass is the smallest amount of fissionable material which will sustain a chain reaction.

6. Increases its explosive power.

7. a. Simple neutron capture.

   b. Neutron capture with particle emission.

Training Outline No 6

1. Much greater intensity and travels faster.

2. Alpha, beta, electro-magnetic and neutron radiation.

3. About one mile.

4. a. Neutron-induced isotopes.

   b. Fission products.

   c. Unfissioned bomb material.

5. Surface heating of surrounding areas.

[redacted]

THIS PAGE IS DECLASSIFIED IAW EO 13526

[redacted]

6. Fall-out is the phenomena wherein radioactive material, carried away from the area by winds, eventually falls to earth miles from an explosion.

<u>Training Outline No 7</u>

1. First, second and third degree flash burns.

2. Destroys cells in the body.

3. a. Outside the body - none.

   b. Inside the body - produces cancerous growths.

4. Similar to gamma - lesser degree.

5. 0.1 R/Day.

6. External hazards are those which can cause harm while outside the body. Internal hazards are those which can cause harm only when inside the body.

Training Outline No 11

No questions.

Training Outline No 12

No questions.

Training Outline No 13

1. Gamma only radiation and gamma plus beta radiation.

2. About 20 mr/hr (.48 R/Day).

3. Measurement of ionization produced in gases by high energy radiation passing through the gases.

4. Gamma only radiation.

5. Ion chambers are more accurate because they measure total ionization produced, whereas geiger counters count ionizing events.

RESTRICTED

1787

[redacted]

6. Up to several hundred R/Day.

Training Outline No 14

1. Beta and gamma radiation.

2. a. 0.2 - 0 to 0.2 mr/hr.

   b. 2 - 0 to 2 mr/hr.

   c. 20 - 0 to 20 mr/hr.

3. Background count is the ionization produced by cosmic radiation which is heard as a clicking noise in the headphones or a geiger counter.

4. Probe is held up to a strong light with the beta shield open. Any sudden increase in background count indicates light sensitivity.

5. By use of beta shield.

6. a. Decide intensity which is desired.

   b. Using a source, place meter at a point where the desired intensity is obtained.

   c. Listen to signal in headphones and become accustomed to the noise level and pulse repetition rate.

   d. Move probe back and forth from sample. Notice viariations in audio signal.

   e. Close your eyes and have someone move sample a short distance.

   f. Try to determine the proper point where the desired intensity exists. When this is possible within 10% error, it is possible to run an audio survey.

CONAC MANUAL 125 - 2

4 19.2242125-2
April 1949

CRIMINAL INVESTIGATION

OFFICE OF THE PROVOST MARSHAL

CONTINENTAL AIR COMMAND

5-2260-12

APRIL 1949

Atch 13

THIS PAGE IS DECLASSIFIED IAW EO 13526

FOREWORD

1. This manual was prepared by Lt Colonel Clifford V. Oje Sr., Office of Provost Marshal, Headquarters Continental Air Command, Mitchel Air Force Base, New York, and is published for the information and guidance of personnel assigned to the Provost Marshal activity who are required to make investigations of crimes and offenses during their tour of duty.

2. With the establishment of the Office of Special Investigations, a centrally directed investigative service was provided for the United States Air Force. As a result, some confusion and uncertainty has developed regarding the investigative functions of Provost Marshals. This manual was written specifically to clarify and delineate the residual investigative responsibilities of the Provost Marshal activity.

3. This publication should be issued to each Air Force Policeman as a manual for reference and study.

A. E. TANNER
Lt Colonel, USAF
Provost Marshal
Continental Air Command

5-2260-12

THIS PAGE IS DECLASSIFIED IAW EO 13526

TABLE OF CONTENTS

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION VI - OPERATIONAL PROCEDURES

SECTION VII - COOPERATION AND LIAISON WITH OTHER AGENCIES

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION I - GENERAL

1. Purpose of Manual.

a. This manual is intended to be used as a ready reference and guide by Air Force Policemen and other interested personnel in the investigation, prevention and suppression of crime and military offenses.

b. It is anticipated that the information and suggestions embodied herein will clarify the responsibility of Air Force Policemen in the field of criminal investigation. Cognizance has been taken of the important role of the newly organized Office of Special Investigations under The Inspector General in the investigation of major crimes. There has been no attempt to infringe on the prerogatives and requirements that have been established for the OSI in the fulfillment of their mission in criminal investigation. On the contrary, it is the intent of this manual to provide procedures for Air Force Policemen in which they will better be enabled to assist and cooperate with the OSI and at the same time, assume their own responsibilities in the investigation of crime.

c. It is further hoped that this manual will assist in the standardization of investigative procedures that come within the purview of the Provost Marshal activity.

d. It is not the purpose of this manual to discuss and portray every detail necessary in the investigation of crime. Detailed criminal investigative techniques will be found in other military manuals and publications. Particular reference is made to FM 19-20, "Criminal Investigation".

1803

THIS PAGE IS DECLASSIFIED IAW EO 13526

2. Responsibility.

a. Regardless of the availability of the services of the OSI, commanders will continue to make inquiry into all matters which adversely affect the efficiency, morale or welfare of their commands. (See par. 5c, AFL 20-4)

b. The Provost Marshals will still assume the responsibility for the investigation, prevention and suppression of all minor crimes and offenses.

c. Air Force Policemen (MOS 677) will supplement their duties by making investigations of those cases that come within the purview of the Provost Marshal activity.

SECTION II - FUNCTIONS

3. Functions. The functions of the Provost Marshal in the investigation of crimes and military offenses are governed by the following:

a. The complete investigation of certain minor crimes and offenses.

b. The preliminary investigation of major crimes and subsequent necessary action prior to transfer of such cases to the OSI.

c. The transfer of such cases to the OSI that deal with major crimes, those that require investigation in locations not contiguous to the local Air Force base and such other complicated and complex cases that warrant the attention of highly trained investigative technicians.

1804

d. The completion of necessary action upon the return of a completed case from the OSI.

e. The establishment of oral or written agreements with the OSI on necessary administrative details.

f. The maintenance of a roster of individuals engaged in investigative activities with whom coordination and cooperation are necessary.

g. The preparation and maintenance of a local up-to-date standing operating procedure for the investigation of crimes and military offenses.

h. The clarification and interpretation of existing policies, directives and publications pertaining to the criminal investigative responsibilities within the Provost Marshal activity.

i. The proper supervision and control of all investigative matters.

j. The preparation of reports and the maintenance of records of all investigative cases.

k. The provision for adequate training in criminal investigations through the medium of interim Provost Marshal training, on-the-job experience and attendance at The Military Police School.

l. The preparation of reports for the commander of all investigative cases that are completed or referred to the OSI.

m. The preparation of reports for the commander that will indicate trends and patterns of conduct, discipline and incidents of crime.

n. Initiation of procedures and methods for the prevention and suppression of crime.

o. Ascertain that proper standards of military discipline are in effect in each unit on the base.

p. Establishment of coordination with proper agencies on the base to insure adequate provision for those factors that provide for good welfare and morale among the airmen.

q. The maintenance of an esprit de corps between the Air Force Policemen and other airmen.

SECTION III - ADMINISTRATION

4. Personnel.

a. Assignment.

(1) Criminal investigative sections or branches will not be organized or designated as a part of the organization of the Provost Marshal activity.

(2) Air Force Policemen will be assigned to investigative duties who have had the most experience and training in such activities.

(3) Before an Air Force Policeman is assigned full responsibility for investigating any case, he should have had some specialized training in investigative techniques and should have been assigned to investigative details with other experienced and trained Air Force Policemen for at least sixty days.

(4) An Air Force Policeman who has been assigned to investigative duties should possess an unusual aptitude for investigative work but should not have

THIS PAGE IS DECLASSIFIED IAW EO 13526

"cloak and dagger" leanings.

(5) Air Force Policemen performing investigative duties will not be known as investigator, agent, Mister, or detective. They will be known only as Air Force Policemen.

(6) Air Force Policemen should be extended every opportunity to display their ability and to learn techniques incident to investigations. All personnel of the Air Police who are assigned to an MOS of 677 should be potential investigators. The best men should be considered when called upon to make nominations to fill vacancies in the OSI.

(7) A criminal investigator, MOS 301, is not authorized for investigative duties in the Provost Marshal activity.

b. Qualifications. In the assignment and selection of Air Force Policemen for investigative duties, consideration should be given to the following criteria:

(1) Investigative experience in civilian and military life.

(2) Airmen who formerly possessed an MOS No. 301 and who were not transferred to the OSI - providing there are no pertinent reasons which barred them from being satisfactory investigators.

(3) Graduate of the Special Investigator's Course at The Military Police School.

(4) Legal training and experience.

(5) Civilian police training and experience.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(6) A natural leaning to and reasoning power for investigative activities.

(7) A graduate from high school.

(8) An AGCT score of 110 or more.

(9) A character rating of "Excellent" and is known to possess temperate habits.

(10) Has not been convicted of a felony by either a military or a civilian court.

(11) Possesses an MOS No. 677.

(12) Has served at least sixty days as an assistant to an Air Force Policeman assigned to investigative duties.

(13) Air Force Policemen engaged in investigative activities must be tactful and courteous; must understand the duties and responsibilities involved in the Provost Marshal activity; must possess a working knowledge of all regulations and directives pertinent to criminal investigations; must have knowledge of essential handweapons; must possess a personal dignity and be serious and conscientious; must not be patronizing, demanding, boastful or egotistical; and must possess an everlasting industry and a wholesome proportion of common sense.

5. <u>Credentials</u>.

a. No special identification cards, badges or credentials will be provided Air Force Policemen engaged in investigative activities. The brassard will remain the symbol of authority and the

THIS PAGE IS DECLASSIFIED IAW EO 13526

official means of identification of all Air Force Policemen.

6. Uniforms.

a. Air Force Policemen engaged in investigative duties will wear the identical uniform prescribed for Air Force Policemen. Civilian clothes will not be worn at any time during the official investigation of any case. Concealed weapons will not be carried. The .45 caliber pistol or revolver is authorized for use by Air Force Policemen in their official duties.

7. Incidental Expenses.

a. No special project funds have been authorized for Air Force Policemen engaged in investigative assignments other than those allotted to the regular Provost Marshal activity.

b. Commutation of rations and quarters are not authorized for investigative duties. When an investigation of a case requires that investigation be made at a distance from the base, necessitating additional travel, personal expenses and overnight delays, the entire case or that phase of the investigation requiring travel will be transferred or turned over to the OSI.

8. Transportation.

a. Ordinary transportation facilities available to the Provost Marshal activity will be used. The use of civilian vehicles is not authorized for investigative assignments.

9. Supply and Equipment.

a. The equipment and supplies for investigative activities is authorized in T/A 1-1, "Equipment for Air Force", and T/O & E 1-8014, "Air Police Squadrons", and T/O & E 1-0001A.

THIS PAGE IS DECLASSIFIED IAW EO 13526

10. Training.

a. Criminal investigative techniques will be taught to all Air Force Policemen in special interim training classes provided for Air Police Squadrons. A long-range program of technical criminal investigative subjects should be devised.

(1) The following list of subjects will serve as a guide in the preparation of a course of study in criminal investigations:

Articles of War	Report Writing
Interrogations	Statements and Confessions
Interviews	Crime Prevention
Arrests	Fingerprinting
Searches and Seizures	Casting and Molding
Sources of Information	Firearms Identification
Observation and Description	Preservation and Handling of Evidence
Allied Investigative Agencies	Expert Testimony
Notes and Sketches	Crime Scene Searches
Investigative Photography	

b. Problems that arise from the investigation of criminal cases should be made a matter of discussion and study at special training periods set aside for the Air Police Squadrons.

c. All Air Force Policemen should be provided with on-the-job training conducted by experienced investigators.

d. Arrangements should be made for the outstanding Air Force Policemen within each Air Police Squadron to attend The Military Police School. Quotas should be submitted in accordance with existing directives on the subject.

SECTION IV - FUNCTIONS AND RESPONSIBILITIES OF THE OSI

11. **Responsibilities and Functions.**

a. Specific functions and responsibilities of the OSI are outlined in paragraph 5, AF Letter 20-4, AF Letter 124-3 and AF Letter 124-4, as follows:

(1) Establishment of a competent and centrally directed special investigative service to all Air Force activities.

(2) The availability of trained investigative specialists and technicians to perform all types of investigations for commanders when required or requested by them.

(3) Submission of interim or progress reports to commanders advising them of the activity on a current basis.

(4) Forward completed reports of investigation to the interested commanders for appropriate action.

(5) Apprise commanders of trends and patterns of irregularities and offenses as disclosed by a centralized operation to commanders.

(6) The establishment of procedures for the investigation of all major offenses including fraud and conspiracy, major crimes of arson, black market operations, bribery, burglary, embezzlement, forgery, larceny involving more than $50.00, perjury, robbery, smuggling and such other major

THIS PAGE IS DECLASSIFIED IAW EO 13526

violations of the Articles of War and federal statute as come within the purview of the OSI.

(7) The detection and investigation of espionage, sabotage, treason, sedition, subversion, disloyalty and disaffection.

(8) Investigation of violations of AR 380-5 and personnel backgrounds and loyalty checks.

(9) The summarization and analysis of information regarding the status and extent of disaffection, subversion, espionage and sabotage, and the dissemination of this information to appropriate Air Force agencies and commanders.

SECTION V - TYPICAL CASES WITHIN THE PURVIEW OF THE PROVOST MARSHAL

12. Typical Cases.

a. A great majority of crimes committed in the military services are minor crimes, and thereby warrant investigation by the Office of the Provost Marshal. Typical cases in which Air Force Policemen will assume the responsibility for making complete investigations are indicated by the following:

(1) AWOL and desertion.

NOTE: When an AWOL or desertion case is involved in a major crime, or when the investigation necessitates overnight travel and additional expenses, they will be transferred in part or in toto to the OSI, except when the case is assigned to apprehension teams.

(2) Straggling, malingering and misbehaving before the enemy.

(3) Improper use of a countersign or forcing a safeguard.

(4) Fraudulent reenlistment, false muster, false returns or false pretenses.

(5) Escape, attempt, or conspiracy to escape.

(6) Releasing prisoners without proper authority, or failure to report the commitment of a prisoner to a commander.

(7) Misbehavior of a sentinel or guard.

(8) Conduct - bringing disrespect to the military service, or conduct unbecoming an officer or a gentleman.

(9) Disrespect or disobedience toward superiors.

(10) Violations of local rules and regulations.

(11) Drunkenness.

(12) Failure to pay debts or failure to keep promises to pay debts.

(13) Larceny less than $50.00 in value.

(14) Minor cases of arson or mayhem.

(15) Violations of regulations regarding captured property.

(16) Vehicle accidents - involving a government vehicle where negligence may have been the cause for an accident or where a claim may be made against the government.

NOTE: When the facilities of the Provost Marshal are inadequate for the proper investigation and handling of any of the above offenses, the Provost Marshal will solicit the cooperation and assistance of the OSI. It might be necessary in some instances to transfer entire cases to the OSI.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Offenses in which an officer is the offender or subject will be investigated personally by the Provost Marshal at the base concerned.

b. Normally, Air Force Policemen will be the first law enforcement agency to arrive at a scene of crime. It will be compulsory for them in every case to take the necessary action to insure that all preliminary details will be resolved in their initial investigation. If it is found that the investigation is a case for the OSI, the crime scene will be left intact in as far as possible. Proper security will be provided in such cases, arrests will be made as warranted and the OSI will be notified immediately.

SECTION VI - OPERATIONAL PROCEDURES

13. General.

a. The operational procedures as outlined and described in this section do not represent a complete study of the operational techniques employed in criminal investigative activities. Many textbooks and publications have been written on the operational procedures involved in criminal investigations. Particular attention is called to FM 19-20, "Criminal Investigation" and the syllabi prepared by The Military Police School on criminal investigations.

b. While this manual is not intended to cover every detail necessary in the operation of a criminal investigative program, it will serve as a reminder of the many fundamental operational details which might easily escape the attention of our Air Force Policemen in their investigation of crime.

THIS PAGE IS DECLASSIFIED IAW EO 13526

14. Making Initial Investigation.

a. When an Air Force Policeman discovers a crime or a violation of military rules or regulations, he will take immediate action as follows:

(1) Take such steps as are necessary in the protection of human life and government or civilian property.

(2) Arrest offenders, when warranted.

(3) Record initial statements of witnesses and suspects.

(4) Insure that the crime scene remains intact until such time as proper pictures are taken and a crime sketch is made.

NOTES: In the case of a murder, it is necessary that no one touch or move the body, that none of the physical properties in the vicinity of the murdered person be disturbed until such time as a crime sketch is made and adequate pictures are taken.

In case of suspected suicide, the person, if dead, should not be taken down if he is hanging. The surrounding physical properties should not be moved until a crime sketch has been made and proper pictures have been taken.

(5) Sketch and photograph the scene of crime.

(6) Immediately notify your superior upon the discovery of any crime.

(7) Assimilate all data and information.

(8) Take necessary steps to prevent any further criminal action or violation of military rules or regulations at the scene of crime.

THIS PAGE IS DECLASSIFIED IAW EO 13526

b. Preliminary investigations by Air Force Policemen are justified in certain major cases where the OSI are not immediately available and where the conduct of the investigation will suffer.

(1) Furthermore, cases at first might appear to be minor crimes but after initial investigation may assume the proportions of major crimes that necessitate investigation by the OSI.

15. <u>Taking Subsequent Action</u>.

a. Upon completion of initial action, the Provost Marshal will determine whether or not the case warrants investigation by the OSI.

b. If it is determined that the case warrants further action by the OSI, the Provost Marshal will take such steps as have been previously arranged by verbal or written agreement with the OSI and transfer the case with all pertinent data to the proper district office of the OSI.

(1) In some cases, it will be necessary to review the case with the commanding officer in order to determine whether or not the case should be transferred to the OSI for investigation.

c. Immediately upon the transfer of a case to the OSI, the Provost Marshal will notify the commanding officer of the action taken.

(1) A special file will be maintained by the Provost Marshal on all cases transferred or referred to the OSI. A copy will be filed of correspondence in all cases that are transferred to the OSI.

THIS PAGE IS DECLASSIFIED IAW EO 13526

d. Cases that require action by the Provost Marshal will be completed by Air Force Policemen who are designated by the Provost Marshal.

e. Upon receipt of completed cases that are returned from the OSI, necessary action by the Provost Marshal will be taken as follows:

(1) Immediately report the return of the case to the commanding officer.

(2) When warranted, discuss further possible action with the commanding officer and the legal officer.

(3) Process case to the subject's immediate commanding officer for prosecution.

(4) Confine suspects, when warranted.

(5) Insure that necessary charge sheets are prepared by subject's immediate commanding officer.

(6) Request the commanding officer responsible for the preparation of charges notify the Provost Marshal of completed action including results of trial. Close out the case and file under completed OSI cases.

(7) Notify OSI of completed action in order that case may be closed in their files.

f. Prepare adequate reports on all cases.

16. Reporting Incidents to Superiors.

a. Upon the discovery of a crime either through observation or by report, the immediate superior in command available at the time will be notified without delay.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(1) This report will include a brief estimate of the situation and incorporate the details outlined in the suggested form in Appendix II.

b. Provost Marshals will keep commanding officers informed on incidents of major importance.

17. Supervising Investigations.

a. Provost Marshals will maintain close supervision and control over all those investigative activities that come within the purview of their offices.

b. All incidents will be carefully screened by Provost Marshals to ascertain that all cases have been transferred to the OSI that require their attention.

c. Investigations will be conducted in accordance with military standards as provided in FM 19-20 and other pertinent directives. Provost Marshals will supervise the inspection techniques to ascertain that they comply with existing policies and procedures.

18. Preparing Reports.

a. The fundamentals and procedures of writing reports as described in Chapter 14, FM 19-20 and amplified herein will be observed in making written reports on the results of investigations.

(1) Before writing a report, the Air Force Policeman should read the Courts-Martial Manual to determine what type of crime the report covers and what proofs are necessary to render a conviction.

b. The standard report forms WD AGO 19-65, 19-66, will be employed in making written reports of completed investigative cases.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(1) The provisions of paragraph 7a and b(1), and paragraph 8, AR 380-5, 15 August 1946 will cover the classification of reports.

(2) Care will be exercised to insure that reports of investigations are not overclassified.

c. Provost Marshals will review investigative reports to the extent necessary to insure that desirable standards of investigative procedures are maintained and that all possible clues have been uncovered and that the maximum development of such clues has been executed.

(1) When warranted, they will initiate necessary action to correct deficiences or irregularities in investigative procedures.

d. Reports of investigative activities required by this and higher headquarters will conform to instructions published from time to time.

(1) Directives governing such reports in existence as of the date of this manual are:

(a) ConAC Letter 37-2, "Reports of Offenses and Criminal Investigative Activities", 9 April 1947, as amended.

(b) ConAC Letter 37-3, "Flash Report of Serious Crimes", 14 May 1947.

e. Air Force Policemen should always take notes preparatory to writing a report.

THIS PAGE IS DECLASSIFIED IAW EO 13526

NOTES: A good set of notes is a prerequisite to a good report. Anything worth remembering is worth writing down. A report is a word-picture of an investigation conducted.

(1) Every good set of notes must answer the five basic questions:

(a) Who?
(b) What?
(c) How?
(d) Where?
(e) When?

(2) Notes must be:

(a) Neutral.
(b) Definite.
(c) Clear.
(d) Concise.
(e) Brief.
(f) Free of superfluous words.

(3) The date on the notes should be the calendar date when the notes were actually taken. Pages should be numbered and titles given to the pages. Initial all notes.

(4) Personal opinions should not be included in notes.

(5) Divulge information only to or through superiors. Never discuss promiscuously any information on any case.

(6) Report things as they are actually found, not as you would like them to be or as you think they should be or might be.

(a) Do not adopt the statement of an informant as your own. It might be wrong.

f. The five cardinal principles essential in the preparation of a report include the following:

(1) Accuracy.

(2) Completeness.

(3) Brevity.

(4) Fairness.

(5) Clarity and arrangement.

THIS PAGE IS DECLASSIFIED IAW EO 13526

19. Maintaining Records.

a. Provost Marshals will maintain their own administrative records and files on all cases to meet local requirements and to the extent necessary to prepare statistics and periodic reports required by higher headquarters or by their commanding officers.

b. An adequate filing system will be established by each Provost Marshal to insure that all pertinent information, exhibits and evidence pertaining to a given case are properly assembled, to provide ready access to such material and to afford full and complete control over all such material.

20. Advising Personnel of Rights Under the 24th Article of War

a. The 5th Amendment to the Constitution of the United States provides that in a criminal case, no person shall be compelled to be a witness against himself.

(1) The principle employed in this process applies to trials by courts-martial and is not limited to the person on trial but extends to any person who may be called as a witness.

b. The use of coercion or unlawful influence in any manner whatever by any person to obtain any statement, admission or confession from any accused person or witness, shall be deemed to be conduct to the prejudice of good order and military discipline.

c. No statement, admission or confession obtained by coercion or unlawful influence will be received in evidence by any courts-martial.

d. It shall be the duty of any person in obtaining a

1821

THIS PAGE IS DECLASSIFIED IAW EO 13526

statement from an accused to advise him that he does not have to make any statement at all regarding the offense of which he is accused or being investigated and that any statement made by the accused may be used as evidence against him in a trial by courts-martial.

21. Interrogating Suspects and Interviewing Witnesses.

a. In interrogating or obtaining statements from suspects or in interviewing witnesses, the use of fear, force, intimidations or threats and promises is not authorized in investigative procedures. This method of operation will not be tolerated in obtaining statements from suspects or in interrogating and interviewing witnesses and suspects.

b. In the interrogation of personnel subject to the Articles of War, the individual concerned will have his rights under the 24th Article of War fully explained to him prior to questioning in each instance.

c. In the interrogation of a civilian, his rights under the 5th Amendment to the United States Constitution will be fully explained.

(1) Whenever practicable, interrogation of civilians will be made in the presence of civilian police officers.

d. Care must be exercised to insure that practices are not indulged by Air Force Policemen that would preclude the use of written statements or the admission of confessions in courts of competent jurisdiction.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(1) In this connection, paragraph 127, MCM, 1949, should be carefully considered.

(2) If a statement amounts to a confession, the mere recitation in the statement that the person making it was informed of his rights and the statement was voluntarily made is not sufficient to render the statement admissible as evidence upon subsequent trial of a person.

(a) If, in fact, the statement was induced by threats or promises or by subjecting the person to prolonged discomfort and such facts appear at the trial, it might not be submitted as evidence.

(b) The Supreme Court of the United States has held that the use of a confession obtained by force or fear would violate the constitutional guarantee against self-incrimination and constitutes a denial under due process of the 5th and 14th Amendments which cannot be cured by other clear evidence of guilt.

1. In such cases, regardless of the preponderance of other clear evidences of guilt, a conviction would be overruled (See Page 13, JAG Bulletin, Department of the Army, January to March 1948).

e. In addition to the procedure described in Chapter 4, FM 19-20, April 1945, the following practices will be observed in

THIS PAGE IS DECLASSIFIED IAW EO 13526

obtaining written statements from witnesses or suspects:

(1) The exact wording used in explaining the individual's rights will be included at the beginning of the written statement.

(2) Whenever possible, a sworn statement will be obtained.

(a) Such statement will be read, signed, witnessed by one or more persons and sworn to before a Summary Court Officer, Notary Public, or any other person, authorized to administer oaths.

(3) Statements not in the handwriting of the witness will include a phrase in the concluding paragraph to the effect that the deponent has read the foregoing or has had it read aloud to him in the presence of a person whose signature is affixed.

22. <u>Handling and Preserving Evidence</u>.

a. There are two kinds of physical evidence - fixed or immovable and removable.

(1) Fixed evidence cannot be presented in court. Fixed evidence includes such things as footprints in the soil, tire prints in the mud and anything that cannot be removed or carried from the crime scene in its entirety or as a whole.

(2) Removable evidence is that which can be picked up at the scene, properly preserved and identified and later used to assist in the solution of a case. It is material found at the crime scene

THIS PAGE IS DECLASSIFIED IAW EO 13526

that can be removed in its entirety.

b. The principal factors necessary in handling physical evidence includes the following:

(1) Protection. Protection is necessary to:

(a) Guard against any changes by mutilation, pollution or alteration.

(b) Maintain proper chain of custody.

(c) Minimize the possibility of examination by unauthorized persons.

(d) Maintain identity of evidence.

(2) Collection.

(a) In collecting evidence, caution should be exercised in guarding against damage or destruction in removing evidence, or danger of destruction of other evidence in the process of removal.

(b) A systematic procedure will be adopted in the collection techniques.

(c) In addition to any removable evidence that is collected, it might be necessary to collect such evidence as photographs, notes and sketches, casts and molds.

(3) Identification.

(a) The primary factor in identification is the type of articles to be identified.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(b) Methods of identification include such items as letters, symbols, files, tags and labels.

(4) Preservation.

(a) The purpose of preserving evidence is to insure that the evidence will arrive at the laboratory or court in its original condition.

(b) A record must be kept of all personnel handling the evidence.

(c) Sealing is necessary to prevent handling or inspecting by unauthorized persons.

(d) Evidence should be stored in a safe, filing cabinet or other protective container.

(5) Evaluation.

(a) All evidence should be evaluated to eliminate nonpertinent material.

c. Laboratory Examination.

(1) Full advantage will be taken of laboratory facilities that are available in each locality for the scientific development of evidence.

(2) Many of the civilian and federal investigative agencies will furnish laboratory assistance when requested.

(3) The Criminal Investigation Laboratory at The Military Police School will furnish technical assistance provided the physical evidence is forwarded to that facility.

(a) The rules set forth in Chapter 16, FM 19-20, will be observed in handling and preparing evidence for transmittal to a laboratory.

(b) Evidence must reach the examiner with the least possible delay.

(c) The letter of transmittal will not go through channels but will be directed to The Scientific Investigation Laboratory, The Military Police School, Camp Gordon, Georgia.

(d) The body of the letter of transmittal will include the following:

Paragraph 1 - Itemized list of evidence submitted.

Paragraph 2 - Examinations desired.

Paragraph 3 - Instructions as to return or retention of evidence by the laboratory.

(e) Evidence will always be double-wrapped with a legend on the inside wrapper as follows: "Evidence Do Not Open"

23. Processing Recovered Property.

a. Accountability and adequate security will be maintained for all monies and property recovered during the course of an investigation.

(1) In the event monies or property are to be used as evidence in a criminal case, the general rules

THIS PAGE IS DECLASSIFIED IAW EO 13526

for the preservation of "the chain of evidence" must be observed.

(2) Closed case reports will show the distribution of recovered monies and property.

(3) Receipts for all monies and property will be maintained in the headquarters to which the investigator is assigned.

(a) Certified copies of such receipts will be attached to the closing report.

b. The following procedure will be followed in investigative activities in accounting for all recovered monies, property and other valuables including all evidence pending final disposition of the case concerned:

(1) The investigative activity will be responsible for the final disposition of all evidence and recovered monies, property and other valuables fixed as evidence by an investigative activity.

(a) Whenever possible, the signature of the person from whom the evidence is taken will also be affixed on the receipt to verify its accuracy. Three copies will be prepared, one for the files, one to be attached to the initial investigation report and one to be furnished to the person from whom the evidence is taken.

(2) When delivering evidence to an authorized prosecuting agency, a receipt will be obtained from the prosecutor

THIS PAGE IS DECLASSIFIED IAW EO 13526

and filed as a matter of record and for proper accountability.

(a) Upon final disposition of the case concerned, the investigative activity will repossess and deliver said evidence to its legal owner, accountable or finance officer, as applicable.

(3) When making final disposition of monies or property, the investigative activity will prepare the receipt according to the situation (Column A below), the type and number of receipts (Column B below), and make distribution of such receipts as shown in (Column C below).

__NOTE__: This latter distribution is mandatory for the investigative activity and is in addition to the distribution required to meet the needs of the supply agency or finance officer.

(A) Situation	(B) Type of Receipt	(C) Distribution
(1) Return of private property or monies.	Letter type receipt in duplicate.	1. Office of Investigative activity. 2. Final report of investigation.
(2) Return of government property to a supply agency.	WD AGO Form 447 in quadruplicate.	1. Office of Investigative activity. 2. Final report of investigation. 3. Appropriate AF Audit Agency. 4. Supply agency.

1829

(A) Situation	(B) Type of Receipt	(C) Distribution
(3) Return of monies to United States Treasury (through Finance Officer)	WD AGO Form 14-44 in triplicate.	1. Office of Investigative activity. 2. Final Report of investigation. 3. Appropriate AF Audit Agency.

- - - - - - - - - - - - - -

(4) When two or more persons claim the same property and it is not possible for the officer to determine positively the rightful owner, the disputed property will be retained and the question will be referred to the Judge Advocate. (Reference: Page 329, Digest of Opinions of TAG, 1912-40). A copy of the disposition order will be filed with the investigative activity with the record copy of the investigative report.

(5) Abandoned private property will be held until the period of time, prescribed by local laws for the recovery of personal property, has elapsed and then disposed of by the investigative activity in the manner prescribed in paragraph 35, TM 38-505.

(6) Final disposition of evidence, recovered monies, property and other valuables will be indicated in closing or final investigative report.

24. Appearing As a Witness in Court. (See Chapter 6, FM 19-20)

a. The trial of a criminal is not the responsibility of a criminal investigator. The trial is the culmination of the history of a crime. However, in order that the guilty will be convicted and the innocent acquitted at a trial, it is necessary frequently for the investigator to testify in court.

b. The investigator, when appearing as a witness in court, must conduct himself as a gentleman and be courteous and even-tempered. He must never become irritated but must answer all questions in a quiet and dignified manner but absolutely impartial in speech and action.

c. Prior to going to the court, the Air Force Policeman should review thoroughly his original notes and arrange them in logical order.

(1) The investigator has the right to consider his notes on the witness stand, if necessary to refresh his memory, before replying to questioning.

(2) Notes may be put into evidence, if they are brought into the court.

d. Important rules that must be observed by investigators for testifying in court include the following:

(1) Testimony should be given slowly and distinctly.

(2) Replies to questions should be clear and definite.

(3) Offer an opinion on a point only if requested.

(4) Avoid making conflicting or contradictory statements.

(5) All questions must be answered truthfully whether the answer be adverse or beneficial to the accused.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(6) He must maintain an unbiased attitude.

(7) If he is unable to answer a question, the investigator should reply, "I don't know".

25. Preventing and Suppressing Crime.

a. Two factors must be co-existent before a crime can be committed, first the desire or impulse, and secondly the opportunity.

(1) Air Force Policemen should be interested in preventing and suppressing both factors.

b. Techniques and methods that may be employed in the prevention and suppression of crime include the following:

(1) Establish educational and orientational programs with all personnel on the base.

(2) Employ a system of warnings in the enforcement of rules and regulations.

(3) Establish rehabilitation programs for prisoners and offenders.

(4) Segregate hardened criminals from petty offenders.

(5) Secure the assistance of such civilian agencies as Alcoholics Anonymous for preventing serious recurrence of drunkenness.

(6) Separate undesirables from the Service.

(7) Maintain a pass system for all personnel on the base.

(8) Establish adequate security for warehouses and storage facilities.

(9) Provide adequate checks on the loading, unloading, transporting, storing of supplies and equipment, and

THIS PAGE IS DECLASSIFIED IAW EO 13526

for the proper handling and storage of damaged cases and supplies.

(10) Provide for an adequate number of trained Air Force Policemen in the enforcement of laws and regulations and for proper security.

(11) Restrict the use of keys and combinations to certain personnel.

(12) Provide for a periodic spot-check of all drivers entering and leaving a base.

(13) Establish "off limits" and "restricted" areas.

(14) Provide for locking public buildings during hours of non-use, such as the Officers' and NCOs' Clubs, Exchanges and Service Clubs.

(15) Ascertain that an adequate investigative procedure has been initiated on the loyalty character and background history of all personnel assigned tasks which warrant the use of classified documents and materials.

(16) Provide for the security of all valuable merchandise, equipment and supplies.

(17) Provide adequate security for valuable merchandise that is displayed in Exchanges, Officers' and NCOs' Clubs (bingo and bridge prizes) and Service Clubs.

(18) Establish proper liaison with civilian law enforcement agencies.

(19) Provide for undercover checks to apprehend pilferers.

THIS PAGE IS DECLASSIFIED IAW EO 13526

(20) Conduct surveys of warehouses, exchanges, supply and storage areas to reduce or eliminate the possibility of larceny and misappropriation of government food, clothing, equipment and supplies.

NOTE: These surveys are limited solely to crime prevention and the apprehension of criminals. Reasonable safeguards will be placed in effect to prevent and discourage theft.

(21) Apprise commanders of the investigative activity on a current basis by the submission of interim or progress reports of all current cases.

(22) Furnish commanders with information concerning an analysis of trends and patterns of irregularities and offenses within their commands and take such corrective action necessary to prevent and suppress crime.

SECTION VII - COOPERATION AND LIAISON WITH OTHER AGENCIES

26. Office of Special Investigation

a. Personnel of the Provost Marshal's Office will cooperate to the fullest extent with the OSI in the following:

(1) Render maximum investigative assistance when requested by the OSI.

(2) Initiate initial investigation of major crimes and offenses when the OSI are not readily available and the progress of the case will suffer.

(3) Refer cases to the OSI with all essential pertinent data and information on cases initially investigated by the Air Force Policemen that come

THIS PAGE IS DECLASSIFIED IAW EO 13526

within the purview of the OSI.

(4) Establish, preferably in writing, a working agreement with the OSI relative to the transfer and administration of cases in which the OSI is requested to make a partial or complete investigation.

(5) Maintain a list of investigators from the local district office of the OSI together with their addresses and telephone numbers.

27. Civilian Agencies.

a. Provost Marshals should cause proper liaison and coordination to be established with all civilian investigative agencies within their areas.

(1) An up-to-date directory of key personnel, including their telephone numbers and addresses, will be maintained.

b. Full use will be made of all pertinent allied agencies as listed in Chapter 2, FM 19-20.

28. Other Armed Services.

a. Active liaison with other Air Force commands, Army commands and Naval authorities will be established and maintained to secure the maximum cooperation in the investigation of cases that might come under their jurisdiction or in which they might render valuable assistance.

1835

THIS PAGE IS DECLASSIFIED IAW EO 13526

APPENDIX I - DEFINITIONS

(A glossary of criminal phrases, terms of expression commonly used by criminals and those dealing with them is listed in Appendix II, Part I, FM 19-20, "Criminal Investigation")

Accomplice	A person who unites in or is in some way concerned in the commission of a crime for which an accused is on trial.
Admission	An incriminatory statement falling short of an acknowledgement of guilt.
Alias	An assumed name.
Allege	To state without proof.
Anthracene	An invisible powder used in apprehending thieves; it cannot be cleansed easily from any article or person touching it and can be readily seen under an ultra violet light.
Apprehend	To seize, take a person into custody.
Arson	The wilful and malicious burning of a dwelling house or outhouse of another.
Assault	The attempt or offer to do a corporal hurt to another; physical contact is not necessary in assault - merely to put the person in fear of death or bodily harm.
Attempt to Commit a Crime	An act done with specific intent to commit a particular crime and proximately tending to, but falling short of, its consummation.
Battery	The act of beating; unlawful physical constraint or violence used by one person against another without justification.
Ballistics	The science of firearms identification of bullets and cartridge cases with weapons from which they were fired.
Benzedrine Inhaler	A narcotic inhaler used to alleviate colds; also used by criminals as dope, which will either produce a stupor, sleep or great exhileration. (Pro-

THIS PAGE IS DECLASSIFIED IAW EO 13526

hibited in places of confinement)

Biomo-Thymol Blue	An acid used in detecting stolen gasoline.
Burglary	The breaking and entering in the night, of another person's dwelling house, with intent to commit a felony therein; a tent is not a subject of burglary.
Carnal Knowledge	The act or state of assaulting a woman by force with intent to overcome any resistance, actual or constructive, to penetrate her body; rape.
Case	A crime which authorities are investigating.
Chain of Evidence	The course thru which evidence passes from the time it is secured until it is presented in court.
Clue	A fact or hint forming the key to a solution of a problem, plot or crime.
Complainant	A plaintiff or petitioner; the one in an action or proceeding who makes a complaint against another; the defendent.
Coercion	Force, compel
Confessions	A confession is an acknowledgment in express terms by the accused in a criminal case of his guilt of the crime charged.
Contempt, Direct	An act committed in the presence of a court which interrupts the proceedings.
Contempt, Constructive or Indirect	A refusal to comply with an order of a court.
Corpus Delec-ti	The whole body of essential and fundamental facts connected with an alleged act, which make the act a crime or a breaking of the law.
Crime	Any act or omission prohibited by public law for the protection of the public and made punishable by the State in a judicial proceeding in its own name.
Crime Laboratory	A scientific laboratory for the study and examination of evidence presented in criminal cases.
Crime Scene Search	A careful, methodical, and detailed examination of all objects and conditions at the scene of a crime.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Criminal Investigation	The art of finding and discovering the true facts of a crime and of an offense; the action necessary in determining the true identity of the perpetrator of a crime.
Criminal Investigation Division	An integral part of a law enforcement agency or a private firm responsible for the investigation of crime.
Criminal Receivers (Fences)	A person who earns a livelihood by criminally receiving and disposing of stolen goods.
Dermyl Nitrates	Paraffin test to determine whether the subject has fired a weapon.
Derogatory Information	Information which indicates disaffection or disloyalty to the Government; information of the character traits and associations of an individual which might be disqualifying as a good security risk for a position of trust.
Description	The act of giving an account of anything; a word picture.
Desertion	AWOL plus intent not to return; or AWOL to avoid hazardous duty and for important service.
Document	An original or official paper that furnishes information, proof or support of anything.
Duress	Constraint or compulsion.
Embezzlement	The fraudulent appropriation of property by a person to whom it has been intrusted and into whose hands it has lawfully come.
Evidence	That which tends to prove or disprove any matter in question; it includes all that may be submitted to a court-martial whether it be the statement of witnesses from the stand, disposition, the contents of papers, documents, or records, or the inspection by the court of whatever it may be permitted to examine during the trial.
Evidence, Direct	That which tends to show a fact or matter in issuing without intervention of proof of any other fact.
Evidence, Circumstantial	That which relates to facts other than those in issue but from which facts either alone or in connection

1838

THIS PAGE IS DECLASSIFIED IAW EO 13526

with other facts, a court may, according to the common experience of mankind reasonably infer the existence or non-existence of a fact in issue.

Evidence, Opinion — Generally, a witness must state only what he has learned through his five senses as being a fact. However, on matters within the common observation and experience of men, a witness may express an opinion. A witness who is skilled in some art or trade, service, or who is peculiarily learned in some particular field may express an opinion on a state of facts that need "expert" interpretation. His qualifications as an expert should be shown to the court before he gives an opinion.

Evidence, Physical — Any article or material found in an investigation which might assist in the solution of a case.

Felony — An offense punishable by death or imprisonment for a term exceeding one year.

Fence — One who receives stolen goods; a place where stolen goods are received. (See Criminal Receivers)

Forgery — The act of making, with intent to defraud, a false or counterfeit document.

Fraudulent — Characterized by, or obtained by, unfair methods; guilty of trickery; dishonest.

Hearsay — Evidence of the existence of a fact based not on a witness's own personal knowledge or observation but on what someone said.

Housebreaking — Unlawful entering of another's building, with intent to commit a criminal offense therein.

Impeachment — Diminish credibility; an accusation.

Incarcerate — To place in prison.

Informant — Any person who willingly gives police information without any thought of gain.

Information, Source of — Any personal element of contact which furthers the progress of an investigation.

Informer — One who confidentially provides an investigator with information with thought of personal gain.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Infra-red Photography	Photography accomplished by use of invisible light.
Interrogate	To question subject.
Interview	To question victim or witness.
Investigate	To search into by patient inquiry, observation and study of facts.
Investigative Photography	Taking of photographs which are satisfactory for an investigation, and are proof of facts.
Investigative Report	An official written record of information obtained by investigation.
Judicial Notice	Recognition by the court of certain kinds of facts that need not be proved because the court is authorized to recognize their existence without proof.
Larceny	The taking and carrying away, by trespass, of personal property which the trespasser knows to belong either generally or specially to another, with intent to deprive such owner of his property therein; as distinguished from robbery - accomplished by stealth; intent to permanently deprive owner of the use of the property taken.
Lead	A possible source of pertinent information which may contribute to the solution of a case.
Manslaughter	An unlawful homicide without malice aforethought, and is either voluntary or involuntary.
Manslaughter, Involuntary	Homicide unintentionally caused in the commission of an unlawful act not amounting to a felony; culpable negligency in performing a lawful act.
Manslaughter, Voluntary	Where the act of causing death is committed in the heat of sudden passion caused by provocation.
Mayhem	A hurt of any part of a man's body whereby he is rendered less able in fighting either to defend himself or to annoy his adversary; must be wilfully and maliciously done, but need not be premeditated.
Military Crimes	Commonly recognized civil crimes when committed by persons subject to military law are also military crimes, the punitive Articles of War 54 through 96 define various types of military offenses and crimes.

Misconduct	Implies a wrongful intention and not a mere error of judgment.
Misdemeanor	All offenses not felonies are misdemeanors.
Modus Operandi	Method of operation used by a criminal.
Motive	That which urges into action; inducement; inner reason for performing a given act.
Murder	The unlawful killing of a human being with malice aforethought; murder is not tried in military court when committed within geographical limits of the United States in time of peace; death must take place within a year and a day of the act or omission that caused it.
Negligence	The absence of due care.
Office of Special Investigation (OSI)	An investigative agency whose duty is the investigation of: the loyalty of both civilian and military personnel, contract employees and Atomic Energy Commission through National Agency checks and background investigations: major crimes and petty larceny of more than $50.00; and matters involving crime, violations of public trust, subversion and related activities within the jurisdiction of the Air Force.
Perjury	The willful and corrupt giving, upon a lawful oath, or in any form allowed by law to be substituted for an oath, in a judicial proceeding or course of justice, of false testimony material to the issue or matter of inquiry.
Perpetrate	To commit (an offense).
Perpetrator	One who commits(an offense).
Photostatic Copy	Duplicated pictures of documents and other pictures.
Pilferage	Larceny to plunder or steal; especially to steal in small amounts.
Polygraph	Commonly known as a "lie-detector" and is a combination of pneumograph which records respiration, the sphygmograph which records blood pressure, the cardiograph which records heart movement through the pulse, and the galvanograph which records the activity of sweat glands.

Portrait Parle	The art of describing a person; spoken picture or speaking likeness including description of person, personal data, physical description and general background.
Prima Facie	At the first view: as it appears on the surface.
Rape	Ravishment of a woman by force.
Report "Wrapper"	Title given report (or in blotter entry, title given blotter entry).
Report Writing	A connected word picture of an entire investigation in outline form and chronological order.
Res Gestae	Circumstances, including exclamations, declarations and statements of participants and bystanders, substantially contemporaneous with the main fact under consideration and so closely connected with the main fact as to throw light upon its character.
Robbery	The taking, with intent to steal, of personal property of another, from his person or in his presence, by violence or intimidation.
Sabotage	The willful and deliberate destruction of property, or, any conceivable act which destroys or interrupts the normal function of any person, place, or thing aiding in the war effort, or, any subversive action or omission which slows up or stops war production.
Scopolamine	A drug that produces semi-sleep and removes inhibitions. Under the influence of the drug, the subject will speak out frankly without fear of consequences of his statement. (Information received in this manner is not admissible as evidence in court).
Self-Incrimination	No person shall be compelled in any criminal case to be a witness against himself.
Sketching a Scene	A sketch made of a crime scene which shows location, approaches and entrance to building or area; size and number of rooms, location of finger-prints and footprints or tracks; objects on the floor, ceiling and walls; windows and doors opened or closed; and all other physical description to the crime.
Sodomy	Unnatural sexual intercourse between males, or of human beings with animals.

Subject	The accused or the offender in the report of a case.
Subpoena	A process (method) to cause a witness to appear and give testimony.
Suicide	The act of intentionally taking ones own life; self-murder; self-destruction.
Surveillance	The process of watching suspected persons, vehicles or premises with a view to obtaining information regarding activities, operations, associates and contacts.
Surveillant (Shadow or Tailman)	The person who performs and maintains the surveillance.
Surveillance, Moving	When the investigator actually follows subject on foot or by vehicle.
Suspect	One believed to be guilty of some crime, without having sufficient proof or evidence.
Toxicology	The science of poisons, their sources, effects, tests and antidotes.
Ultra-violet Photography	Photography under an ultra-violet light which reveals certain kinds of secret writing, invisible laundry marks, semen stains, scars and certain other invisible stains or materials.
Undercover Work	Differs from surveillance in that in undercover work the agent makes direct contact with the subject.
Unlawful	Without legal justification or excuse.
Usuary	Loaning money for interest.
Victim	Person who has suffered as a result of a violation or an infraction of law.
