[1] Smokeless powder in containers is intended to mean any smokeless powder stored in boxes, powder cans, cartridge storage cases, or any container used for the storage of smokeless powder.

[2] Unbarricaded distances as shown always will be used when considering above-ground magazines in which smokeless powder is stored. One-half the above distances are authorized for separation of igloo type magazines containing smokeless powder.

[3] Distances shown are applicable to operations succeeding the graining operation in smokeless powder plants.

Figure 8–4. Class 2—Quantity-Distance Table.

Class 1. Small-arms ammunition and mechanical time fuses without boosters. These materials are principally fire hazards. No limit is placed on the storage of small-arms ammunition.

Class 2. Smokeless powder, pyrotechnics, and chemical ammunition filled with phosphorus. These materials may become unsafe under extreme conditions of moisture and high temperature. They burn with intense heat.

Class 3. Point-detonating fuzes, minor caliber base-detonating fuzes, powder train and antitank-mine fuzes, packed separately in boxes; bomb fuzes, packed with fin assemblies. The amount of explosives in articles of this class, including the booster, varies from 30 to 500 grains, except in the case of bomb fuzes packed with fin assemblies, which contain a charge of approximately 1,000 grains. These fuzes usually explode progressively, not more than a box or two at a time. Pressures which would cause serious structural damage to adjacent magazines are not usually generated, and missiles are small and of light weight, usually falling within 300 feet. The quantity of fuzes stored in a single magazine will be kept to the minimum consistent with available

[1] These distances will not be reduced by barricades. One-half the above distances are authorized for concrete igloo magazines, except at the door end.

storage capacity. The storage of more than 50,000 fuzes of any one model, or a total of more than 150,000 fuzes of all models in a single magazine will not be permitted except by specific authority.

Class 4. When packed in accordance with ordnance drawings and specifications: fixed and semifixed high-explosive shell (complete rounds), light-mortar ammunition, fragmentation bombs in wooden crates, grenades, and shrapnel of all calibers, fuzed or unfuzed, and blank ammunition for cannon. Articles in this class usually explode progressively, only a few boxes at a time, many explosions of individual rounds being of a very low order. Pressures which would cause serious structural damage to adjacent magazines are not usually generated, and most missiles would fall within 600 feet.

Class 5. Separate-loading shell of all calibers, loaded with explosive D, fuzed or unfuzed, and shell loaded with explosive D fuzed or unfuzed; and shell loaded with explosive D fuzed or unfuzed, not assembled to or packed with cartridge cases. These shells usually explode one at a time, and in practically all cases, with a low order. As only one shell should be involved in an explosion, the missiles are limited both as to number and range. Most of the missiles will fall within a distance of 1,200 feet.

Class 6. Major and medium-caliber base-detonating fuzes; bomb fuzes; adapters and boosters for high explosive shell, bursters for

of this Class are stored in igloo magazines the quantity and distance requirements prescribed for classes 9 and 10 will apply, except that no distances smaller than one-half the distances quoted in the above Class 6 Quantity-Distance Table are authorized.

[2]Missile distance.

[3]Maximum permitted in any one magazine.

100,000[3]	1,500	900	450	300

[1]These distances will not be reduced by barricades. For concrete igloo magazines (except at the door end) one-half of the above distances are authorized. When items

Figure 8–8. Class 6–Quantity-Distance Table.

chemical shell, and for bombs, packed separately in boxes. The amount of explosives in single items of this class usually does not exceed one-half pound. They usually explode progressively, by piles. The number involved in any explosion is limited by making piles small and separating them by prescribed distances determined by actual detonation tests. Structural damage caused by the pressures generated usually is limited to adjacent magazines. The missiles are light and usually fall within 600 feet. The quantity of fuzes stored in a single magazine will be kept to the minimum consistent with available storage capacity. The storage of more than 50,000 fuses of any one model, or a total of more than 150,000 fuzes of all models in a single magazine will not be permitted except by specific authority.

Class 7. Separate-loading HE shell of all calibers, except shell loaded with explosive D. All in a magazine may explode but the explosion may be limited to one pile by arranging the material in accordance with instructions for piling separate-loading shell. Structural damage usually is limited to adjacent buildings. Most missiles will fall within 500 yards.

Class 8. Primers, detonators, primer-detonators for bombs, grenade fuses, and blasting caps, packed in accordance with Ordnance

Quantity, pounds of explosives not over	Unbarricaded distance[1] in feet from the nearest - Inhabited Building[2]	Public R.R.[2a]	Public Highway[2b]	Magazine
500,000	1800	1800	1800	300

[1]These distances will not be reduced by barricades. For concrete Igloo magazines (except at the door end) one half the above distances are authorized. when items of this class are stored in an Igloo magazine (except when segregated into piles in accordance with drawing No. 19-48-12) the quantity distance requirement for class 9 and 10 will apply except that no distance less one half the distance quoted in the above class 7 table are authorized.

[2]Missile Distance.

Figure 8–9. Class 7. Quantity-Distance Table.

drawings and specifications. All in a magazine may explode at one time, but as the total amount of explosives involved is limited, structural damage usually is limited to adjacent magazines. This class of ammunition forms light missiles which have a very limited range.

Class 9. Flashlight powder, demolition blocks, spotting charges, black powder, bulk priming explosives; bulk initiating explosives such as tetryl, and bulk high explosives such as TNT and explosive D. Priming explosives such as mercury fulminate and lead azide will be stored in accordance with special instructions. In a fire, black powder usually explodes and TNT and explosive D usually burn, but may explode. Since these explosives are similar to the commercial explosives on which the American Table of Distances was based, they are stored in accordance with this table.

Class 10. Demolition bombs, fragmentation bombs in metal crates, or bundles, photoflash bombs, and HE antitank mines. All in a magazine may explode. In this case, structural damage will be limited to the distances specified for inhabited buildings in the American Table of Distances for similar quantities of commer-

Note Enclosure #5

Figure 8–11. Classes 9 and 10–Quantity-Distance Table.

cial bulk explosives, and most missiles will also fall within these distances. Quantities of class 10 explosives will be stored in accordance with the table for classes 9 and 10, except that the distances applicable to fragmentation bombs will not be less than those stated in the class 4 quantity-distance table; however, they may be one-half the distances as stated in the class 4 quantity-distance table when storage is in concrete igloo magazines; however, the door end is not considered barricaded.

Class 11. Chemical ammunition (except ammunition containing phosphorus). This ammunition is not considered an explosive hazard and no limit has been placed upon the storage of this material except that the storage must comply with the requirements for the storage of chemical ammunition.

Class 12. Explosives such as ammonium nitrate, TNT and wet nitrocellulose. These items are relatively insensitive and can be initiated

Maximum Quantity Per F.S.U.	800 tons
Maximum Quantity Per Stack	40 tons
Minimum Unbarricaded distance between stacks	50 yds.
Minimum Inter.F.S.U. distance	150 yds
Outside Safety distance	500 yds.

It will be noted in the information above that the maximum quantity per stack is 40 tons and that a distance of 50 yards is required between each of the 40 ton stacks. These are maximum figures. If it is desirable that stacks be smaller than 40 tons the distance required between them may also be reduced in accordance with Table I below.

Figure 8–12. Maximum Quantities and Minimum Distances for Field Storage.

only by means of a very intense detonation. When stored in an explosive area where there is a possibility that explosives might be projected into them, they will be stored like ammunition in class 9. When stored in an area with fire hazards and separated by inhabited building distance from areas containing ammunition and explosives, these materials may be stored in accordance with the requirements for smokeless powder which is class 2 ammunition.

5. QUANTITY-DISTANCE REGULATIONS UNDER FIELD CONDITIONS

Definitions

Inter F. S. U. Distance. These distances are those required between the nearest edges of adjacent field storage units, to keep one safe if the other should explode or catch on fire. This distance is comparable to the magazine distance indicated in quantity distance tables.

INTERSTACK DISTANCES FOR AMMUNITION IN FIELD STORAGE GROUPS I AND IV

Gross tons of Ammunition	Inter stack Dist. unbarricaded (yards)	Inter stack Dist. barricaded (yards)
10 or less	25 (min)	20 (min)
10-20	35	25
20-30	45	30
30-40	50	35
40 (max.)	50	35

It will be noted in the table above that there are barricaded distances indicated. It is very seldom that stacks of Group I and IV ammunition are barricaded because there is not sufficient space gained to warrant the labor necessary to erect the barricades.

Figure 8–13. Table I.

*Maximum Quantity per F.S.U.	100 tons, of explosive content
Maximum Quantity per stack	No requirement
**Minimum distance between stacks	No requirement Note Table II
Outside Safety Distance	500 yds.

*Just as in Quantity Distance Tables the quantity of bombs per stack is computed on the basis of the weight of the explosive content of the bombs rather than on the gross or overall weight.

**There is no required distance between individual stacks of aircraft bombs in that one bomb storage revetment generally constitutes a complete Field Storage Unit. It is assumed that should one stack of bombs detonate the entire contents of that unit will be lost. Were there sufficient distance left between individual stacks of bombs to render safe from one another they would occupy too much space.

Figure 8—14. Maximum Quantities and Minimum Distances for Field Storage.

Interstack Distance. This is the distance required between individual stacks within a single field storage unit.

Outside Safety Distance. This is the distance between a field storage unit and anything requiring complete safety from it. In the quantity distance tables inhabited building, public railroad, and public highway distances were the equivalent of the above described distance.

6. FIRE HAZARD

General

Many of the fires involving explosives and ammunition are preventable, for the causes have been well established and can, therefore, be anticipated and eliminated. It is the duty of all concerned in the handling of explosives and ammunition to study the causes of fires and thoroughly inform themselves of the safety precautions that must be taken to prevent them.

As fire-fighting facilities, organizations, and methods vary quite widely at the various establishments and are affected by local conditions, the general subject of fire prevention and fire fighting is covered by regulations and administrative orders.

Many of the general safety regulations are primarily for the prevention of fires. In addition thereto, certain special fire-preventive regulations are necessary and are contained in this section, being preceded by a brief discussion of the causes of fires. Their purpose is to explain and emphasize the importance of all safety and fire-prevention measures.

This section also contains regulations and advice as to fire-fighting facilities, organizations, and methods insofar as these differ from those ordinarily employed when stores of explosives and ammunition are not involved.

Causes of Fires

Fires in magazines and magazine areas in which explosives and ammunition are stored may result from several causes, of which the following are the most common:

Dry Grass, Leaves, and Underbrush. These may be ignited by sparks from locomotives, by smoking, or the careless use of matches and camp fires. Such fires often originate in areas adjacent to military establishments not

SAFETY DISTANCE (EDGE TO EDGE) FOR AMMUNITION IN FIELD STORAGE GROUP II

Tons of Bombs/FSU	Inter FSU distance, yds. Unbarricaded	Barricaded	Outside Safety Distance (yards)
20	100	25	500
30	120	30	500
40	135	33	500
50	150	37	500
60	160	40	500
80	180	45	500
100 (max.)	200	50	500
			500

(d) Maximum Quantities and Minimum Distances For Ammunition In Field Storage Group III

Maximum Quantity Per F.S.U.	800 tons
Maximum Quantity Per stack	40 tons
* Minimum Distance between stacks	35 yds.
Minimum Inter F.S.U. distance	500 yds.
Outside safety distance	1500 yds.

* This is a barricaded distance in that all stacks of rockets must be barricaded both front and rear.

Figure 8—15. Table II.

under the direct control of the commanding officer. If they are not detected and controlled, they may spread quickly and become uncontrollable.

Deteriorated Explosives and Ammunition. Explosives and ammunition deteriorate in storage. Normally, this deterioration occurs at such a slow rate that most explosives and ammunition remain serviceable for many years. However, under unfavorable storage conditions where the ammunition is subjected to abnormally high temperatures (above 80 F) or exposed to moisture for a prolonged period, the rate of deterioration is greatly accelerated. Practically all explosives and ammunition give off heat as they deteriorate but where the rate of deterioration is slow the heat thus generated is dissipated by conduction or radiation and no noticeable rise in temperature takes place. When deterioration becomes rapid, however, heat may be generated so fast that it cannot be thus dissipated and the temperature rises. This accelerates the deterioration still more until finally the temperature may become high enough to cause the explosive or ammunition to burst into flame. In certain cases where the explosive or ammunition is confined, an explosion or detonation may result.

Repacking, Renovation, and Salvage Operations not Properly Supervised and Conducted in Accordance with Recognized Safety Standards. The most common sources of trouble are excessive quantities of powder and loose explosives, accumulation of waste paper, broken boxes, etc.; failure to provide proper barricades and fire breaks where necessary to prevent the spread of fire.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Carelessness or Violation of Regulations. Untrained personnel may cause fires by smoking, or striking matches in forbidden areas and buildings, or by tampering with explosives or ammunition, particularly grenades, fuzes, etc.

Failure to Understand and Observe Carefully the Safety Precautions Prescribed by Regulations for Destroying Explosives and Ammunition. The most frequent sources of trouble are flying fragments which cause grass fires or explode piles of explosives and ammunition awaiting destruction.

Failure to safeguard heating appliances, such as torches and furnaces used in making repairs to magazine roofs and magazines.

Lightning striking buildings, trees, or other objects in or near explosive areas.

Electric transmission lines, blown down or in contact with combustible materials.

Special Fire-prevention Rules

Fire prevention is of the utmost importance because of the difficulties encountered in controlling fires involving explosives and ammunition. The special fire-prevention rules set forth below are minimum requirements for establishments storing explosives and ammunition. They will be supplemented by such additional rules as the commanding officer deems necessary to secure adequate protection against fires at his establishment.

During the absence of the commanding officer, there must be present at the establishment a competent person to act for him in case of fire or other emergency.

The duties of guards, firemen, military personnel, and others must be so arranged that an adequate fire-fighting force is available at all times.

Ammunition personnel must be instructed thoroughly in the hazards due to fire and explosion, the safety precautions to be taken, and the means and methods to be used in preventing and fighting fires.

Fire drills and inspections must be conducted carefully to insure that all personnel understand their duties and that fire-fighting equipment functions dependably under actual working conditions.

All fire-fighting equipment, especially hand fire extinguishers, water barrels and buckets, and the supplies of auxiliary equipment, such as gunny sacks and brooms, must be inspected regularly as prescribed by the commanding officer. Any deficiences reported will be corrected promptly.

Repacking, renovation, salvage, and all operations involving the handling of explosives and ammunition, must be inspected regularly as prescribed by the commanding officer to see that the necessary fire-fighting equipment is present and in good working order

When explosives and ammunition are being handled, or work is being done in the immediate vicinity of such stores, there must be present, ready for immediate use, two chemical or other type hand fire extinguishers.

To combat grass or forest fires in or near magazine areas, there must be maintained at suitable locations an adequate supply of gunny sacks, brooms, rakes, hoes, or other similar equipment. It is good practice to provide a railway tank car, truck, or trailer equipped with a pump and fire hose for fighting fires in a magazine area. This equipment should be inspected regularly and protected against theft or unauthorized use.

Vegetation in the form of grass, undergrowth, weeds, etc., which is, or may become, a fire hazard, should be controlled by mowing, plowing, cutting, or, in calm weather and under adequate safeguards, by burning. Burning is not permitted within the fifty-foot space specified in the paragraph below, and brush, grass, wood, etc., in piles, may not be burned within two hundred feet of a magazine.

A fire break at least fifty feet wide and as free as practicable from combustible material, must be maintained around each aboveground magazine. The earth adjacent to, and extending over igloo magazines must not be cleared of vegetation other than dry debris.

The vegetation on and along railroad tracks must be controlled so that it will act as firebreaks.

In addition to those specified above, firebreaks around the entire magazine area and at other places within the magazine area should be maintained wherever necessary.

Keys to gates, magazines, and other buildings, which fire-fighting forces may enter, must be kept readily available at such places as the commanding officer may designate.

Fire-fighting Facilities

A fire involving explosives or ammunition may result in an intense conflagration or an explosion. Means for immediately attacking the first small blaze detected in a magazine or magazine area are vital, and reliance often must be placed upon hand equipment which can be maintained ready for immediate use. The following types of fire-fighting equipment may, under certain conditions, be used to good advantage and to supplement the regular fire-fighting facilities ordinarily maintained.

Water barrels and buckets placed at each magazine or at places specified by the commanding officer. If this class of fire-fighting equipment is always maintained so that it can be depended upon in case of fire, it is a valuable fire protection. However, in the summer time, the barrels must be frequently refilled, and in freezing weather, brine must be used. Buckets deteriorate rapidly unless they are painted frequently or protected from the weather, and sometimes they are blown about by wind storms if they are not fastened securely. Any device used for this purpose must be capable of being released at will.

Tank cars, trucks, or trailers may be filled with water and so located that they are readily available. Such protection, however, cannot be relied upon in freezing weather or when facilities for rapid movement to the scene of a fire are lacking.

Fire Fighting

To combat fires involving explosives and ammunition successfully, it is necessary that personnel understand thoroughly what a particular kind or class of explosive or ammunition will do when subjected to heat or flame. This section outlines in as much detail as possible what the experience has been with fires for the various classes of material, and also the general safety precautions to be observed in fighting the fire.

General instructions which should be followed in combating any fire involving explosives and ammunition are as follows:

When any person discovers smoke coming from a magazine, or sees other evidence that a magazine is on fire, he should give the alarm as quickly as possible. He will fail in his duty if he attempts to go into the burning building, as there is a possibility that he may be trapped and cannot give the alarm. When any person discovers a grass fire he immediately should give the alarm.

If the fire is small, and he is sure that he alone can extinguish it, he should do so at once.

Fire-fighting forces, when they arrive, should attack the grass fire vigorously even when it is close to a magazine.

In case a fire has actually gained headway in a magazine, fire-fighting forces must be warned not to endanger themselves in hopeless efforts to extinguish the fire, but to devote their efforts toward saving adjacent ammunition or buildings.

Methods of Combating Ammunition Fires

General. For the purposes of fighting or controlling ammunition fires all items of ammunition and explosives have been divided into four groups. These groups are called "fire hazard" or "fire symbol" groups. The four groups to which an item of ammunition will belong depend on the type of burning or explosive action and the degree of hazard in combating the fire. The burning and explosive actions are defined broadly as follows:

Deflagration. The building up of explosive power through a burning process, that is, an item of ammunition which is hazardous principally because of the fact that it burns.

Progressive Detonation. The uncontrolled, intermittent detonating of single items or packings within a stack, that is, all that is known is that the material will detonate. There is no knowledge of how many or when.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Simultaneous Detonation. Mass detonation. This action will result in items having a high explosive filler.

Ammunition in Fire Symbol Group I constitutes the minimum degree of hazard and Group IV constitutes maximum hazard.

Fire Symbol Groups

Fire Symbol Group I. All ammunition belonging to quantity-distance classes I, II and 12.

Q.D. Class I. Small-arms ammunition except 20-mm H.E.I., small fuses w/o boosters and A.T. practice grenades.

Q.D. Class II. Chemical ammunition except ammunition containing white phosphorus.

Q.D. Class 12. Insensitive fillers such as ammonium nitrade and TNT, etc.

The above listed types of ammunition are hazardous primarily because of fire. Therefore, their action is that of deflagration. Burning small-arms ammunition and small fuzes will propel small, hot missiles which will carry for a distance of approximately two hundred yards. However, these missiles are a secondary problem as they have very little penetrating capacity. When the war gases are involved, all personnel should be equipped with complete protective clothing, particularly in the case of the vesicant gases. In case the fire involves only the toxic gases, a gas mask is sufficient. Symbol Group 1 fires are extinguished by means of applying a large volume of either water spray or fog. Should there be any H.C. smoke-filled items present it will be necessary to segregate them prior to applying the spray or fog as the effort to extinguish them will be ineffective and the material is liable to detonate. H.C. smoke must be drowned in water. In extinguishing a Symbol Group I fire it is also desirable to knock down the stacks. This tends to minimize the possibility of detonation.

Fire Symbol Group II. Quantity-distance class 3 ammunition.

Q.D. Class 3. Fuzes which contain from 30 to 500 grains of explosive material except in the case of bomb fuzes which come packed with fin assemblies which contain approximately 1000 grains of explosive material. Ammunition in this category detonates progressively. Explosions will occur and light, hot missiles will be propelled. Should it seem impossible to extinguish the fire, an effort should be made to localize it. The method of extinguishing this type of fire is the same as in the case of Fire Symbol No. 1.

Fire Symbol Group III. Quantity-distance class 2.

Q.D. Class 2. Fires caused by pyrotechnics are hazardous because of intense heat. Its hazard is therefore that of deflagration. This type of fire can be extinguished only when it is in an incipient stage. After the fire has progressed beyond the incipient stage, effort should be limited to the prevention of spreading. In order to extinguish pyrotechnic materials, it is necessary to smother them with some form of inert material such as dirt, sand, etc. Bulk dry cement is probably as effective an agent as any. A special talc is manufactured for the purpose of extinguishing pyrotechnic materials. The application of water to this type of fire will result in detonation. Care should be exercised to see that there are no carbon tetrachloride of carbon dioxide fire extinguishers in the vicinity of a pyrotechnics magazine as the application of either of these chemicals will result in poison gas.

White Phosphorus-filled Ammunition. To extinguish white phosphorus it is necessary to cut off all oxygen as phosphorus ignites spontaneously when exposed to oxygen. Phosphorus should be entirely submerged in water. Covering it with inert material would extinguish it but there would be no point in using this procedure in that removal of the inert material would result in immediate ignition. The application of water spray or fog will tend to accelerate the burning of the phosphorus and will cause it to be projected about the surrounding area. Normally it will burn in a mass.

Fire Symbol Group IV. Quantity-distance classes 4, 5, 6, 7, 8, 9, 10.

This fire symbol group contains all of the rest of the quantity-distance classes. These quantity-distance classes are made up of am-

munition containing high-explosive fillers and all of the bulk high explosives. It is imperative that every possible effort be made to keep a fire from spreading to ammunition in this category. Once the fire has reached this ammunition, personnel should retire to a distance of 1000 feet for each 50,000 pounds of material in the storage facility. This distance may be increased or reduced proportionally. These types of ammunition will detonate in mass, and effort should be limited to keeping the fire from spreading.

7. STACKING AND PILING

Ordnance Drawings

The 19 series of ordnance drawings is used as a guide to the proper methods of stacking and piling ammunition and explosives within standard ammunition magazines. Within the 19 series of ordnance drawings there is a complete blueprint of every type of packing for every type of military ammunition and explosives. The drawings contain the following specific items of information:

Maximum of specific items that may be stored in each of the three sizes of standard types of magazines.

Maximum explosive weight that may be stored in each of the three types of standard magazines.

Quantities and distances prescribed for individual stacks within a single magazine.

Dunnaging requirements.

Required aisle spaces within a single magazine.

General Rules for the Stacking and Piling of Ammunition and Explosives

Ammunition and explosives are to be segregated by type, caliber (in the case of bombs, weight will replace caliber), lot number, and type of packing.

Ammunition and explosives must be adequately dunnaged. Two inches of dunnage is the minimum accepted height for dunnage when ammunition is stored in magazines. When ammunition is stored under field conditions or out-of-doors, the minimum accepted dunnage height is four inches, however six inches is desirable.

Materials should be so stacked so as to assure that ample ventilation is available to all stacks and all parts of each stack.

Unless otherwise specified, on ordnance drawings, aisles are to be maintained so that units within a stack can be readily inspected, inventoried, or removed.

Whenever possible, lids, opening ends and bomb fuze cavities should face into an aisle.

Partially filled boxes or containers should be clearly marked and placed conspicuously in a stack.

Items should be placed in such a manner that the nomenclatures will be visible.

In magazines containing ammunition in quantity-distance classes 9 and 10, there should be no inflammable materials stored.

Compliance with quantity-distance regulations. Individual stacks. Stacks must be erected and kept in a stable manner. (A level stack is generally a stable stack. Stability can be determined by sighting a stack both vertically and horizontally.)

Outdoor stacks should be properly and adequately and in such a manner so that the ventilation to the stack is not cut off. This is accomplished by erecting a ridge pole across the top of the stack (tent like) with the tarpaulin extending outward from the sides of the stack so that there is approximately a foot of space between the bottom of the stack and the ends of the tarpaulin.

Wet or damaged ammunition containers should not be stacked. When repairing or replacing containers, care must be exercised to insure that all identifying markings have been transferred to the repaired or replaced container.

One should not "nest" aircraft bombs unless absolutely necessary. This practice is not only considered to be unsafe, but it presents a possibility of damaging suspension lugs and bomb bodies. It also is not conducive to safe and efficient bomb handling.

One must make sure that each end of each layer within a stack of bombs is securely blocked in place.

THIS PAGE IS DECLASSIFIED IAW EO 13526

8. STORAGE AND SURVEILLANCE OF SPECIFIC ITEMS OF AMMUNITION

Surveillance, General Information

The term "surveillance" as used herein includes the observation, inspection, investigation, and test of explosives and ammunition in storage and use; inspection of containers and buildings in which they are stored, and the inspection of facilities and methods used in storing, handling, shipping, maintaining, renovating, salvaging, and destroying explosives and ammunition.

The purpose of surveillance is to detect in stores of explosives and ammunition all conditions tending to increase deterioration or danger; to determine the state or nature of deterioration and the degree of serviceability, and to segregate seriously unstable conditions.

The Chief of Ordnance exercises general supervision over the surveillance of all explosives and ammunition in storage and service; prescribes the tests, technical methods of inspections to be made; and maintains records of the condition of all lots in service and storage.

Ammunition inspectors are personnel trained in the surveillance of explosives and ammunition. They are appointed and assigned by the Chief of Ordnance, but are under the control and supervision of the commanding officer.

Lot Numbers, Grades, and Packing Marking

General. Lot numbers are used in the identification of military explosives and ammunition. Except for certain unserviceable material, the lot number always appears upon the packing boxes or containers. It also appears on the data cards and in most cases upon the ammunition itself.

Lot numbers usually consist of letters and figures which represent the initials of the manufacturer or loading company, the number of the War Department procurement order, the serial number of the lot and, in some cases, the date.

The identification of military explosives and ammunition by lot number is essential for surveillance activities. It is the means whereby stocks are conserved or utilized to the best advantage, and defective or deteriorated ammunition is withdrawn from service. It is used also in selecting ammunition for issue, because the ballistics or performance of ammunition may vary from lot to lot.

Bulk High Explosives. A lot of TNT usually ranges from 5,000 to 100,000 pounds. As each lot has definite characteristics, its identity must be carefully maintained. A history of the manufacture of each lot is filed in the office of the Chief of Ordnance and is used in the investigation of any unusual action or deterioration occurring in service or in storage.

TNT is graded in accordance with United States Army Specification No. 50-13-5.

The containers used for packing bulk high explosives will comply with Interstate Commerce Commission regulations.

Small-arms Ammunition. The size of a lot of small-arms ammunition is determined by the quantity which may be manufactured conveniently, inspected, and tested under uniform conditions. An acceptable lot must exhibit uniform characteristics in acceptance tests. It may vary from a few thousand to a million rounds, but averages approximately half a million rounds. As each lot has definite characteristics its identity must be maintained. A lot number once assigned remains unchanged until the ammunition is expended.

All small-arms ammunition is not divided into lots. Caliber numbers for shotgun shell are designated as Lot 1, Lot 2, etc., followed by the year of purchase.

The term "cartridge lot" as well as "ammunition lot" has been used at times to identify small-arms ammunition. The latter name is preferred. The various systems that have been used in designating ammunition lots of small-arms ammunition are described in applicable technical regulations.

Lots of cal. .30, cal. .45, and cal. .50 ammunition designed for target practice or combat use in standard service weapons are assigned grades representing degrees of serviceability. The grades are determined by ballistic tests, surveillance tests, and reports of

performance from the using arms and services. Assignments to grades and changes therein are made by the Chief of Ordnance. A grade is usually assigned to an entire lot. However, portions of the same lot stored under different conditions may develop defects which would not apply to the entire lot. Different grades sometimes may be established for parts of lots at different places. Ungraded ammunition will not be issued or used for any purpose, but will be reported to the office of the Chief of Ordnance. The grades of ammunition are not marked on packing boxes or on slips inside the box; they are found only in ordnance field service bulletins.

Ammunition which is not used for target or combat purposes is not ordinarily graded; but special tests, both ballistic and surveillance, may be ordered by the Chief of Ordnance if at any time such ammunition appears to be unfit for storage or issue.

The various grades to which lots of cal. .30 and cal. .45, small-arms ammunition are assigned and described in field service bulletins and Army regulations.

Small-arms ammunition is packed in wooden boxes, practically all of which have metal liners. Each metal liner is made airtight and tested after it is packed. It should remain airtight unless subjected to rough handling. Most ammunition is packed in boxes which are made in accordance with Ordnance Department drawings. Other types of boxes are in use but will be discontinued when those now on hand have been expended. Cartridges are packed in containers in accordance with the methods described in appropriate technical manuals.

The details of marking and printing of small-arms ammunition containers may be obtained from the technical regulations governing small-arms ammunition.

Aircraft Bombs

Bombs are divided into lots varying in size from several thousand for the smaller types to a few hundred for large bombs. Each is marked with an ammunition lot number which is used to identify the lot when reporting evidences of deterioration or malfunctioning.

The present prescribed methods of packing bombs is as follows:

A detailed description of the packing boxes and crates, including details as to size and contents, will be found in technical regulations and on ordnance drawings and specifications. Spotting charges for practice bombs normally consist of a few pounds of black powder. These charges are stored, handled, and shipped under the regulations for black powder, with the exception that M1A1 spotting charges are not removed from their boxes but are stored as received.

Bombs, packing boxes, and crates for bombs are marked to show the size, lot number, filler, and other characteristics, including marking required by Interstate Commerce Commission regulations. The painting and marking of each type of bomb and its packing box or crate are described in applicable technical regulations. Bomb packing boxes which contain fuzes, or primer-detonators may be marked with a stripe of red paint to show the location of the fuze, or primer-detonator.

Fragmentation and chemical bombs are packed in metal tubes assembled in bundles (20 lb., M41), wooden boxes (25 lb., M3), or metal crates containing from two to five bombs each (30 lb., M5). Usually, fuzing components are packed in the same container.

One hundred-pound demolition bombs are packed in metal crates, one in a crate, or are packed as described below. The fuzes, primer-detonators, arming wire, swivel loop, and one fin brace for the 100-pound Mk IMI bomb will be inserted in a component metal box which will be assembled to the metal crate.

All demolition bombs except the 100-pound bomb are shipped without fins with metal shipping bands to protect the suspension lugs, and to facilitate handling. Fin assemblies are shipped separately from the bomb in wire-bound, veneer-wood, packing boxes. When shipments are made to using services, fuzing components are packed in a wire-bound accessory box which is inclosed in the fin-assembly box. In interdepot shipments, fuzing components are shipped in their respective boxes.

Fuzes, Primers, Boosters, and Detonators

Loaded components are divided into lots, and always will be identified by lot number. The size of a lot usually varies from 5,000 to 25,000 components and is dependent upon the stage of manufacture and other factors. Each lot is made and tested under uniform conditions and has certain characteristics which require that the identity of all components in the lot be carefully maintained. Where practicable, the lot number is stamped on the components, but it always appears on the containers in which they are packed.

Packing and Marking. The practice with respect to packing of those loaded components which are packed separately from the ammunition or bombs with which they are to be used, differs from one component to another, depending upon the character of the component. Provision is made for the packing of every item of issue to the field. Bomb fuzes which contain no explosives are packed in wooden boxes without metal liners, with the fuzes supported in trays to avoid their striking together. Bomb fuzes of more modern design, containing explosive components, will be shipped in individual containers within wooden boxes. Primers intended for assembly into complete rounds of ammunition are packed in paper cartons, waterproofed by dipping in paraffin, within hermetically-sealed metal liner, in wooden boxes. Primers for separate loading ammunition, that is, for issue to the field as primers, are packed in small metal boxes within wooden boxes. Adapter-boosters for bombs and adapters and boosters for artillery ammunition are packed in trays within unlined wooden boxes for shipment to loading plants. For detailed information regarding the method of packing each type of component, reference should be made to the proper drawing.

Safety Precautions. Fuzes, primers, boosters, and primer-detonators are loaded with explosives which are sensitive to shock and friction. Components of these types are supported in trays or racks, to protect them against shock, but they must be handled with care at all times. The covers of wooden boxes for these components are fastened with screws. Nails must not be used.

Pyrotechnics

Pyrotechnics for military use are divided into two general classes: illuminating and signaling. These two classes are further subdivided into pyrotechnics for ground troops and aviation pyrotechnics. Pyrotechnics are described in technical regulations, on ordnance drawings, and in specifications.

Pyrotechnics are divided into lots which represent a definite quantity that has been manufactured and tested under uniform conditions. The lot number usually appears on the individual pyrotechnics and on the containers.

Packing and Marking. Pyrotechnics are packed in metal-lined or unlined, nailed or wire-bound wooden boxes. Those in unlined boxes are packed in inner containers consisting of sealed, corrugated-board cartons, cylindrical fiber containers, or metal containers. The cartons are dipped in paraffin to protect the contents from moisture. The M8A1 aircraft flare is packed in an individual fiber container which in turn is inclosed in a single-flare, wire-bound box. The methods of packing pyrotechnics made during 1917-1918 are described in O.O. Form 2027, "Military Pyrotechnics"; for pyrotechnics manufactured since the war, they are described in technical regulations, on ordnance drawings, and in specifications. Pyrotechnics and their containers are labeled or marked to comply with Interstate Commerce Commission regulations and Army specifications and drawings. This marking includes the type or kind, date packed, lot number, and quantity. The M8A1 flares, their containers, and their packing boxes, are marked to indicate the date before which they must be expended.

9. STORAGE AND MAINTENANCE OF SPECIFIC ITEMS OF AMMUNITION AND EXPLOSIVES

Bulk High Explosives

Containers of high explosives are stored with the top side up to prevent the explosive

from sifting out. New stocks are piled, and existing stocks rearranged in compliance with applicable Ordnance Department drawings.

High explosives are usually very stable in storage, but their containers are subject to deterioration. Damaged or deteriorated containers must be repaired, or their contents transferred to new or serviceable containers. This work should be done in a room or building free from all other explosives or in suitable weather in the open, at sufficient distance to comply with quantity-distance table requirements, but in no case closer than 100 feet from any building containing explosives or ammunition. The amount of explosives at or near such operations must be limited to one open container of 100 pounds and four closed containers. Safety tools must be used for all repacking or repairing operations. The contents of damaged containers should be examined for the presence of dirt or foreign matter, which must be removed before repairing or repacking.

If a standard container is not available for repacking, a strong wooden box not exceeding 140 pounds gross weight when packed may be used. Such containers must be lined carefully as specified for the standard container. Containers must be marked to comply with Interstate Commerce Commission regulations.

Small-arms Ammunition

Small-arms ammunition is not an explosive hazard in storage, although under adverse conditions of storage it may become a fire hazard. With reasonable care in storage, and under the surveillance prescribed in these regulations, small-arms ammunition may be stored safely in any weatherproof magazine or warehouse. In small quantities it may be kept in a barracks storeroom. The conditions most likely to affect small-arms ammunition adversely are dampness, lack of ventilation, and extreme heat such as might be obtained in storing near steam pipes. If the atmosphere is damp or unusual temperatures are experienced, layers of boxes should be separated by dunnage to permit free circulation of air. Ammunition must be piled by lot, and each pile placarded to show readily the manufacturer, lot, caliber, and grade of the ammunition in each pile.

Small-arms ammunition in containers is piled and arranged in a magazine in accordance with instructions set forth in Army regulations and in ordnance drawings.

Maintenance activities in connection with small-arms ammunition include repairs to damaged containers, repacking, resoldering, and air testing containers. Ammunition which contains an excessive number of visible defects is sorted out to reclaim that which is still satisfactory for issue.

When damaged containers are repaired, or small-arms ammunition is repacked, the metal liner is sealed to protect the ammunition from deterioration. The apparatus use for air-testing smokeless powder containers is used if more suitable equipment is not available. A pressure of approximately two pounds per square inch is used. If the cover of the metal container is damaged, or is difficult to resolder, new covers must be requisitioned from the Chief of Ordnance. Ammunition must be repacked in the same manner as it was originally packed, unless the Chief of Ordnance issues specific instructions to the contrary. The identity of the ammunition must be maintained carefully by lot, and the markings on a repacked container must be a facsimile of those on the original container.

The sorting of lots of ammunition which cannot be issued because they contain an excessive number of visible defects, or the reclaiming and repacking of the serviceable ammunition in the lots must not be undertaken except upon specific instructions from the Chief of Ordnance. The process of reclaiming serviceable cartridges includes all of the operations necessary to remove defective cartridges and repack the ammunition for shipment. It involves removal of the ammunition from the old containers, culling out defective rounds, repacking serviceable cartridges into clips, bandoleers, cartons, etc., and resealing the metal container. New cartons, clips, bandoleers, covers for metal lines, etc., required for repacking must be requisitioned from the Chief of Ordnance. However, where practicable, the old containers, etc., must be used. When a lot of ammunition is reclaimed, it changes its lot number or grade only as specified in ordnance field service bulletins, except that defective cartridges culled from the lot are automatically classified as grade 3 ammunition.

Salvaging of small-arms ammunition consists of reducing the rounds to their principal components, such as cartridge case, bullet, and propelling charge. The method employed in breaking down the rounds will depend upon the facilities available, and any special instructions issued by the Chief of Ordnance. Since the principal hazard involved is that of fire, care must be taken to guard against an accumulation of powder at the breaking-down operations. Floors and benches must be kept clean, and powder from cartridges must be continuously removed from the immediate vicinity of breaking-down operations so that in case of fire not more than one or two pounds will be involved, and personnel will not be exposed to unnecessary hazards. Powder obtained from breaking-down operations should be placed in standard containers and stored in the open under tarpaulins or in a shed where a fire cannot cause great damage. Primers in cartridge cases usually are rendered inert by placing the cases in a fire. All salvaged components must be kept separate until disposed of in accordance with Army regulations or directions of the Chief of Ordnance.

Aircraft Bombs

In storing, a distinction is made between fragmentation and demolition bombs. Fragmentation bombs, when packed in wooden boxes like fixed ammunition, are not likely to detonate en masse if a fire occurs in the magazine.

Fragmentation bombs packed in metal crates are susceptible to mass detonation and must be stored in a manner similar to that specified for demolition bombs.

Demolition bombs have very thin walls. They are regarded as one of the most hazardous types of ammunition because of their tendency to detonate en masse if a fire occurs or a heated fragment is projected into the magazine in which they are stored. One of the most distastrous explosions on record originated from a fire in a magazine in which was stored a large number of demolition bombs packed in boxes. No feasible way of separating bombs or barricading piles of bombs in a magazine to reduce the hazard of mass detonation has been found. Safety can be obtained only by reducing the possibility of fire to an absolute minimum. Bombs should be stored in fireproof magazines without combustible dunnage.

To minimize the fire hazards, demolition bombs which may be packed in wooden boxes or crates must be removed therefrom before storing. Steel dunnage is preferred and must be used unless instructions to the contrary are issued by the Chief of Ordnance. Fuzes and primer-detonators must not be packed with bombs except in the case of metal-crated 100-pound bombs. Fuzes and primer-detonators may be stored with 100-pound bombs in igloo magazines.

Demolition bombs are so piled that fuze cavities can be readily inspected and visible signs of exudation detected. Bombs with fin assemblies attached are piled carefully to avoid damage to fin assemblies.

Bombs will be stored in those magazines which offer the best protection against fire and missiles. Approved, arch-type, earth-covered, concrete igloo magazines must be used if available.

Bombs in storage must not be fuzed or fitted with primer-detonators.

Maintenance activities include removal of rust, repainting, remarking, removal of exudate from the bombs and floors of the magazine, and repairs to containers. The removal of rust and repainting must not be done in a magazine in which explosives or ammunition are stored. These operations, however, may be conducted in an empty magazine, or in suitable weather in the open at sufficient distances to comply with intraplant quantity-distance requirements, but in no case closer than one hundred feet from any building containing explosives. Exudate is a dangerous fire hazard and must be cleaned from bombs and floors of magazines. When bombs are repainted the painting and marking must be a facsimile of the original painting and marking.

In renovation and salvage bombs may not be renovated, salvaged, or modified except with the specific approval of the Chief of Ordnance, who issues the necessary instructions for the performance of such work.

Fuzes, Primers, and Detonators

Components must be stored with the tops of the boxes up. Storing of all of one type in a magazine should be avoided, if possible, because a fire or an explosion may result in the loss of the entire quantity. In no case may more than 50,000 fuzes of any one model nor more than 150,000 of all models be stored in a single magazine. This prohibition does not apply to grenade fuzes, which are included in class 8 of military explosives and ammunition, with primers, detonators and like components. All boxes and containers opened for inspection must be resealed. They are piled in accordance with ordnance drawings. Incomplete boxes must be marked plainly for identification and placed on top of the piles. Open boxes of loaded components may not be stored in a magazine.

Maintenance includes repairs to containers, sealing and air testing of containers which have been opened for inspection. Containers opened for inspection must be resoldered or effectively resealed with adhesive tape. No work, such as removing rust, or repainting, may be done except by specific direction of the Chief of Ordnance, who will furnish the necessary instructions. Containers must not be opened or repaired in a magazine containing explosives or ammunition. This work must be done in a near-by empty magazine, in a repacking room, or during clear weather in the open at sufficient distance to comply with intraplant quantity-distance requirements, but in no case closer than one hundred feet from any building containing explosives.

In renovation and salvage, loaded components are to be renovated, salvaged, or modified only in accordance with specific instructions furnished by the Chief of Ordnance.

Descriptions of components such as fuzes, boosters, and primers are found in appropriate technical publications.

Pyrotechnics

Storage. Pyrotechnics are stored in containers as indicated in current ordnance drawings. Some pyrotechnics deteriorate rapidly in the presence of moisture and high temperature and may become unsafe. Good protection against moisture or dampnes and high temperature should be provided. Containers which show signs of dampness or moisture must be carefully examined; if the pyrotechnics have been damaged, they must be destroyed.

Only pyrotechnics in metal cases, such as aviation cartridges and airplane flares are reconditioned or renovated. Such work is done in accordance with specific instructions of the Chief of Ordnance.

Pyrotechnics should be protected against moisture, should be handled with care, and protected against shocks. The boxes should not be dropped or thrown. If pyrotechnics are exposed to moisture, they should be segregated from all other materials until an examination has been made to make sure that they are serviceable and are not dangerous.

10. DESTRUCTION OF EXPLOSIVES AND AMMUNITION

Explosives and ammunition which are dangerously deteriorated or which cannot be economically salvaged must be destroyed. Destruction of explosive material is accomplished by burning, exploding, or dumping at sea as specified in following paragraphs of this section. Burying explosives or ammunition, or dumping them into waste places, pits, wells, marshes, shallow streams or inland waterways is prohibited except for black powder and chemical ammunition.

Destruction must not be undertaken without prior approval of the Chief of Ordnance in each case, except that commanding officers may order the immediate destruction of dangerously deteriorated explosives or ammunition when in their opinion such action is necessary to protect life or property. When destruction is authorized, the provisions of Army Regulations 35-6640, "Lost, Destroyed, Damaged, or Unserviceable Property," will be observed.

Instructions for destroying duds are incorporated in appropriate technical and field manuals.

11. SPECIAL SAFETY REGULATIONS FOR THE DESTRUCTION OF EXPLOSIVES AND AMMUNITION

All dry grass, leaves, and other combustible materials must be removed within a radius of two hundred feet from the point of destruction. Fire-fighting facilities for combating grass fires should be maintained readily available and, if practicable, the ground at the point of destruction should be wetted down with water at the close of each day's operations.

Explosives and ammunition must not be destroyed by detonation if magazines and other buildings are in danger of being damaged by fragments or shock. If the distance from the place of destruction to magazines or buildings is less than eight hundred yards, a pit or trench which will limit effectively the range of fragments must be used.

Demolition of explosives may be accomplished either by the use of electric blasting caps with hand exploders (blasting machines) or by nonelectric blasting cups and safety fuze.

The signal for detonation will be given by one designated responsible individual only, who before each detonation will insure that all persons in the vicinity are protected by substantial cover, or have reached a safe distance. If a blasting machine is used, the wires must not be connected to the terminals until all personnel have reached cover.

If nonelectric blasting caps and miners' safety fuze are to be used the fuze must first be tested as follows: a piece of fuse twelve inches long is cut from the roll to be used and burned to determine the approximate time rate of burning in order that sufficient length of fuze will be used to permit all personnel to retire to a safe distance. The rate of burning of fuze varies with atmospheric conditions, degree of tightness of tamping, etc. Fuze which is too large in diameter to enter the blasting cap without forcing must not be used.

Electric blasting caps are exploded by an electric current. Nonelectric blasting caps are exploded by flame or sparks from safety fuse. Both types of caps are copper cylinders loaded with very sensitive and violent explosives and must be handled with extreme care. The use of improvised methods for exploding blasting caps is prohibited.

One-half pound TNT blocks, one-quarter or one-half pound blocks of nitrostarch explosives are provided for demolition purposes. These blocks must not be broken into smaller pieces.

Material to be burned must always be removed from containers as attempts to burn certain explosives or ammunition under even slight confinement may result in explosions.

The amount of material to be destroyed at one time must be kept at the minimum consistent with reasonable and safe operation. The number of units that may be destroyed safely at one time will be determined carefully by starting with a limited number and then gradually increasing that number until the maximum which can be destroyed without risks to life and property is determined.

As some types of ammunition are rather difficult to explode, a search of the surrounding grounds should be made after each blast and any dangerous material which has been thrown from the pit and not detonated should be collected and destroyed.

Material awaiting destruction must be protected against accidental ignition or explosion from fragments, grass fires, or burning embers. The base of supplies should be so isolated that if explosives should burn or detonate prematurely, surrounding property will not be damaged.

In repeated burning operations, care must be taken to guard against material being ignited from burning residue or heat retained in the ground.

Sufficient and suitable protection for personnel must be provided in the form of temporary or permanent barricades, depending on local conditions. Necessary action must be taken to insure that barricades are used and safety distances observed by all persons. In cases of misfire, personnel must not approach

the pit, trench, or point of detonation until a period of thirty minutes has elapsed.

The destruction of ammunition by explosion or detonation requires very careful control by those in charge. Such work must not be attempted with inexperienced or untrained personnel. The number of employees engaged in such operations must be maintained at the minimum consistent with safety.

In the absence of specific regulations or information covering any phase of the destruction of explosive material, instructions must be requested from the Chief of Ordnance.

At establishments which are located near a deep-sea water-way, and which are too restricted in area to make burning or detonating safe, explosives or ammunition to be destroyed may be placed on barges, towed out to sea, and thrown overboard. In this case, however, the port authorities must be consulted, and their regulations regarding the transfer and disposal of material of this nature must be observed. The material is removed from containers before being dumped overboard. Instances are on record in which ammunition thrown overboard in heavy containers has washed up on shore from great distances and depths.

ConAC Manual 50-11 Vol. II is published for the information and guidance of all concerned. It will be used in conjunction with the current program of instruction pertaining to Air Force ROTC Training.

BY COMMAND OF LIEUTENANT GENERAL WHITEHEAD:

GORDON P. SAVILLE
Major General, United States Air Force
Vice Commander

HEADQUARTERS — OFFICIAL — CONTINENTAL AIR COMMAND

OFFICIAL:

NEAL J. O'BRIEN
Colonel, United States Air Force
Adjutant General

This publication has been reproduced in quantities sufficient only t[o] meet the requirements of the Continental Air Command and the di[s]tribution of information copies in accordance with paragraph 5c, AF[R] 5-22A. Additional copies will be requested in accordance wth paragrap[h] 5c. AFR 5-22A.

THIS MANUAL SUPERSEDES ConAC Manual 50-140-1, Vols. I, II, III.

Preface

DECLASSIFIED EO 11652

THIS textbook has been prepared specifically for the college or university student who is participating in the Air Force ROTC program. It is one volume of a series designed to qualify him as an officer specialist in the United States Air Force.

The text is planned to indoctrinate the officer candidate in the fundamental principles of Air Force Armament, rather than to present a detailed treatise of the entire complex field.

In order to achieve maximum efficiency and effectiveness in the performance of his duties, the Air Force officer must be constantly aware of new developments in his specialty and its allied fields. A receptive mind, nurtured by supplementary research and reading, can be a vital force in the personal and professional development of the officer specialist throughout his career.

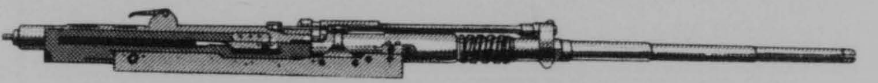
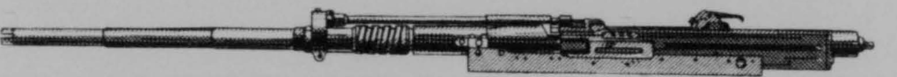
CHAPTER 1—20MM AUTOMATIC GUN



20 MM AUTOMATIC GUN M3—RIGHT SIDE VIEW



20 MM AUTOMATIC GUN M3—LEFT SIDE VIEW

SECTION I—DESCRIPTION

1. INTRODUCTION

The following chapter pertains to the nomenclature, identification, use, care, inspection and maintenance of the 20-mm automatic gun, M3 and allied equipment. Reference should be made to Air Force Regulation 50-13 concerning safety instructions and regulations for use of this weapon and firing ammunition in training, target practice, and combat.

2. GENERAL

The 20-mm automatic gun M3 is a combination blow-back and gas-operated aircraft weapon. It is air-cooled and has a cyclic rate of fire of from 650 to 800 rounds per minute. It is designed for fixed-position mounting in the wing or fuselage of an airplane or as a flexible gun in a turret. The gun can be fed from either right or left side.

Differences in Models

The differences between the 20-mm automatic guns AN-M2 and M3 which affect troop use are shown in Figure 1-1.

Serial Numbers

The gun serial number is stamped on the receiver. (See Figure 1-2).

The tube serial number is stamped on the tube just ahead of the gas cylinder bracket.

3. CRADLE GROUP

The gun is mounted in a cradle assembly which is so designed as to allow the gun to move backward in recoil and forward in counter-coil. The nonrecoiling recoil housing assembly of the gun, which fits around the recoiling gun tube, is secured to the mounting bracket of the cradle by means of two trunnion blocks and four trunnion block and mounting bracket screws safetied by a plate, the corner of which is bent up. The receiver, which is recoiling, engages one horizontally rotating roller and two vertically rotating rollers at the rear of the cradle. The rollers carry the weight and control the vertical movement of the gun. (Figure 1-3).

The cradle also mounts the anchor support bracket to which the magazine slide is fixed by means of a magazine slide anchor. In this manner the magazine slide is made nonrecoiling, whereas the receiver, on which it is mounted, recoils during firing. This condition is utilized in the operation of the 20-mm feed mechanism AN-M2 which is recoil operated.

The sides of the cradle are drilled and tapped for mounting the various chargers.

Left- or right-side feeding, using 20-mm feed mechanisms AN-M2, M3, and AN-M1A1. 20-mm electric triggers AN-M1A1 and AN-M4.	Left- or right-side feeding, using 20-mm feed mechanism M3, AN-M1A1. Manual firing, using 20-mm sear mechanism M1; 20-mm electric trigger AN-M1.

The differences between the 20-mm automatic guns AN-M2 and M3 which affect ordnance maintenance are as follows:

20-mm Automatic Gun M3	20-mm Automatic Gun AN-M2
Gas cylinder bracket can be removed for replacement or for cleaning. Rear buffer is lubricated at assembly; it is not to be disassembled bur replaced as a unit. Length of tube is 52.5 inches.	Gas cylinder bracket is shrunk on and pinned in place. Rear buffer can be disassembled for cleaning or replacement. Length of tube is 67.5 inches.

Figure 1—1. Comparative Features of 20-mm Automatic Gun M3 and AN-M2.

4. TUBE AND RECEIVER GROUP

General

For the purposes of description, disassembly, and assembly, the following components are treated as parts of the tube and receiver group:

Gun tube
Receiver
Rear buffer and driving spring guide
Magazine slide

Gun Tube

The tube serves to accommodate the front mounting arrangements, recoil housing, and the gas cylinder sleeve group (Figure 1-4).

The threaded muzzle end is for attaching the flash hider (Figure 1-5). The threads to the rear of the threaded muzzle end serve for attaching certain types of British mounts but are not used for mounting the gun in U.S. airplanes. When these threads are not in use, they are protected by a thread protector sleeve and cap.

Receiver

The receiver houses most of the working parts. (Figures 1-6 and 1-7)

The front of the receiver is threaded internally to receive the tube.

A guideway on each side of the opening on top of the receiver accommodates the magazine slide by means of which the feed mechanism is secured to the gun.

The rear of the receiver has vertical dovetail grooves for attaching the rear buffer.

The rear underside of the receiver accommodates the sear mechanism.

The front underside of the body is open to permit ejection of empty cartridge cases. Above the ejector opening are two receiver slides which are bolted to the sides of the receiver and serve to support the breechblock in its forward movement. The slides have cammed surfaces at the rear which engage corresponding cams on the breechblock lock, to cam it into the locked position with the assistance of the camming action of the

GENERAL DATA	
Weight of gun, including cradle	99.5 lb.
Over-all length of gun	77.7 in.
Weight of the tube	26.2 lb.
Length of the tube	52.5 in.
Muzzle velocity	2,730 ft per sec.
Rate of fire	650 to 800 rounds per min.
Rifling:	
Number of grooves	9.
Depth of grooves	0.015 in.
Width of grooves	0.205 in.
Width of lands	0.068 in.
Twist, uniform, right-hand, slope	7 deg.
Length	48.06 in.
Travel of projectile in tube	48.66 in.
Feed Mechanism. 20-mm feed mechanism AN-M2.	
Weight	13 lb.
Over-all length	10.2 in.

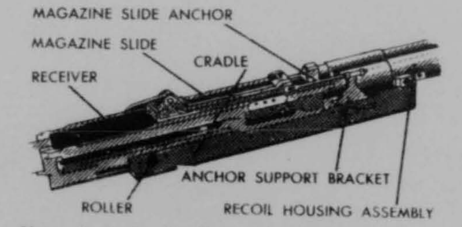

Figure 1—3. Cradle (Assembled to Gun).

breechblock slides. At the rear of the ejector opening, a transverse slot is cut in each side of the receiver body to accommodate the breechblock locking key. The breechblock locking key engages the breechblock lock when the lock is cammed down into the locked position.

The cradle mounting plate on the middle of the underside of the receiver serves to support the gun and control its vertical movement by means of rollers fitted in the gun cradle.

The electric heater is installed on the breechblock locking key and receiver slides.

5. REAR BUFFER AND DRIVING SPRING GUIDE

General

The function of the rear buffer is to cushion the shock of the rearward movement of the breechblock, and to start the breechblock on its forward movement. This action is accomplished by a series of ring springs guided by a sleeve, and a coil spring placed inside the sleeve.

As the breechblock moves to the rear, it compresses the driving spring; this absorbs much of the inertia of the breechblock. As the breechblock hits the rear buffer, it transmits the shock of recoil to the springs. The springs absorb the remaining shock and bring the breechblock to a stop. At this time, expansion of the rear buffer springs and the driving spring forces the breechblock forward.

Removal

With a blunt chisel, the rim of the driving-

THIS PAGE IS DECLASSIFIED IAW EO 13526

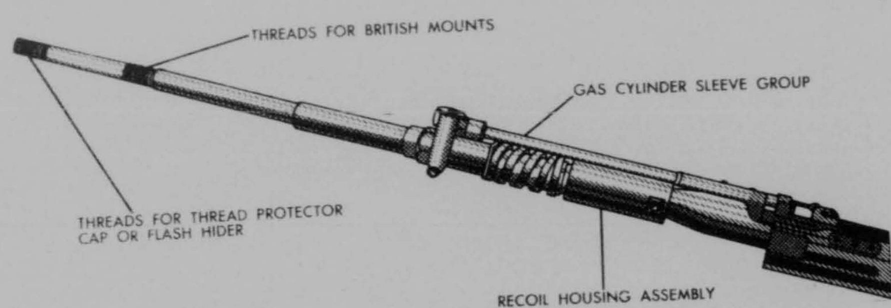

Figure 1—4. Gun Tube Showing Components Mounted on Tube—Close-Up View.

spring guide retainer is straightened so that it does not engage the driving-spring guide head (Figure 1-8). Similarly, the driving-spring guide-cap lock plate is disengaged from the cap (if one is used), the cap is unscrewed, and the plate removed.

The driving-spring assembling tool is inserted through the driving spring guide head and the tool pushed forward until it engages the driving-spring guide plunger.

The driving-spring guide-sleeve assembly is unscrewed with the special rear buffer wrench. The guide with the driving spring and plunger is removed (Figure 1-9).

The rear buffer-lock plunger is retracted and the rear buffer group removed by sliding it out of the dovetail grooves in the receiver.

The driving-spring guide retainer must be kept with the rear buffer.

Note: Disassembly of the rear buffer is prohibited.

6. MAGAZINE SLIDE

General

The magazine slide has a guide on each side which provides for sliding engagement with corresponding guideways on the receiver. The feed mechanism is secured to the magazine at the front by two hook-shaped projections on the slide, and at the rear by the magazine slide latch. (Figure 1-10).

Figure 1–13. Parts of Gas Cylinder Sleeve Group.

The ejector fits into the lower two grooves in the magazine slide beneath the latch. It has two prongs projecting from a steel plate. The upper, inner surfaces of the prongs are shaped to center the incoming round into the path of the breechblock as it moves forward. The top shoulder of the breechblock moves between the two prongs of the ejector which deflect the empty cartridge case downward as the breechblock moves to the rear.

The slide is connected by the magazine slide anchor and anchor support bracket to the cradle; it is, therefore, fixed while the gun recoils during firing.

7. BREECHBLOCK GROUP

General

The function of the breechblock group is to carry the round from the mouth of the feed mechanism into the chamber, fire the round, extract and eject the empty case, and support the case until it is deflected out of the receiver by the ejector. (Figure 1-11).

Figure 1–14. Recoil Group.

Sear. The sear mechanism is a part of the breechblock. Component parts of the sear mechanism are illustrated in Figure 1-12.

8. GAS CYLINDER SLEEVE GROUP

General

The function of the gas cylinder group is to unlock the breechblock so that it can be forced back by straight blowback action. (Figure 1-13).

9. RECOIL GROUP

General

The function of the recoil group is to absorb the shock of recoil of the gun and return it into battery. (Figure 1-14).

SECTION II—DISASSEMBLY AND ASSEMBLY

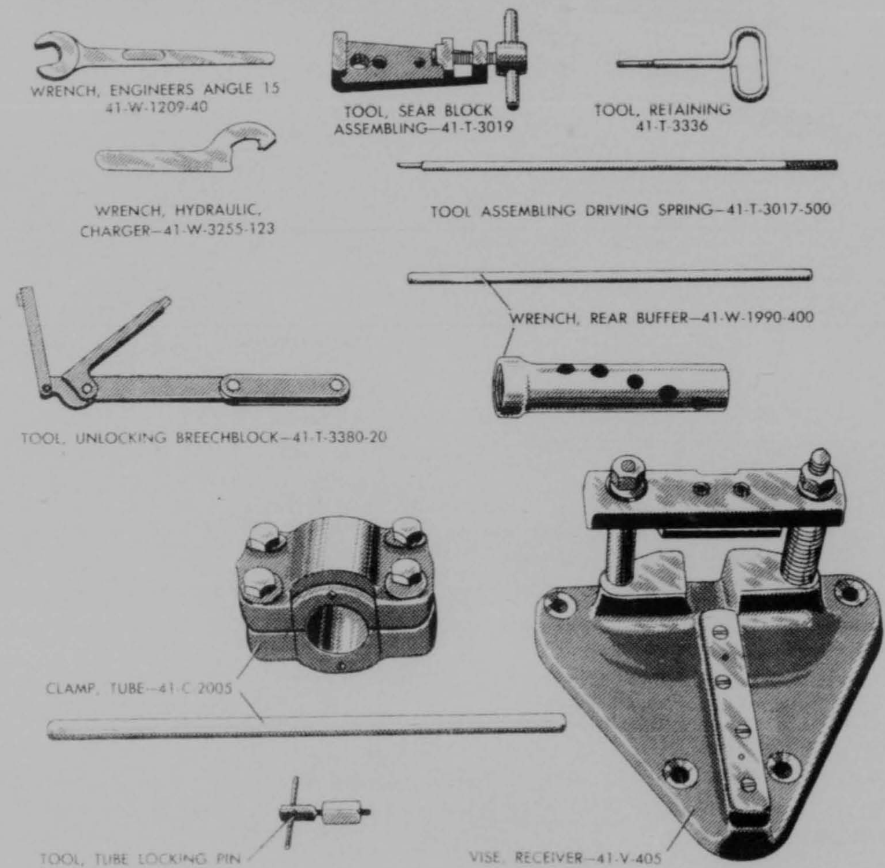

Figure 1—15. Tools for Automatic Guns M3.

1. SPECIAL TOOLS

Special tools used for the 20-mm automatic gun M3 are illustrated in Figure 1-15.

2. CRADLE GROUPS

Removal

The two front magazine slide anchor nuts are unscrewed (Figure 1-16) and the magazine slide moved to the rear as far as it will go.

The locking plate is removed and the two trunnion-block and mounting-bracket screws on each side of the gun are unscrewed. (Figure 1-16). The two trunnion blocks are then removed.

The cradle is moved forward until the magazine slide anchor bracket clears the magazine slide anchor. The cradle is slipped to the

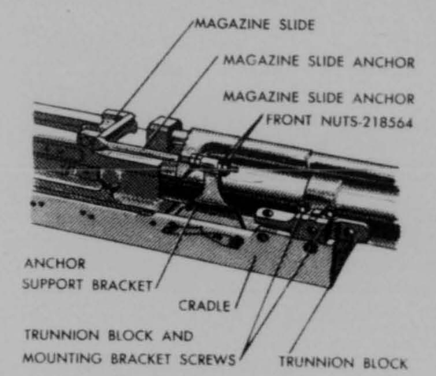

Figure 1—16. Removal of Cradle.

rear and removed from the gun.

The locking wire is removed and the two anchor support bracket screws are unscrewed to disconnect the anchor support bracket (Figure 1-17).

Note: Further disassembly of the cradle is prohibited.

Installation

The cradle is moved from the rear onto the gun as far as it will go, the rollers on the cradle engaging the cradle mounting plate.

The cradle is moved slightly rearward so that magazine slide anchor will recess into the anchor support bracket. The two anchor front nuts are then replaced.

The two trunnion blocks are replaced so that they engage the trunnion adapter, and so that lugs on blocks fit into slots in the mounting bracket. Slotted vertical flange of block should point toward muzzle (old-type blocks have one flange; new-type blocks have a flange at each end).

The locking plates are replaced, the trunnion block and mounting bracket screws are screwed in and secured by bending up the corners of the plates.

The anchor support bracket is secured to the inside wall of the cradle by means of the two anchor-support bracket screws which are lock-wired. The bulging side of the bracket should point toward inside of cradle.

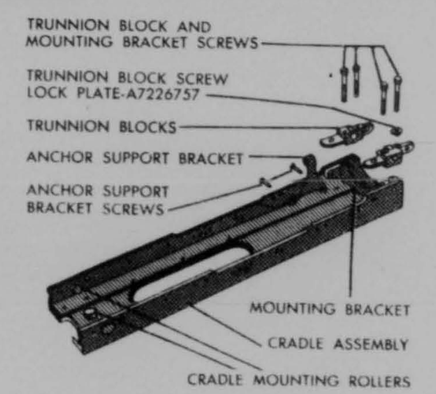

Figure 1—17. Parts of Cradle.

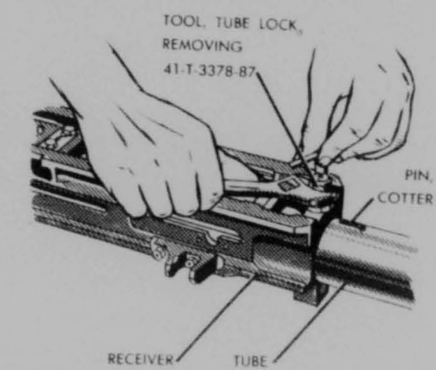

Figure 1—18. Removing Tube Locking Pin.

3. TUBE AND RECEIVER GROUP

Removal and Installation

A gun tube is replaced by first removing the cradle and then the gas cylinder sleeve group. The cotter pin is extracted and the tube locking pin removed with a tube-lock removing tool (41-T-3378) (Figure 1-15).

The receiver is placed in a receiver vise (41-V-405) as shown in Figure 1-15, and clamped securely.

The tube clamp (41-C-2005) (Figure 1-15) is installed over the tube as close to the receiver as possible.

The tube is unscrewed and the threads in the front of the receiver are cleaned.

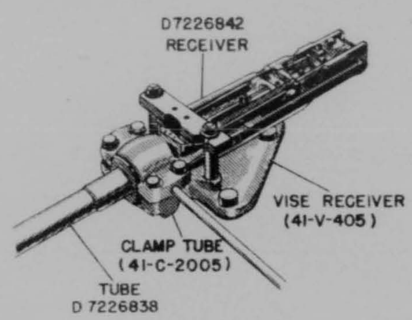

Figure 1—19. Replacing Tube.

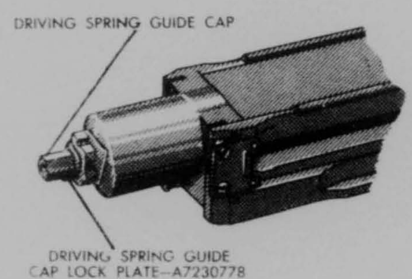

Figure 1—20. Removal of Driving Spring Guide Cap and Cap Lock Plate.

Before installing a new tube, the threads are examined and coated with a light film of graphited grease (light) to aid in assembly.

The tube is installed and the hole in the receiver aligned with the hole for the tube locking pin.

A 25/64-inch hole is reamed in the tube.

The tube locking pin is installed and secured with a cotter pin. (Figures 1-18 and 1-19).

4. REAR BUFFER AND DRIVING SPRING GUIDE

Removal

The rim of the driving spring guide retainer is straightened with a blunt chisel so that it does not engage the driving spring guide head (Figure 1-8). Similarly, the driving spring guide cap lock plate is disengaged from cap (if used), the cap is unscrewed and the plate removed (Figure 1-20).

The driving spring assembling tool is inserted through the driving spring guide head, the tool being pushed forward until it engages the driving spring guide plunger (Figure 1-21).

The driving-spring guide-sleeve assembly is unscrewed with a special buffer wrench. The guide is removed along with the driving spring and plunger (Figure 1-9).

The rear buffer lock plunger is retracted and the rear buffer group removed by sliding it out of the dovetail grooves in the receiver (Figure 1-22).

The driving spring guide retainer must be kept with the rear buffer.

Note: Disassembly of rear buffer is prohibited.

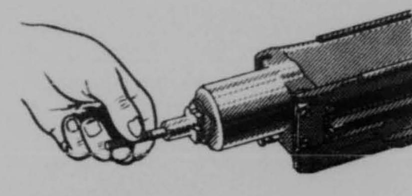

Figure 1—21. Inserting Driving Spring Guide Assembling Tool.

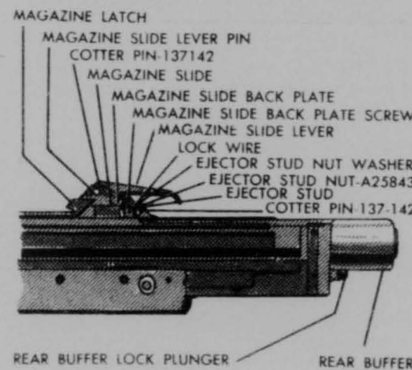

Figure 1—22. Removal of Rear Buffer and Magazine Slide.

Installation

The rear buffer is slipped up in the dovetail grooves of the receiver.

The rear buffer lock plunger is retracted and the buffer moved upward until the plunger snaps into position in the slot in the receiver.

The driving spring retainer (old-type) is positioned on the rear buffer so that pin on the retainer fits into hole on rear buffer. The new-type retainer does not have a pin, instead it has a flange which fits under rear buffer.

The split end of the driving spring assembling tool is inserted into the driving spring guide plunger and the driving spring placed over the tool and plunger. The driving spring guide is inserted into the driving spring so that it fits over the tool.

The assembled unit is then inserted into the receiver through the opening of the rear buffer, sliding into the bore of the breechblock (Figure 1-23).

The rear buffer wrench is placed on the guide, which is pressed in until it contacts the rear buffer; the tool is then turned to screw the guide into the buffer.

The rim of the retainer is bent on a flat of the guide.

The cap lock plate (if used) is assembled on the guide, the cap is screwed onto the guide, and the rim of the plate is bent on a flat of the cap.

5. MAGAZINE SLIDE GROUP

Disassembly (Figure 1-24)

The two magazine slide anchor front nuts are unscrewed; the rear buffer is removed and the cotter pin is removed from the ejector stud.

The ejector stud nut is unscrewed, and the ejector withdrawn, taking care not to lose the two ejector springs.

The ejector stud nut washer (steel) and ejector stud washer (fiber) are removed.

The lock wire and the magazine slide backplate screws are removed, keeping the screws even.

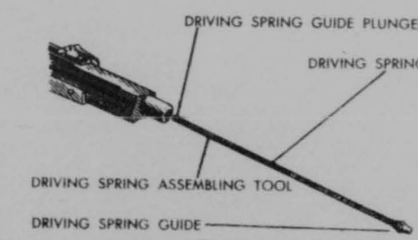

Figure 1—23. Inserting Driving Spring, Guide, and Plunger.

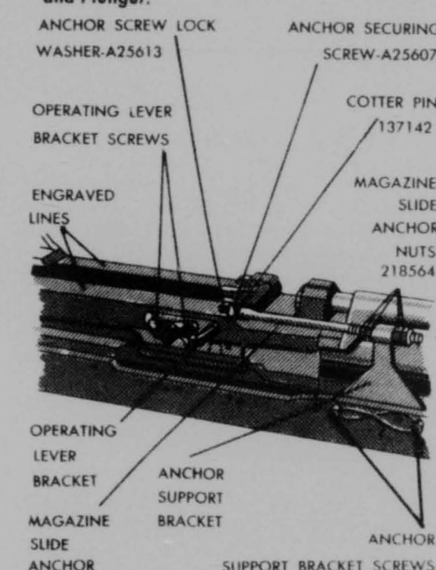

Figure 1—24. Adjustment of Magazine Slide and Installation of Operating Bracket.

The backplate and the two latch springs are removed.

The cotter pin is taken out of the magazine slide lever pin and the lever pin, lever, and latch removed.

The magazine slide is slipped to the rear and off the receiver.

The cotter pin is removed from the anchor securing screw, and the anchor screw lock washer is taken off.

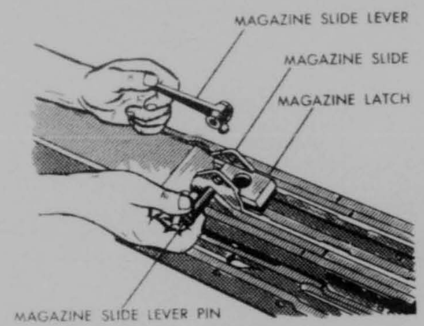

Figure 1—25. Assembly of Magazine Slide.

The anchor securing screw is removed and the magazine slide anchor withdrawn from the magazine slide. (Magazine slide parts are shown in Figure 1-10.)

Assembly (Figure 1-7)

The magazine slide anchor is fitted to the magazine slide. (The threaded end of the anchor should point away from front end of slide (Figure 1-10). The anchor should be on same side with anchor support bracket.)

The anchor securing screw is screwed in; the anchor screw lock washer is replaced, and secured with the cotter pin.

The magazine slide (anchor leading) is slipped on the gun.

The magazine latch is placed on the upper grooves in the rear of the magazine slide. (The sharp end of the latch should point toward the muzzle of gun so that the angle surface on the latch can be seen when looking down.)

The magazine slide lever is positioned on the magazine latch. (The ball on the lever should fit into the hole of the latch, the lever handle should point to the rear, and the holes in the magazine slide should align with the hole in the lever.) The lever pin is pushed in and secured with the cotter pin (Figure 1-25).

The two latch springs are seated in the rear of the latch.

The magazine slide backplate is placed flush against the latch springs and the two magazine slide backplate screws are inserted evenly. The screws are then lock-wired.

Figure 1—26. Positioning Breechblock Unlocking Tool in Gun.

The two ejector springs are seated in the rear of the ejector. The ejector is positioned in the two grooves of the magazine slide below the latch and slipped to the rear until the ejector stud protrudes through the hole in the backplate.

The fiber ejector stud washer is placed on the ejector stud, followed by the steel ejector stud nut washer. The ejector stud nut is then screwed on and the nut secured to the stud with a cotter pin.

The anchor front nuts are then replaced.

6. BREECHBLOCK GROUP

Removal and Installation

Removal of Breechblock. The rear buffer is removed. The two magazine slide anchor rear nuts are backed up all the way (Figure 1-26) and the magazine slide moved forward as far as it will go.

The breechblock unlocking tool is placed on the right side of breechblock in the receiver and the tool manipulated so that the projection on the arm of the tool engages the front face of the right breechblock slide, and the other arm of the tool is along the top of the breechblock with its end against the receiver.

The lever of the tool is pressed forward until the breechblock is unlocked.

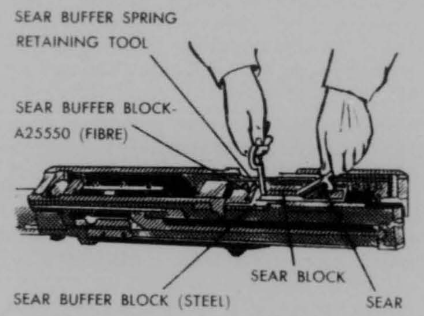

Figure 1—27. Removing Sear and Sear Block from Receiver.

The breechblock then is moved to the rear of the receiver. As soon as it starts to come out, the breechblock lock is grasped and held in the unlocked position. (Failure to do this may cause the breechblock to jam in the rear portion of the receiver.) The breechblock is pulled out of the receiver. (Care should be taken so as not to drop the breechblock lock.

Installation of Breechblock. The breechblock lock is attached to the breechblock by forcing the breechblock slides rearward and, at the same time, exerting pressure against the lock until it is in the unlocked position. The breechblock is held firmly in this position and pushed into the receiver as far as it will go so that the lock will not spring out of position.

The breechblock is then pushed home, the rear buffer replaced and the magazine slide adjusted.

Removal of Sear Mechanism. The cradle is removed from the gun. The twc mounting screw lock plates are straightened, the cradle mounting plate is unscrewed from the receiver.

The sear buffer retaining tool is inserted into the hole in the sear block. The tool is pushed through the sear block so that it fully engages the circumferential grooves on the sear buffer spring plungers (Figure 1-27).

The sear block and sear are lifted out of the receiver with the retaining tool in place. The steel and fiber sear buffer blocks are removed from the receiver.

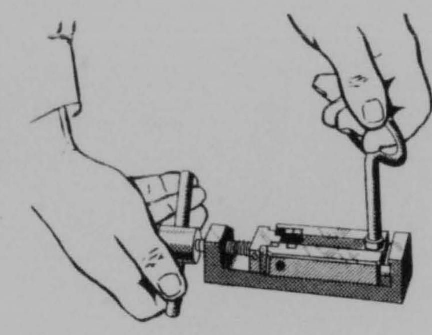

Figure 1—28. Disassembling Sear Block.

Installation of Sear Mechanism. The sear, with sear block, is replaced in the receiver. (The sear buffer spring retaining tool should not be removed.)

The sear buffer steel block is then replaced in the receiver adjacent to the sear block.

7. DISASSEMBLY AND ASSEMBLY

Disassembly of Breechblock

The breechblock lock, and the left and right inertia blocks (Figure 1-11) are removed.

The left breechblock slide is withdrawn in such manner as not to let the breechblock slide spring and guide fly out. The breechblock slide plate assembly is then withdrawn. The breechblock slide key should not be removed except for replacement.

The extractor is pressed against the contractor spring and the extractor pin drifted out. The extractor and extractor spring is withdrawn. The front end of the breechblock is lifted and the firing pin allowed to slide out through the rear. (The firing pin must not be dropped.)

Assembly of Breechblock

The firing pin is inserted in the bore of the breechblock, sliding it forward to a position

THIS PAGE IS DECLASSIFIED IAW EO 13526

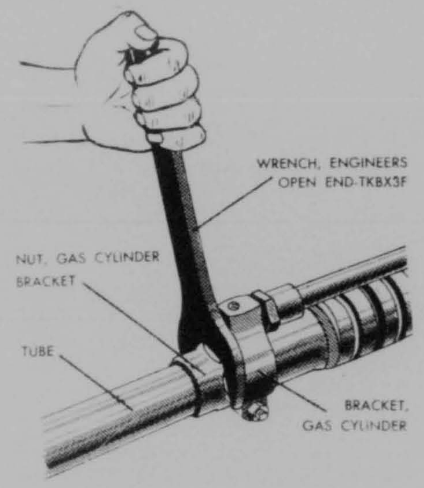

Figure 1–29. Removing Gas Cylinder Bracket Nut.

where the slot in the firing pin aligns with the recess of the breechblock slide key.

The extractor spring and extractor is installed and secured with the extractor pin.

The right-hand breechblock slide assembly is installed so that the slide key engages the slot in the firing pin. The left-hand breechblock slide is then put into place.

One breechblock slide spring is mounted on the guide. The rear end of the spring (and guide) is positioned in the hole of the breechblock pin, and the plunger and spring forced against the pin and sideways into the slide until the ball on the guide is in circular seat position in the slide. The second spring and guide are similarly installed.

The inertia blocks are then placed in position.

Disassembly of Sear Mechanism

The sear is detached from the sear block by withdrawing the sear pin.

The sear block is placed in the sear block assembling tool so that the radial bearing surface of the sear block contacts the jaw of the tool, while the plungers which protrude from the sear block engage the hook-shaped projection at the front of the tool (Figure 1-28). The sear buffer spring retaining tool should enter the hole in the sear block assembling tool.

The handle of the sear block assembling tool is turned sufficiently to take the tension off the sear buffer spring retaining tool. The retaining tool is removed and the handle of the tool is gradually turned to release the tension of the springs. The plungers and springs are removed. If the special sear block assembling tool is not available, an ordinary vise will serve. If the retaining tool is not available, a slightly tapered steel rod, which nearly fills the hole, may be used.

Parts of the sear mechanism are shown in Figure 1-12.

Assembly of Sear Mechanism

The sear buffer springs are inserted in their recesses in the sear block and the plungers replaced with their hollow ends against the springs.

The unit on the sear block assembling tool is replaced with the flanged side of the sear block up, and with the radial bearing surface against the jaw of the tool. The springs are compressed until the sear buffer spring retaining tool can be inserted to engage the grooves of the plungers.

The handle is loosened and the sear block removed with the retaining tool from the assembling tool.

The sear is attached to the block so that the forked end of the sear is on the same side as the flanged side of the sear block.

8. GAS CYLINDER SLEEVE GROUP

Disassembly

The cotter pin and lock washer are removed from the gas cylinder guide which is then unscrewed (Figure 1-13).

The gas cylinder sleeve spring is removed.

The locking wire from gas cylinder bracket plug and then the gas cylinder lock washer are removed. The gas cylinder bracket plug is then unscrewed.

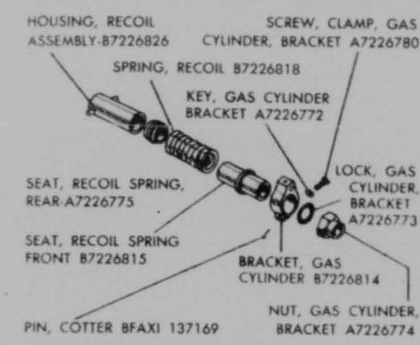

Figure 1—30. Parts of Recoil Group.

The gas cylinder lock plate is removed and the gas cylinder vent plug is unscrewed.

The gas cylinder is pushed to the rear and the gas cylinder removed with the sleeve.

The gas cylinder sleeve push rods are then withdrawn.

Assembly (Figure 1-13)

The gas cylinder sleeve push rods are inserted into their recesses in the receiver.

The gas cylinder is attached to the gas cylinder piston on the sleeve, the unit is positioned on the gun tube and slipped forward so that the gas cylinder fits in the opening in the gas cylinder bracket.

The gas cylinder vent plug is screwed in and the gas cylinder lock plate replaced.

The gas cylinder bracket plug is screwed in; the gas cylinder lock washer is replaced and secured with locking wire.

The gas cylinder sleeve spring is replaced.

The gas cylinder guide is screwed in, the lock washer is replaced and secured with the cotter pin.

9. RECOIL GROUP

Disassembly

The gas cylinder sleeve group and trunnion blocks are removed.

The cotter pin is extracted and the gas cylinder bracket clamp screw nut backed off several turns.

The tab of the gas cylinder bracket lock is straightened and the gas cylinder bracket nut is unscrewed (Figure 1-29). (It will be noted that the helical recoil spring is decompressed slowly as the nut is backed off.) The bracket nut should not be removed without first loosening the bracket clamp screw (Figure 1-30). (To do so would be dangerous, as the bracket would be thrown off with considerable force by the recoil spring.)

The screw, key, and nut are removed from the gas cylinder bracket.

The bracket, front recoil spring seat, recoil spring, rear recoil spring seat, and the recoil housing assembly are slipped from the tube.

Assembly

The recoil housing assembly, rear recoil spring seat, recoil spring and front recoil spring seat are installed over the tube in the order given.

The bore of the gas cylinder bracket and also its bearing surface on the tube are cleaned. The bracket on the tube is positioned with the side nearest the vent plug opening toward the muzzle of the gun.

The key is positioned in the slot at the bottom of the bracket and aligned with the keyway in the tube. The clamp screw and nut are installed and tightened lightly to hold clamp screw assembly in place.

A new bracket lock is installed with the tang located in keyway of the tube.

The front spring is positioned to have the flat directly on top (Figure 1-14). (This allows clearance for the gas cylinder hex head.)

The bracket nut is installed and tightened until the gas cylinder bracket is seated against the tube shoulder. The nut must be drawn up snug and secured by bending an edge of the bracket lock down over one flat of the nut.

Trunnions of the ring spring housing are positioned in a horizontal position. The nut is tightened on the clamp screw and the cotter pin installed.

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION III—CYCLE OF OPERATION

1. OPERATION UNDER NORMAL CONDITIONS

Hand Loading of Belts for Feed Mechanism AN-M2

General. Belts for the 20-mm feed mechanism AN-M2 must be made up of 20-mm metallic belt links M7 or M8 only. No special end link is required.

All links must be inspected for rust, dirt, or deformation. All links are dipped in preservative lubricating oil (special) and the excess oil drained off just before using. A clean cloth is dipped in the special oil and wrung out; this is used to oil the cartridge cases, avoiding the joint where the case is crimped to the projectile.

For right-hand feed. The links are laid along a belting board with their open sides up, single loops to the right, and single loops positioned between the double loops (Figure 1-31).

The rounds are inserted into the loops and pushed forward.

The position of the cartridges relative to the links is checked. (The distance from the base of the cartridge case to the rear edge of the double loop should be 2 9/32 inches plus or minus 1/16 inch.)

The belt is tested for flexibility by lifting the left-end loop and drawing it along the top of the belt to the right. Any faulty link will cause the belt to kink instead of folding over smoothly. Any link which does not hinge freely must be replaced by another and the test repeated.

The above test is repeated, starting with the right-end loop and drawing it to the left. If a stiff link is found, it must be replaced by another and both right-end and left-end tests repeated.

The belt is tested for oversize links by suspending it from one end and twisting the lowest link until resistance is felt. If the belt breaks, the faulty link must be replaced by another and the tests repeated.

For left-hand feed. The procedure is the same as directed for right-hand feed but the links are placed on the belting board with their single loops to the left (Figure 1-32).

Joining of belts. The round is removed from the last double loop of one of the belts.

The empty single loop of the second belt is joined to the empty double loop of the first belt by inserting a round.

The position of the newly inserted round and the flexibility of the newly formed belt is then checked.

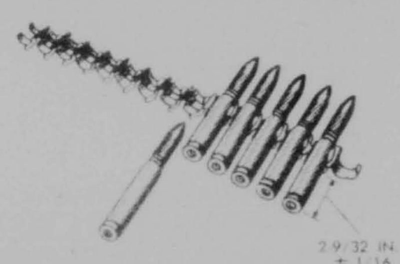

Figure 1—31. Hand Loading of 20-mm Links M8 for 20-mm Feed Mechanism AN-M2 (Right-Hand).

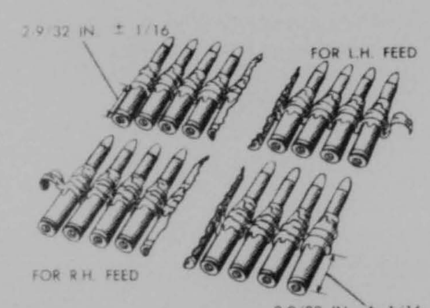

Figure 1—32. Loaded Belts (M8 Links) for 20-mm Feed Mechanism AN-M2 (Right and Left-Hand).

The position of the cartridges relative to the links is checked. (The distance from the base of the cartridge case to the rear edge of the double loop must be 2 5/16 inches plus or minus 1/16 inch.)

Note: The leading double loop must have a round; the single closed end loop must be empty.

The belt is then tested for flexibility and for oversize links.

Hand Loading of Belts for Feed Mechanism M3

General. Belts for the 20-mm feed mechanism M3 can be made up of 20-mm metallic belt links M3, M3A1, M7, or M8. A special end link is employed as the trailing link of the belt. (The use of different types of links in the same belt is prohibited.)

The links and rounds are then inspected and oiled.

For right-hand feed. The links are laid along a belting board with their open sides up, double loops to the right, and single loops positioned between the double loops. The last link on the left end must be of the special type with the closed loop (Figure 1-33).

The rounds are inserted into the loops and pushed forward.

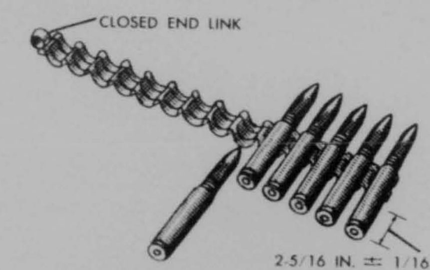

Figure 1—33. Loading 20-mm Belt Links M3 for 20-mm Feed Mechanism M3 (Right-Hand).

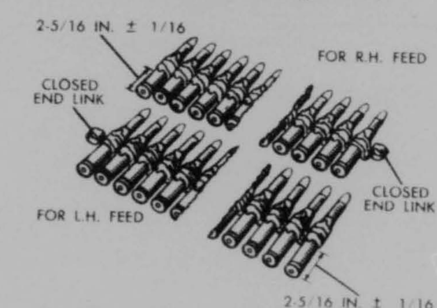

Figure 1—34. Loaded Belts (M7 Links) for 20-mm Feed Mechanism M3 (Right-Hand and Left-Hand).

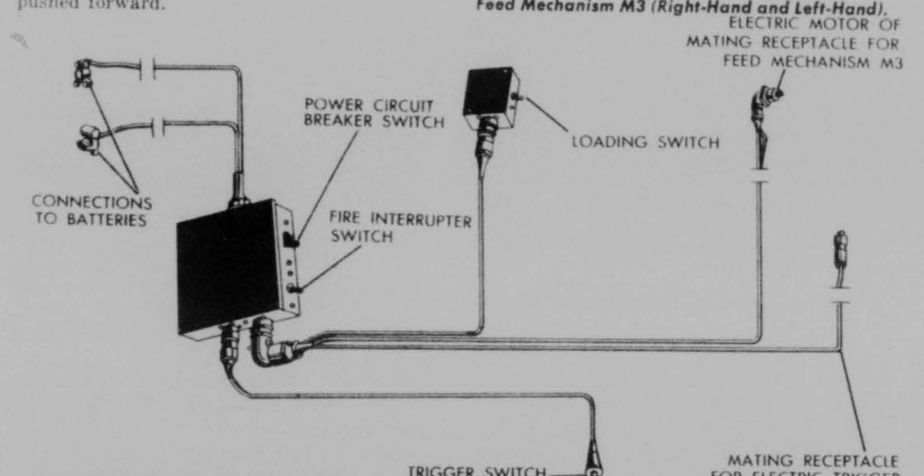

Figure 1—35. Controls for Firing of Gun Equipped with 20-mm Feed Mechanism M3.

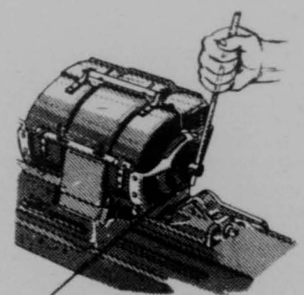

DRIVE SPRING RELEASE SHAFT PUSH SHAFT IN ABOUT 3/16 INCHES WHEN UNWINDING DRIVE SPRING

Figure 1—36. Unloading the Gun (Using 20-mm Feed Mechanism AN-M2).

For left-hand feed. Procedure is the same as directed for right-hand feed, but the links with double loops are placed to the left, and the special end link on the right (Figures 1-33 and 1-34).

Joining of belts. The round and the special end link are removed from the end of one belt, and the round from the first double loop of the second belt.

The two belts are joined by means of a round and the position checked.

If the new belt does not have a special end link, the special end link is joined to the new belt by means of a round. Position of round is then checked.

2. FIRING OF GUN

Using 20-mm Feed Mechanism AN-M2

The firing switch is closed to fire the gun. To cease firing, the firing switch is released.

Using 20-mm Feed Mechanism M3

The fire interrupter switch is moved to "fire" position and the trigger switch is closed (Figure 1-35). To cease firing, the firing switch is released and the fire interrupter switch moved to the "safe" position.

Correction of Stoppages in Combat Firing. The design of the gun and its location outside the reach of the gunner usually make it impossible to remedy stoppages during combat firing.

When a stoppage occurs during combat firing, the gun should be recharged immediately. If the gun cannot be recharged, no corrective action is possible.

3. UNLOADING GUN

Using 20-mm Feed Mechanism AN-M2

The selector switch must be in the "off" position.

If the belt of ammunition has been completely expended, the feed and link chutes are disconnected from the feed mechanism, the magazine slide cover is raised, and the mechanism lifted off the gun.

If the belt of ammunition has not been completely expended, the drive spring release shaft is pushed in about $\frac{3}{16}$ inch and, at the same time, the shaft is turned for about three-quarters of a turn in the direction opposite to that of feeding (Figure 1-36). This will completely unwind the drive spring. The belt is pulled from the feed mechanism. The feed and link chutes are disconnected from the feed mechanism, the magazine slide lever is raised, and the mechanism lifted off the gun.

Note: If there is a round in the mouth of the magazine, it is removed by being pushed forward carefully.

Using 20-mm Feed Mechanism M3

The fire interrupter switch is moved to the "safe" position and the power circuit breaker switch to the "off" position (Figure 1-35). The electrical receptacles are disconnected at the feed mechanism.

The feed and link chutes are disconnected from the feed mechanism, the slide latch lever is rotated upward, the rear end of mechanism is disengaged from the feed slide, and the mechanism lifted off the gun.

The cover locking pins are pulled out as far as they will go, the stripper cover is raised, and the belt removed.

Note: If there is a round in the mouth of the magazine, it must be removed by pushing it forward carefully.

4. OPERATION UNDER UNUSUAL CONDITIONS

General

Because of the different climatic and temperature conditions in which this materiel may be expected to operate, special instructions are given in this section. These instructions must be carefully observed.

5. EXTREMELY HIGH TEMPERATURES

Lubrication

The gun is lubricated as directed in section IV. Extremely high temperatures require more frequent lubrication.

Inspection and Care

Materiel should be inspected frequently when being operated in hot, moist areas. Items which may deteriorate from mildew, or which may be attacked by insects or vermin should be aired or dried frequently.

Ammunition should be kept out of the direct rays of the sun. Moisture-resistant seals should not be broken until ammunition is to be used.

6. SUBZERO TEMPERATURES

In temperatures which are below the freezing point, it is essential that all moving parts be kept absolutely free of moisture. Excess oil on the working parts will solidify to such an extent as to cause sluggish operation or complete failure. Extreme cleanliness is essential; oil must be applied sparingly.

When a gun is brought into a heated shop, condensation will occur on the metal surfaces. After the gun has reached shop temperature, all parts must be wiped dry and recoated with oil to prevent rusting.

In applying oil to the bore after cleaning, care must be taken to work the oil in well so that it will reach all surfaces of the lands and grooves.

The breechblock parts are cleaned with rifle-bore cleaner; oil is applied by wiping the rubbing surfaces with a clean cloth which has been wet with the oil and wrung out.

When materiel is protected by canvas or other type of cover, moisture will form on the metal surfaces. To prevent rusting, the cover must be removed at least once each week, and all surfaces thoroughly dried. Where necessary, parts should be reoiled.

7. EXCESSIVELY MOIST OR SALTY ATMOSPHERE

When the materiel is active, exposed metal surfaces, such as the gun, breechblock, and cradle surfaces, should be oiled more frequently, as water will emulsify with oil and destroy its rust-preventive qualities. Parts should be inspected frequently for corrosion.

Preservative lubricating oil (medium) is used in lieu of lubricating oil (special).

The bore of the tube and the breechblock should be kept heavily oiled and should be inspected frequently for rust. The bore should be wiped clean before flight when firing is contemplated.

8. EXCESSIVELY SANDY OR DUSTY CONDITIONS

When the gun is active in dusty or sandy areas, the gun must be inspected and wiped clean every day, or oftener if necessary. Groups should be removed to facilitate thorough cleaning.

Lubrication should be kept to a minimum as oil collects dust which will act as an abrasive and may foul the bore and chamber. Preservative lubricating oil (special) should be applied lightly to working parts.

The breech and muzzle should be covered when practicable.

9. CYCLIC FUNCTIONING OF WEAPON

General

The cyclic functioning of the weapon as a whole, from the firing of one round to the next, is described in the following paragraphs. For purposes of explanation, the

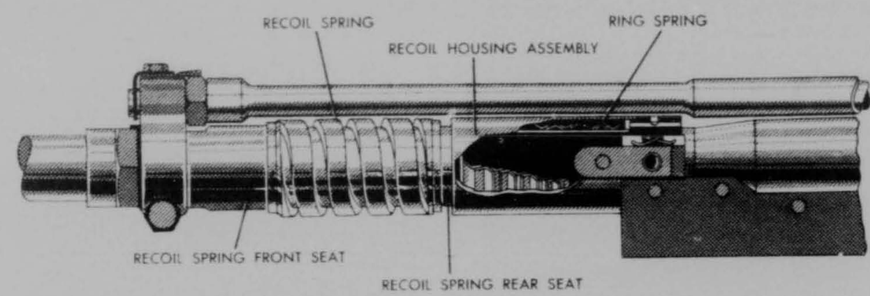

Figure 1—37. Action of Recoil Spring and Ring Spring.

cyclic functioning is divided into the following actions:

- Recoil action.
- Breechblock unblocking action.
- Extraction and ejection.
- Rear buffer and driving spring action.
- Cocking action.
- Feeding and chambering.
- Breechblock locking action.
- Firing action.

Recoil Action (Figure 1-37)

When the round is fired, the pressure of the propellent gases in the tube forces the gun to recoil to the rear for about one inch. As the gun recoils, the recoil spring front seat and the gun tube move to the rear and compress the recoil spring. Since the compression of the ring spring in the recoil housing assembly is greater than the final force of the recoil spring, the recoil spring alone, during this phase of the recoil, will offer resistance to the rearward movement of the gun. This action will continue until the gun has recoiled for about [illegible] inch. At this point, the rear end of the recoil-spring front seat contacts the front end of the recoil spring rear seat, thus stopping the compression of the recoil spring. While the recoil spring rear seat begins to compress the ring spring of the recoil housing assembly which absorbs the remaining shock of recoil, the recoil spring begins to recover. The recovery of the recoil spring returns the gun into battery.

The ring spring of the recoil housing assembly will act as a counterrecoil buffer if the gun should travel past its battery position.

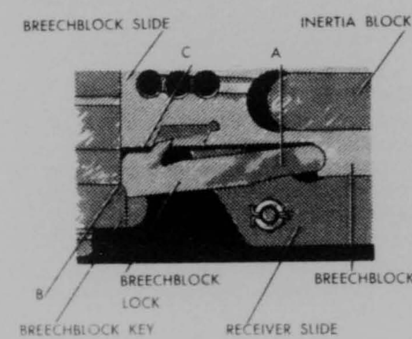

Figure 1—38. Breechblock Lock in Locked Position at Moment of Firing.

The ring springs will be compressed in the same manner as during recoil movement of the gun, but the action of the parts will be reversed.

Breechblock Unlocking Action

The breech is unblocked by the action of the gas cylinder sleeve group. At the moment of firing, the breechblock is held in its forward position by the action of the breechblock lock. The lock engages the breechblock at point A (Figure 1-38) and bears against surface B of the breechblock key. The breechblock slide engages the lock at point C, thus preventing the lock from being forced upward prematurely.

As the round is fired, the projectile is driven forward in the tube, passing the gas port (Figure 1-39). A portion of the expand-

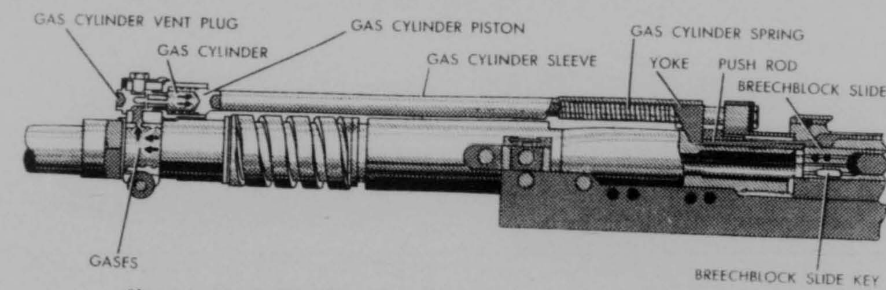

Figure 1—39. Action of Gas Cylinder Sleeve Group for Unlocking the Breech.

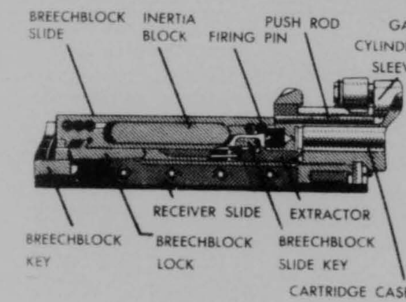

Figure 1—40. Unlocking of Breechblock and Retraction of Firing Pin.

ing gases enters the gas port and passes through the gas cylinder vent plug into the gas cylinder (Figure 1-39). As the gas expands against the gas cylinder piston, it forces the piston and the gas cylinder sleeve (integral with it) to the rear, compressing the gas cylinder spring.

As the sleeve is forced to the rear, the yoke on the sleeve contacts the two push rods which, in turn, move the breechblock slides rearward to unlock the breechblock (Figure 1-40). The slides are connected to the slide key which engages a slot in the bottom of the firing pin. As the slides are forced rearward by the push rods, the key retracts the firing pin. The moment the breechblock is unlocked, it is forced to the rear by blowback action with a resultant drop of gas pressure in the tube. As the gas pressure drops, the gas cylinder sleeve spring expands, returning the sleeve and piston to the original position.

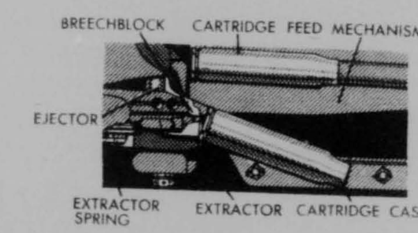

Figure 1—41. Ejection of Cartridge Case.

Extraction and Ejection

When the breechblock assembly is forced to the rear, the empty cartridge case, which has been forcing the bolt back by blowback action, is contacted on the upper edge by the two prongs of the ejector (Figure 1-41), causing the cartridge case to pivot about and forcing down the forward end of the extractor. The cartridge case leaves the lip of the extractor and moves through an opening in the bottom of the receiver, completing the ejection of the empty cartridge case. When the cartridge case frees itself from the extractor, the extractor is returned to its normal position by the action of the extractor spring.

Rear Buffer and Driving Spring Action

As the breechblock is driven rearward, it compresses the driving spring. When the breechblock nears the end of its rearward movement, it strikes the rear buffer washer

THIS PAGE IS DECLASSIFIED IAW EO 13526

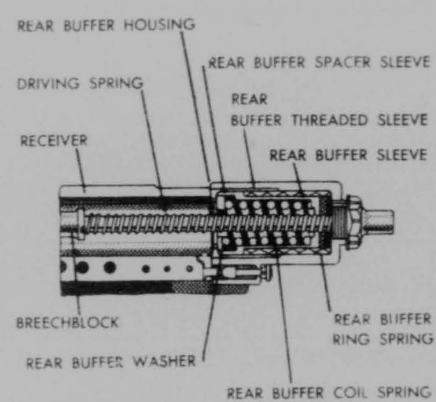

Figure 1—42. Rear Buffer Cross Section.

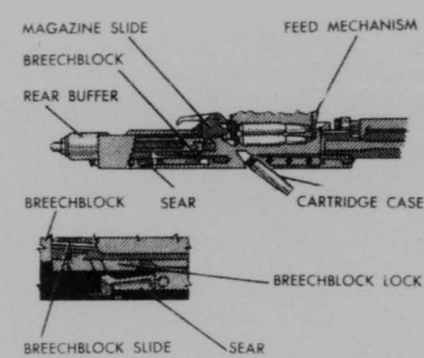

Figure 1—43. Action of Sear During Recoil of Breechblock.

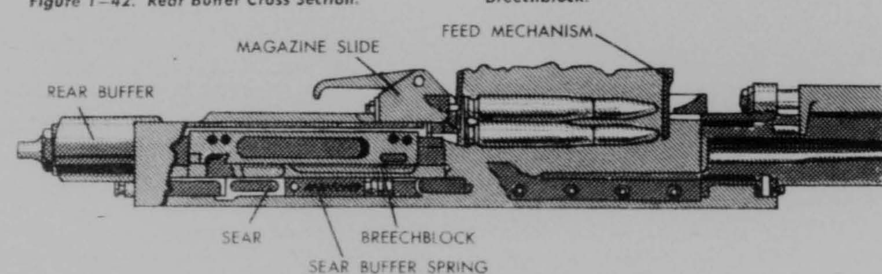

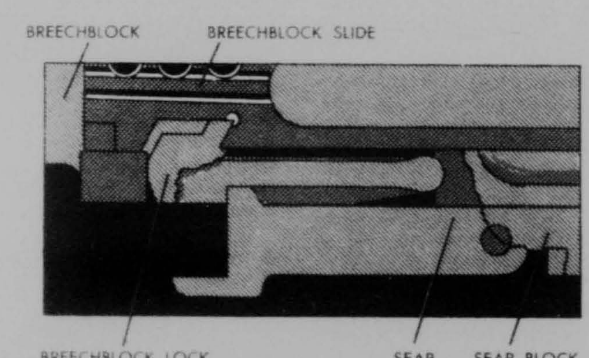

Figure 1—44. Engagement of Sear and Breechblock During Counterrecoil of Breechblock.

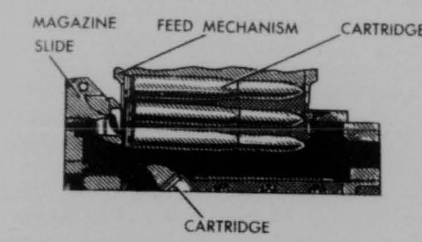

Figure 1—45. New Round Being Forced Downward Into Mouth of Feed Mechanism.

which transmits the shock of recoil to the buffer springs which absorb the remaining force of recoil and bring the breechblock to a stop (Figure 1-42). As the breechblock comes to a stop, the inertia blocks continue to move rearward in their slots in the breechblock slide until they reach the end of the slots. By this time the breechblock has started forward again, and the inertia blocks remain in a rearward position with respect to the breechblock slides during the forward motion of the breechblock. The rear buffer springs and the driving spring expand, forcing the breechblock forward.

Cocking Action

As the breechblock is forced to the rear by blowback, it passes over and depresses the sear (Figure 1-43), then, when the breechblock starts forward, and the sear is released, the sear will engage the breechblock lock and hold the breechblock in the rear position (Figure 1-44). The shock produced when the sear and breechblock engage is absorbed by the sear buffer springs and the sear buffer plates. If the sear is held down by actuating the trigger, the breechblock will move forward into the locked position under the force of the driving spring.

Feeding and Chambering
(Figures 1-45 and 1-46)

When the recoiling breechblock is sufficiently far to the rear to clear the feed mechanism, a new round is forced downward into the mouth of the feed mechanism. As the breechblock is forced forward by the driving

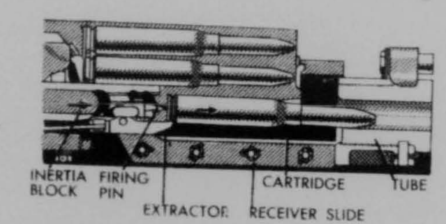

Figure 1—46. Ramming of a Round.

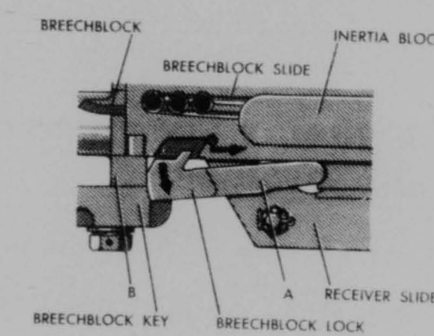

Figure 1—47. Breechblock in Locked Position.

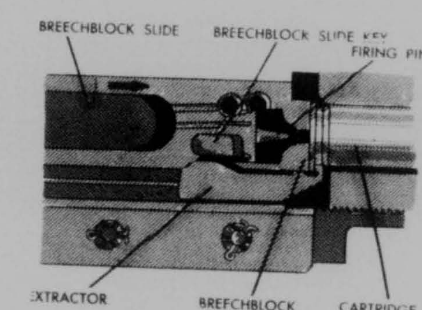

Figure 1—48. Firing Pin Moving to Fire Round.

spring, it engages the new cartridge which has been positioned in the mouth of the feed mechanism. As the cartridge is forced forward, it drops into the recess in the bolt where it is gripped by the lip of the extractor as it enters the chamber.

Breechblock Locking Action

As the breechblock reaches the end of its forward motion (Figure 1-47), it seats against the end of the tube, closing the chamber. The momentum of the slides and the action of the slide springs cause the slides to continue to move forward, releasing the breechblock lock. At the same time, projecting cams of the lock (A, Figure 1-47) are engaged by cam surfaces on the receiver slides which, together with the action of the cams on the bevel of the lock, cam the lock downward. The lock seats against the breechblock key and is locked in its downward position by the lower surface of the breechblock slides which move over the rear end of the lock.

Firing Action (Figure 1-48)

As the slides approach the end of their forward motion, the firing pin is carried forward by the slide key and the driving spring to fire the round. When the slides have reached the end of their forward motion, the inertia blocks continue to move forward for a short distance, striking against the forward end of the slot, thereby counteracting any rebound tendency of the slides or pin.

SECTION IV—INSPECTION, MAINTENANCE AND CLEANING

SPRING SPECIFICATIONS

	Free length (inches)	Allowable free length (inches)
Gun:		
Breechblock slide spring	2.87	2.58
Driving spring	26.5	23.5
Ejector spring	1.89	1.70
Gas cylinder sleeve spring	5.60	5.04
Magazine latch spring	2.83	2.54
Sear buffer spring	1.89	1.70
Feed mechanism M3:		
Operating lever springs	1.218	1.09
Round retaining finger spring	1.187	1.06
Pneumatic charger M4:		
Piston return spring	26	23.4
Head return spring	8.75	7.87
Manual charger M6:		
Slide return spring	14	12
Spring (for latch locking ball)	.406	.366
Hydraulic charger M7:		
Piston return inner spring	22.5	20

Sear return spring	.92	.83
Electric trigger AN-M4:		
Solenoid spring	1.156	1.04

Figure 1—49. Spring Specifications.

1. OPERATIONAL INSPECTION

The following general points should be carefully noted in the inspection of the materiel:

All operating mechanisms are inspected for ease of operation, backlash and sufficient lubrication.

At least every six months a check-up should be made to insure that all modifications have been applied. (A list of current modification work orders is published in FM 21-6, the final edition of which is dated 1 January 1949. Future listings and index of DA publications will be published in the 310-20 series of special regulations. If a modification has not been applied, the local ordnance officer must be notified promptly. No alteration or modification which will affect the moving parts should be made by the using personnel, except as authorized by the Ordnance Department.)

Safety features are inspected to determine proper functioning. Lettering on name plates and direction plates of feed mechanisms should be checked to determine that they are legible.

Weapon covers are inspected.

ORGANIZATIONAL MAINTENANCE SCHEDULE

A. DAILY.

Point	Preventive maintenance
Bore	Check for rust and/or fouling.
Gun	Check for rust and cleanliness.
Feed mechanism	Check for rust and cleanliness.
Chargers	Check for rust and cleanliness.

B. BEFORE FIRING.

Point	Preventive maintenance
Barrel and receiver	Clean and oil
Feed mechanism AN-M2.	Lubricate
Feed mechanism M3.	Lubricate
Magazine slide (feed mechanism AN-M2).	Dynamic torque test. Check alinement of engraved lines on slide and receiver. Check operation of latch.
Feed mechanism	Clean and lubricate. Inspect
Trigger	Inspect and check operation.
Heater	Clean and check operation.

Point	Preventive maintenance
Feed slide (feed mechanism M3).	Check alinement of engraved lines on slide and receiver.
Magazine slide anchors.	Check for tightness of nuts.
Trigger	Check for operation
Charger	Check for operation
	Lubricate (manual charger M6).
Heater	Check for operation

C. AFTER FIRING.

Point	Preventive maintenance
Breechblock	Remove, disassemble, clean, and oil.
Bore	Clean.
Gas cylinder and sleeve group.	Clean and inspect
Gun in general	Inspect for broken and loose parts, proper adjustments, etc.
Charger	Check for operation.
Flash hider	Check for tightness.

Figure 1—50. Organizational Maintenance Schedule.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Accessories, tools, spare parts, and equipment are inspected for completeness and serviceability.

The weapon should be checked for damage or deterioration of paint.

Whenever the items are disassembled, all springs listed below are inspected for free length, kinds, and breaks. Springs which are broken or kinked, or whose free length is less than the allowable, are replaced. (See Figure 1-49.)

2. COMMON PREVENTIVE MAINTENANCE PROCEDURES

The general preventive maintenance outlined below must be observed in addition to that referred to in the schedules listed in Figure 1-50.

Assemblies containing ring springs must not be dipped of washed in dry-cleaning solvent. (These units are lubricated by the manufacturer and if this special lubricant is diluted with cleaning solvent, early failure of the unit will result.)

Rust, dirt, grit, gummed oil, and water cause rapid deterioration of internal mechanism and outer unpainted surfaces. Particular care should be taken to keep all bearing and sliding surfaces clean and properly lubricated. All traces of rust should be removed with crocus cloth.

Loose parts are tightened; broken parts must be replaced; lock washers, safety wire, cotter pins, and other locking devices should be properly applied.

Most of the parts on this weapon are finished by the Parco-Lubrite process. The resistance of this type of finish to corrosion is greatly enhanced by the application of a light coat of oil. Accordingly, a light coat of oil is maintained on all "Parto-Lubrited" parts.

Only those tools which are provided should be used, and they must fit snugly on parts. Tools which do not fit will fail or cause damage to parts. Accessories, tools, and spare parts must be inspected for serviceability. Missing or damaged items are replaced or turned in for repair.

3. ORGANIZATIONAL MAINTENANCE SERVICE

The items or points to be inspected and serviced at scheduled times are listed in Figure 1-50.

4. GENERAL ORDNANCE MAINTENANCE

Inspection and Testing

Every gun received by ordnance maintenance personnel for rebuilding must be thoroughly and completely inspected, put into the best condition possible with the allowable time, materials and technical circumstances. They are then returned to the using arm ready for immediate use.

The general appearance should be noted, a check made for rust formation, missing bolts, nuts, locking devices, and wires. A visual inspection is made for cracks, breaks, or deformed parts. The cradle mounting plate is checked by lifting the gun while it is still in the cradle. Anchor support brackets are inspected for proper tension of screws.

The bolt is cocked and the electric trigger connected to a 24-volt direct current power supply. The sear action should be instantaneous. If the sear is not tripped, and it is known that the solenoid was energized, the solenoid is removed and the amount of effort required to trip the sear is determined. (This should not require more than fifty pounds.) The locking surfaces of both the sear and the breechblock are inspected for scores, mutilation, or a defective sear plunger and spring which would cause excessive firing effort.

With the bolt and rear buffer removed, the bore is cleaned and the rifling examined. (Excessive wear, serious erosion, or deformation of the tube would be cause for its rejection.)

The chamber is examined for scores and burrs. Failure to extract and eject the cartridge properly can be caused by a scored chamber or a faulty extractor. The average life of a tube under favorable conditions is approximately 5,000 to 6,000 rounds. With the bolt retracted, the breechblock locking key and receiver slides are inspected. The key

THREAD SIZES OF PARTS

Item	Ordnance No.	Pitch
Anchor, magazine slide	B7226812	5/16-24NF-2.
Bracket, gas cylinder	B7226814	10-mm—1.5-mm Int. Form.
Bracket, mounting	C7226810	3/8-16NC-2.
Cylinder, gas	B163311	14-mm—1.5-mm Int. Form.
Guide, gas cylinder	A25582	20-mm—1.5-mm Int. Form.
Head, driving spring guide	B7231159	
Outer end		5/8-18NF-2.
Inner end		25-mm—1.5-mm Int. Form.
Key, breechblock locking	B7226047	3/8-24NF-3.
Plug, gas cylinder bracket	B163320	10-mm—1.5-mm Int. Form.
Plug, gas cylinder vent	B7229626	14-mm—1.5-mm Int. Form.
Receiver	D7226842	
Hole to receive tube		52-mm—2.5-mm Int. Form.
Hole for gas cylinder sleeve guide		20-mm—1.5-mm Int. Form.
Holes for securing M6 manual charger		0.190 (No. 10)-32NF-2.
Holes to attach M1 heater		0.190 (No. 10)-32NF-3.
Holes for attaching operating lever bracket of AN-M2 feed mechanism		5/16-24NF-2.
Holes to attach electric trigger		7-mm—1-mm Int. Form.
Slide, magazine	C70497	7-mm—1-mm Int. Form.

Figure 1—51. Thread Sizes of Parts.

must not be loose or show signs of any mutilation. Excessive wear on the key will result in more than the allowable headspace between the cartridge case and the face of the breechblock. Loose or scored receiver slides will cause binding of the bolt action and reduce the firing speed of the gun.

With the breechblock in its forward position, a feeler gauge is used to check the clearance between the push rods and gas cylinder sleeve yoke. The clearance should not be more than 0.042 inch and should check the same on both sides within 0.003 inch. If greater difference is found, a sprung yoke on the gas cylinder sleeve, mushroomed push rods, or defective breechblock slides are indicated. These conditions must be remedied, or a binding action may develop in the bolt. The gas cylinder sleeve is inspected for straightness. A bent sleeve will cause an apparent difference in the length of the push rods.

The slide is checked to determine ease of operation. The ejector is inspected for wear. (Worn or damaged ejectors will cause rounds to position improperly in the feed mouth. Cartridge cases will not eject properly if the ejector is loose or out of position in the magazine slide.) The action of the magazine slide latch and lever assembly is tested to see that it operates smoothly with a positive action.

The cradle must be examined for damaged or loose brackets. (Any play in screws or rivets in this member will soon develop into a serious condition.) Trunnion blocks must be secure on the mounting brackets. (Any play between blocks and the trunnions will necessitate replacement of the worn part.)

The adapter assembly is inspected visually. Dry-cleaning solvent or vapor degreasing methods must not be used on the gun adapter. A check is made for broken recoil springs or damaged parts. The condition of the trunnion on either side of the recoil housing is inspected.

If the gun is equipped with the feed mechanism M3, the loading switch is closed and the action of the feed mechanism observed. The stripper cover is raised and the feed wheels, link stripper and loading levers inspected for wear or damage. The tension of the loading lever springs is checked. The feed mechanism AN-M2 should be inspected in a similar manner, except that it cannot be operated without having rounds in place. The condition of the

THIS PAGE IS DECLASSIFIED IAW EO 13526

stripper cams and link chute is inspected. The tightness of screws holding the operating lever brackets to the cradle is checked and the operating link assembly examined for missing cotter pins or loose nuts.

The current supply is turned on and the heating elements tested. The wiring connections and terminals are inspected.

The charger is tested to determine if all connections are tight. (Loose connections will prevent chargers from operating correctly.)

A report should be made to the responsible officer concerning any pertinent carelessness or negligence in the preventive maintenance procedures and safety precautions. This report should be accompanied by recommendations for correcting the unsatisfactory conditions.

5. COMMON ORDNANCE MAINTENANCE PROCEDURES

General

The general procedures given below should be followed during repair and rebuild operations:

Subassemblies and groups are assembled before mounting them on the gun. As a part of all assembly and mounting operations, the thread, slide surfaces, and mating parts are cleaned and lubricated.

When assembling the gun, new cotter pins, locking plates, and locking wire are used, and tied or fastened in an approved manner. In checking for cracks, it is recommended that magnaflux equipment be employed if available.

All burrs are removed from sliding surfaces with a fine oil stone and the surfaces polished with crocus cloth. All abrasive is washed off with dry-cleaning solvent.

All burrs are removed from threads by chasing with the proper size of taps or dies if available. (Most threads on this gun are metric sizes.) Following is a list of thread sizes of parts which may require cleaning: (See Figure 1-51).

Function Testing

The gun is placed in a suitable fixture, fastened securely, and properly lubricated. The bolt, when cocked, should retract properly with the charger mounted in either the right- or left-hand position. The electric trigger is connected to a suitable source of 24-volt direct current power to test the action of the breechblock and sear. The bolt should go forward to battery position and lock. Any malfunction observed would be due to improperly fitted breechblock components or a faulty electric trigger; therefore, the "dry-firing" test is of utmost importance. The position of the magazine slide on the receiver is checked by observing scribe lines. The anchor rod is adjusted so as to have the center pair of scribed lines coincide. This adjustment is very important. Be sure adjusting nuts and lock nuts on the anchor are tightly secured after alignment is attained.

A feed mechanism is then installed on the gun. If the AN-M2 type is to be used, a belt is made up of dummy rounds. The feed chute adapter and ammunition chute are installed with the feed mechanism. The belt is inserted into the feed mouth with an empty, single-loop leading. The feed mechanism spring is wound the full amount by turning the main drive shaft from the front end and using a wrench on the hex end. This action draws the rounds down into the feed pawls and stops the first round in contact with the top of the bolt. The bolt is operated several times with a charger to test the action of the stripper cams, cartridge pawls, and positioning of rounds in the feed mouth. During this operation sufficient tension must be kept on the feed spring to stimulate actual gun operation. The action of ejector and extractor at this point should be noted.

Feed mechanism M3 is installed on the gun, a belt is made up of dummy rounds. The stripper cover is lifted and a belt of rounds started into the feed wheel. The stripper cover is closed and secured with the pins. The feed mechanism motor is connected to a 24-volt direct current power supply and the bolt operated with a charger to test the stripping and feeding action.

Note: Many malfunctions and jams of the gun and feed mechanism can be caused by faulty or misformed links.

Function Firing

In order to function-fire this weapon a sufficiently sturdy stand must be available to mount the gun. An opening must be situated within the top of the stand, large enough to permit empty cartridges to be ejected. The cradle is fastened securely to this stand in four places. The gun and stand is positioned so as to have projectiles hit in a pit or bank. The bore and chamber are cleaned and all assemblies are checked to see that they are properly adjusted and secured.

When function-firing a gun equipped with a feed mechanism AN-M2, a belt is made up of 25 or 30 M1 ball or T24 practice cartridges. By hanging the belt of approximately thirty rounds from the feed mouth, a suitable drag will be developed which will determine the condition of the driving mechanism spring assembly until the clutch slips. The end of the belt is inserted into the feed mouth and the driving mechanism assembly wound until the clutch slips. The feed operating lever is positioned in the bracket on the receiver and a check made to see that the latch is holding the lever in place. The gun is charged and when the charging lug has returned to the forward position, a short burst is fired to see that the gun recoils properly, ejects cartridges properly, and strips links without jamming. A burst of ten or fifteen rounds is fired to test for any similar malfunction. The rate of fire should not be below 650 rounds per minute. The remaining ammunition is fired in short bursts to test the driving mechanism winding assembly. In case of a jam, no attempt should be made to remove the feed mechanism without unwinding the main drive shaft spring.

When function-firing a gun equipped with a feed mechanism M3, a belt is made up of twenty-five or thirty M1 ball or T24 practice cartridges. Alignment marks on receiver and magazine slide should be rechecked. The stripper cover is raised, the first round is inserted between the feed-wheel fingers, the cover is closed and secured with the locking pins. The bolt should be in a forward position. The feed motor is connected to an electrical power source to feed the ammunition belt into the mechanism until the first round rests on top of the breechblock. The bolt is drawn back with the charger and sufficient time is allowed for the charging lug to return to its free position. A few short bursts are fired to test the trigger action and recoil actions, noting particularly whether links and cartridge cases drop free of the gun. A burst of ten or fifteen rounds is fired while watching the feed mechanism closely to determine any malfunction or slipping. If lag occurs, feed wheel clutch tension must be checked and tightened if found lower than 180 inch-pounds. Firing is continued to exhaust all rounds in the feed mechanism. The rear buffer should be checked carefully while function-firing tests are in progress. The buffer housing will heat up if the springs are broken. The inside of the buffer housing should be checked for pieces of loose metal which indicate broken springs or sleeves.

In the event a "dud" is encountered, it is extracted from the gun with the charger and the primer is examined. Light-struck primers denote a faulty firing pin, a broken or weak driving spring, or a fouled breechblock due to burnt powder or metal chips being built up inside the firing-pin hole. If the indentation in the primer appears deep enough, the round can be considered faulty.

6. CLEANING METHODS

Cleaning

Unless otherwise specified, rifle-bore cleaner should be used to clean or wash all metal parts, whenever partial or total disassembly is undertaken, or when renewing the protective lubricant film on exposed metal surfaces. The use of gasoline is prohibited.

Care must be taken when cleaning internal mechanisms to insure complete removal of all residue or sediment. Necessary wiping should be done with a piece of firm, lintless cloth. Dirt or other foreign matter should not be allowed to get into the lubricant and lubricating openings.

Lubrication

Lubricant should be applied while the parts are being operated by hand to insure proper distribution of lubricant to all moving parts.

THIS PAGE IS DECLASSIFIED IAW EO 13526

LUBRICATION INSTRUCTION

Feed Mechanism AN-M2----

a. Weekly and before firing, clean all accessible parts with a dry cleaning solvent and then wipe with a cloth dampened with preservative lubricating oil (special). If disassembly is undertaken, clean and oil all disassembly parts before assembling.

b. Lubricate the following with a drop of oil:
(1) Front holding cam.
(2) Rear holding cam.
(3) Cartridge control pawl.
(4) Operating crank bracket.
(5) Operating lever.
(6) Joints of link assemblies.
(7) Clutch driven hubs.

Feed mechanism, M3

a. Weekly and before firing clean all accessible parts with dry-cleaning solvent and then wipe with a cloth dampened with preservative lubricating oil (special). If disassembly is undertaken, clean and oil all dissasembied parts before assembling.

b. Lubricate the following with a drop of oil:
(1) Bearing faces of loading levers.
(2) Bearings of operating lever shaft.
(3) Pivotal connection between loading and operating levers.
(4) Bearings of the retaining finger fulcrum.
(5) Bearings of the slide latch.
(6) Oil cup on gear box (3 drops of oil).
(7) Pins of cartridge control pawl and cartridge holding dog.
(8) Balls and sockets of links.
(9) Fronts and rear bearings.
(10) Pivots of cartridge holding cams.

Pneumatic charger, M4 ----

a. Maintenance of the 20mm pneumatic charger M4 consists chiefly of replacement of worn or broken parts and cleaning and oiling daily and after firing.

Hydraulic charger, M7 ----

a. Maintenance of the charger involves mostly the replacement of worn or damaged parts and cleaning and oiling daily and after firing.

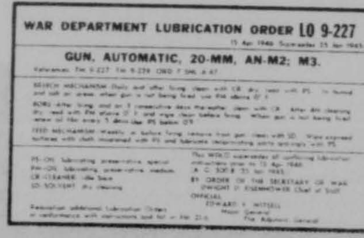
Hydraulic charger, M5 ----

a. Maintenance of the charger consists mainly of replacing worn or broken parts and of cleaning and oiling daily and after firing.

Hydraulic charger, M6 ----

a. Maintenance of the charger involves mostly replacement of worn or broken parts and cleaning and oiling daily and after firing.

Figure 1—51a. Lubrication Instructions.



WAR DEPARTMENT LUBRICATION ORDER LO 9-227

GUN, AUTOMATIC, 20-MM, AN-M2; M3.

Figure 1—52. War Department Lubrication Order LO 9-227.

Because of the extremely low temperatures prevailing at high altitudes, only a thin film of lubricant is applied before flights. At other times, the lubricant may be applied freely but excessive and wasteful practices should be avoided. Excessive lubrication will result in dust accumulations on some moving parts and cause wear and malfunctioning.

7. LUBRICATION ORDER

Reproduction of War Department Lubrication Order LO-9-227 (Figure 1-52) prescribes first- and second-echelon lubrication maintenance. A lubrication order is placed on, or issued with, each item of materiel and is to be carried with it at all times (Figure 1-53). In the event the materiel is received without an order, a replacement is requisitioned in conformance with instructions and lists in FM 21-6.

8. LUBRICATION UNDER NORMAL AND UNUSUAL CONDITIONS

The bore should be cleaned with rifle-bore cleaner after firing and on three consecutive days thereafter. After the fourth cleaning, it is dried, reoiled with preservative lubricating oil (medium) above 0°F. and wiped clean before firing. When the gun is not being fired, the oil film should be renewed every five days, using preservative lubricating oil (special) below 0°F.

Caution: The bore and chamber should not be oiled before firing as dangerous pressures may develop.

INSTRUCTIONS FOR DECALCOMANIA APPLICATION AND MOUNTING OF LUBRICATION ORDER

LO 9-227

1. DECALCOMANIA APPLICATION INSTRUCTIONS.

a. Brush or wipe a light coating of VARNISH, spar, clear, water-resisting or LACQUER, spraying over surface to which the decalcomania is to be applied.

b. Dip decalcomania in water until surface will separate from the backing freely, then then slide decalcomania into designated position.

c. Slide backing paper against face of decalcomania and rub surface with a light, even pressure to eliminate air bubbles.

d. Clean around edges with SOLVENT, dry cleaning.

2. INSTRUCTIONS FOR MOUNTING.

a. Locate on rear buffer housing.

Figure 1—53. Instructions for Decalcomania Application and Mounting of Lubrication Order.

The following points are cleaned with rifle-bore cleaner and lubricated with preservative lubricating oil (special), daily and after firing:

Breechblock group.

Receiver.

Cradle.

Exposed unpainted metal surfaces.

Preservative lubricating oil (medium) is used for the following conditions:

Salt air areas.

Extremely high humidity or other excessively moist conditions.

9. INTERVALS

Lubrication intervals should be reduced whenever the daily inspection reveals evidence of the formation of rust. It usually will be necessary to reduce the intervals when operating in areas characterized by high temperatures, dust, and sand in the atmosphere, or high humidity.

10. MAINTENANCE OF THE GROUPS

Cradle Group

The cradle should be inspected carefully for damaged or loose parts. If parts are allowed to work loose, the mounting holes in the cradle will soon become elongated and render the cradle unserviceable.

The anchor support bracket is tested to see whether the screws have worked loose. If this condition exists the locking wire should be cut, the screws retightened, and secured with new wire.

The rollers are oiled and a check made for chips, cracks and for free rotation. If the rollers bind or are chipped and cracked, the cradle is replaced.

Trunnion blocks and screws are inspected for wear or defects and replaced if necessary.

The tightness of the mounting bracket is tested by tapping the bracket lightly on either end with a hammer. If the bracket is loose, the cradle should be replaced.

The threads in the bracket should be chased out if necessary (ordnance maintenance personnel only).

Rear Buffer and Driving Spring Group

Maintenance by Using Arms. The rear buffer is examined for rough or bruised surfaces on dovetail connections. All rough spots are removed with crocus cloth or fine oilstone to make a good push fit with the receiver. If the fit is too tight, it will tend to spread the receiver; if too loose, it will cause the buffer to hammer the receiver.

The dovetail surfaces are wiped clean with a dry cloth but the rear buffer should not be dipped in any prescribed cleaning fluid. It is lubricated with graphite at the time of assembly; fluid will wash out the graphite and thus impair the functioning of the buffer.

The functioning of the rear buffer lock should be checked. If the lock malfunctions or if the buffer is otherwise damaged, the rear buffer is replaced. All burrs should be removed from the lock plunger but no more metal should be taken off than is absolutely necessary; removal of excess metal will cause the plunger to fit loosely and allow the rear buffer to move vertically in the receiver.

The retainer assembly is examined to determine whether the pin or face of the retainer is broken, bent, or missing. If any of these conditions exist, the retainer should be replaced.

If the threads on the driving spring guide are mutilated or excessively worn, the guide is replaced.

The guide tube is checked for looseness in the head and for deformation. If loose or bent, the guide must be replaced.

The driving spring is examined for any sharp kinks or offset of coils which might cause binding or excess friction; if these conditions exist or if free length is less than 23.5 inches the spring is replaced.

The driving spring guide plunger is checked for straightness, general condition, cracks or indications of fracture just in the rear of the head. The plunger should move freely in and out of the guide; if it is bent or shows cracks, it must be replaced.

Maintenance by Ordnance Maintenance Personnel. Maintenance operations given above are performed whenever necessary.

To check for a broken rear buffer spring a burst of ten or fifteen rounds is fired. If the rear buffer becomes heated, the spring is broken and the rear buffer assembly should be replaced.

Functioning of the rear buffer lock spring is checked. If it is weak or broken, the lock plunger pin should be driven out, the lock collar, plunger and spring removed, the spring replaced, and assembled.

Magazine Slide Group

Maintenance by Using Arms. Movement of the magazine slide on the receiver is checked. Any burrs which may exist on guideways of the slide are removed. If the magazine moves with excessive sideplay, the slide must be replaced.

Functioning of the magazine latch springs is examined. If springs are weak, the free length is checked and replaced if necessary.

The free length of the ejector springs is examined and replaced if necessary.

Maintenance by Ordnance Maintenance Personnel. Maintenance operations as given above are performed when required.

The threaded holes in the magazine slide are replaced whenever necessary.

If the ejector stud is damaged or loose, the ejector stud pin should be driven out, the ejector is unscrewed, and the condition of threads in ejector is examined. If necessary, ejector and pin is replaced securely.

Breechblock Group

Maintenance by Using Arms. Freedom of movement of the breechblock in the receiver is checked.

The breechblock is then disassembled and cleaned.

The front face of the bolt is examined for erosion and wear and the condition of the firing pin hole is noted. If it is enlarged sufficiently to cause blown primers, the bolt must be replaced.

If longitudinal shoulders of the bolt (Figure 1-11) are cracked, the bolt should be replaced.

All burrs and rough spots should be removed from surfaces of the bolt.

The breechblock slides are examined for burrs or rough surfaces on the cam; burrs or rough surfaces should be removed. A check is made for swedging near the front end of the slot for the inertia block (Figure 1-54). The cam surface is examined for cracks.

Movement of firing pin in bolt is examined and any burrs are removed. The firing pin is examined for pitting deformation or cracks. If the firing pin is broken or bent, it should be replaced.

Inertia blocks are examined for general condition. Movement of blocks in breechblock slides is checked and any burrs or rough spots are removed.

The breechblock lock is examined carefully for condition of cams on both sides, for wear or roughness on hinging locking surfaces, and the under side for wear.

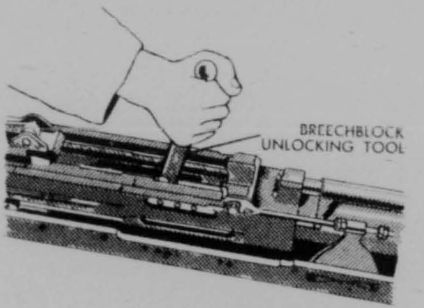


Figure 1—54. Unlocking Breechblock.

Tension of the breechblock slide springs is tested and replaced if broken or shorter than allowable free length.

Sear Mechanism. The sear mechanism is examined for general condition, and for wear or roughness on the surface.

The plunger is checked for burrs or rough surfaces around the disassembling recesses. All rough spots and burrs should be removed.

Tension of sear buffer springs is checked; if they are broken or shorter than the allowable free length they must be replaced.

Maintenance by Ordnance Maintenance Personnel. Maintenance operations are performed as described in preceding paragraphs.

The diameter of firing pin hole is measured (it should be 0.156 inch + 0.004). A No. 22 (0.157) standard drill can be used to clean the firing pin hole to proper size.

The firing pin protrusion also is measured. If the protrusion is less than the prescribed 0.100 to 0.110 inch it should be discarded.

Condition of the breechblock slide key is examined to determine whether the taper pin is in place or loose. If the taper pin in the key is loose, it should be replaced with a new pin.

If the breechblock pins are loose or damaged, the breechblock taper pins should be driven out and the breechblock pins and taper pins replaced.

Radius of sear at point indicated by arrow in Figure 1-12 should be measured. If the radius is less than 0.04 inch, the sear must be replaced.

Gas Cylinder Sleeve Group

Maintenance by Using Arms. All parts are examined for condition. If the sleeve is bent, it should be replaced.

Tension of gas cylinder sleeve spring is checked; if it is kinked or shorter than allowable free length, it must be replaced.

Movement of the gas cylinder sleeve guide in the sleeve is checked. The guide should have a medium close fit in the sleeve; if clearance is excessive, replacement is necessary.

If the gas cylinder vent plug is loose it must be replaced. When replacing the vent plug, the new type (larger vent hole) should be used. This new plug can be identified by the part number B7229626 stamped on its face.

All carbon and any other foreign matter should be removed from the cylinder, piston, bracket, and plugs.

All burrs should be eliminated from the piston. If excessively burred, it will be necessary to replace gas cylinder sleeve with piston.

Movement of push rods in their recesses in the receiver is checked and all burrs are removed from push rods.

Maintenance by Ordnance Maintenance Personnel. Maintenance operations are performed as described in preceding paragraphs.

Guns which were converted to the T31 (M3) included both long and short chamber tubes. To provide proper chamber length, approximately two threads of length were removed from the long chamber tube before installation in the weapon. This resulted in a misalignment between the tube gas port and the bracket gas port. This was originally compensated for by applying a 0.06 x 45 degree chamfer to the bracket gas port. The chamfer was found to be insufficient in all cases, occasionally resulting in a slow rate of fire. The deficiency was corrected in February 1945 by applying a 0.10 x 45 degree chamfer to the bracket gas port. The rate of fire of guns with the converted long chamber tube, if found to be slow as a result of incorrect port alignment, can be increased by removing the gas cylinder bracket and applying a chamfer of 0.10 x 45 degrees.

Recoil Group

Maintenance. All parts are washed in a dry-cleaning solvent with the exception of the recoil housing assembly.

Note: Ring spring assemblies are lubricated at initial assembly and must not be immersed in cleaning solvents. The outside of the housing is cleaned with a dry cloth, and the sleeves inspected in both ends for proper staking. If the recoil housing assembly is damaged, no attempt should be made to repair it; instead, it should be replaced.

The helical recoil spring should not show any evidence of buckling and its free height should be 5¼ inches (plus or minus 10 per cent). If it does not meet these dimensions, it should not be reinstalled.

The gas cylinder bracket should be cleaned and all particles of carbon and burnt powder removed. All rough spots are removed with an oil stone. The opening at the rear of the gas cylinder bracket, in which the gas cylinder seats, must be perfectly formed. Any mutilation or deposit in this opening would greatly impair the operation of the gas cylinder group.

The threads of the gas cylinder bracket nut are inspected. This nut is run up on the threads of the tube by hand to test the condition of the threads. If the thread fit is not satisfactory, it must be replaced.

11. MALFUNCTIONS AND CORRECTIONS

Misfire

General. All stoppages are considered misfires if the receiver is not visible. Immediately after the occurrence of a misfire, the procedure is as outlined below.

Ground Testing. Thirty seconds after the misfire the gun is recharged and the round removed from the vicinity of the aircraft.

Caution: If the gun is hot and the round cannot be removed from the chamber, the breechblock should be closed. It should not be opened until the hand can be placed on the breech or barrel without discomfort.

Air Testing. If the weapon can be recharged, the procedure is the same as for ground testing, described above. If the weapon cannot be recharged, no corrective action is possible.

Note: The possibility of a hangfire of more than thirty seconds after an attempt to fire is very remote in guns using fixed ammunition. The possibility of the propellent or the high-explosive filler being fired by the heat absorbed from a hot gun barrel increases with the length of time the round is in the gun. The safest time to remove a misfire is between thirty to forty-five seconds after its occurrence.

Failure to Fire Chambered Round

Causes: Defective firing pin; defective ammunition; weak or broken driving spring.

Remedies. Immediately after landing, the round is extracted and examined. If the primer of the round is deeply indented, it must be treated as a misfire and immersed in water. If the primer is not indented or only slightly indented, the firing pin is examined as below.

If the firing pin is cracked or broken, it should be replaced. A weak or broken driving spring also must be replaced.

The slide springs are inspected and the receiver is checked for foreign matter. The breechblock slides are examined for swedging which may produce "light hits" by interfering with breechblock action. All obstructions should be removed.

Failure to Feed

The following instructions pertain to feed failures regardless of the type of feed mechanism used, unless otherwise indicated.

Causes: Improper adjustment of magazine (or feed) slide.

Broken components of magazine slide anchor parts.

Deformed or burred feed mouth.

Excessive friction in feed mechanism.

Broken belt or belt jam in ammunition box or feed chute.

Link jam in link chute.

Insufficient recoil of breechblock caused by faulty unlocking or defective ammunition.

Insufficient voltage (feed mechanism M3).

Faulty electrical connections (feed mechanism M3).

Defective electric motor (feed mechanism M3).

Clutch not adjusted (feed mechanism M3).

Loss of tension of driving spring (feed mechanism AN-M2).

Remedies. Adjustment of magazine (or feed) slide correctly.

Tightening of loose components and replacement of broken components of magazine slide anchor parts.

Removal of all burrs from feed mouth, using a fine oilstone or crocus cloth. (If mouth is deformed, feed mechanism should be replaced.) Checking movement of operating parts and lubricating if friction is excessive.

Checking ammunition box and feed chute for jammed links or rounds. Replacement of defective links, rounds, or feed chutes, if necessary.

Checking for jammed links in link chute. Remove jammed links. **Caution:** The finger should not be inserted into the adapter of the feed mechanism AN-M2 to remove a jammed link.

If gun fails to pick up a new round, the procedure is as follows:

The magazine (or feed) slide is adjusted.

The bore is checked to see that there is no round in the chamber.

The gas-cylinder sleeve and piston is checked for free operation. Burrs and dirt are removed from piston and sleeve.

If the piston is deformed or bent on the end, it should be replaced.

Burrs are removed from the breechblock and from interior surfaces of the receiver.

If the voltage is insufficient to operate feed mechanism M3, ordnance maintenance personnel should be notified.

Wiring is checked for proper connections and grounding (feed mechanism M3).

If electric motor of feed mechanism does not function properly, ordnance maintenance personnel should be notified.

The clutch of feed mechanism M3 should be adjusted.

Failure to Extract

Causes: Carbon deposit in chamber or dirty ammunition.

Remedies. When failure to extract occurs, the bolt may be found fully closed with a spent case in the chamber. Generally, most failures to extract can be remedied by charging the gun, except when the extractor, extractor spring, or extractor pin are broken. When this occurs, the case should be pushed out from the muzzle end. The broken extractor, spring, or pin should be replaced.

Sometimes the empty case will be left in the chamber with the extractor ripping through the base of the cartridge case. When this occurs, the bolt will generally attempt to feed a fresh round into the chamber. It will then be necessary to remove this round before the spent case can be removed. If the jammed round is broken, all powder that may be strewn around in the receiver must be removed.

A dirty chamber can be caused by carbon deposit from the oil film on the rounds. If this occurs, the chamber should be cleaned.

Failure to Eject, Feed Mechanism AN-M2

Causes: Broken ejector stud or broken ejector.

Remedy: The ejector must be replaced.

Failure to Eject, Feed Mechanism M3

Cause: Broken ejector.

Remedy: Replacement of the ejector.

Runaway Gun

Causes: Defective firing switch (if used); broken sear, or broken and weak sear spring; jamming of solenoid plunger in sleeve (AN-M1A1 trigger).

Remedies: If firing switch (if used) is defective, ordnance maintenance personnel should be notified.

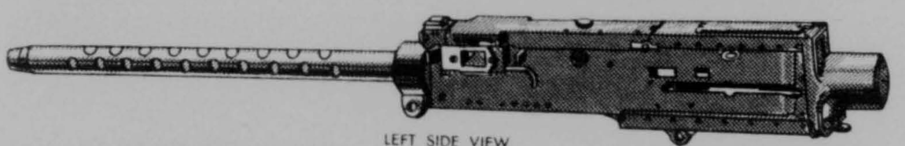
If sear or sear spring is broken, it must be replaced.

If solenoid plunger jams, the trigger must be replaced.

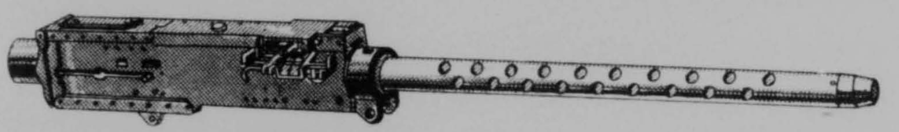
Slow Firing Gun

If the gun fires at a rate of below 650 rounds per minute, it should be turned over to ordnance maintenance personnel.

CHAPTER 2—BASIC AIRCRAFT MACHINE GUN CAL. 50 M3



LEFT SIDE VIEW



RIGHT SIDE VIEW

SECTION I—GENERAL

1. DESCRIPTION

The aircraft machine gun, cal. .50, M3, is essentially the same in general appearance and manner function as the basic aircraft Browning machine gun, cal. .50, M2. It is a recoil-operated, belt-fed, air-cooled machine gun. A metallic link, disintegrating belt is used in all firing of the gun. By properly repositioning some of the component parts, the gun may be fed from either the right or left side.

Differences in Models M3 and M2

The basic aircraft machine gun, cal. .50, M3 differs from the basic aircraft Browning machine gun, cal. .50, M2, as follows:

A **recoil booster** (Figure 2-1) is substituted for the front-barrel bearing.

A new design **cover group** (Figure 2-2) is substituted for the M2 cover group. The cover, which differs slightly in shape from the M2 design, houses a new belt-feed slide assembly with slide retainer, wider belt-feed pawl with two springs, a new cover extractor cam which is steeper than the M2 cam, a new cover extractor spring, and a more rigid belt-feed lever.

The **backplate** (Figure 2-3) has been redesigned to extend around the side plates. Washer springs (Belleville type) are used in the buffer tube in place of fiber disks now used in the gun M2.

The outer driving spring has been changed by removing two of the solid wound coils from each end.

The inner driving spring has been altered by removing three coils from each end.

The **bolt** (Figure 2-4) has been lightened, and has an integral accelerator stop (Figure 2-5), to take the same notched breech lock as the gun M2.

The **cocking lever** (Figure 2-6) has been redesigned to provide thicker cross sections and to eliminate sharp corners. In addition, a

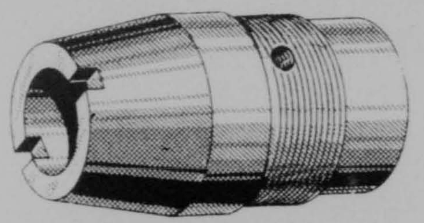


Figure 2—1. Recoil Booster.

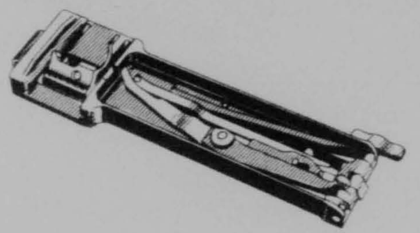

Figure 2—2. Cover Group.

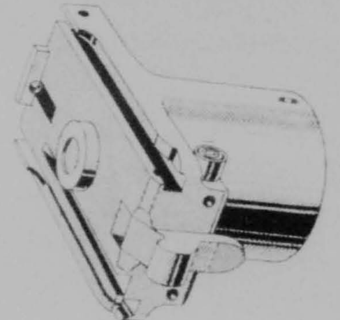

Figure 2—3. Backplate Group—Front and Bottom View.

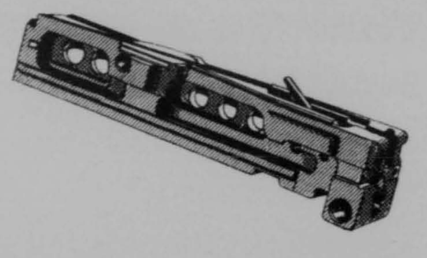

Figure 2—4. Bolt Group with Extractor Assembly Removed.

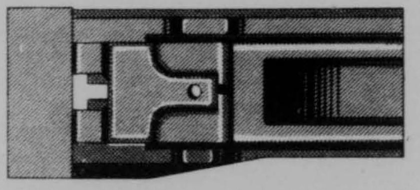

Figure 2—5. Rear End of Bolt Showing Integral Accelerator Stop—Bottom View.

The **sear** (Figure 2-6) has been redesigned to increase its strength and to increase reliability of firing-pin retention. The sear spring is larger and seats over a lug on the bottom of the sear.

The **sear slide** has been redesigned to eliminate the V-shaped notch; an elongated pin hole has been added for retention in the bolt.

A sear-slide stop pin has been added to retain the sear slide in the bolt.

The **firing pin** is stronger and has a larger point (Figure 2-6).

The **bolt switch** has been changed to provide an interlocking tongue on the under side.

The **extractor assembly** has been redesigned so that the position of the ejector may be shifted to facilitate feeding from either side of the gun.

A firing pin spring-stop assembly replaces the sear-stop assembly of the gun M2. When assembled, it acts as a bearing point for compression of the firing-pin spring. The sear is retained in the bolt by the sear slide.

A longer-life barrel is used. (Recently designed M2 barrels are similar.)

shoulder has been added to the lever to facilitate proper assembly.

The cocking-lever pin has been redesigned so that it may be assembled from either side of the bolt and to retain the sear-slide stop pin.

A cocking-lever stop which is housed in the cocking-lever slot in the top of the bolt has been added to cushion the lever.

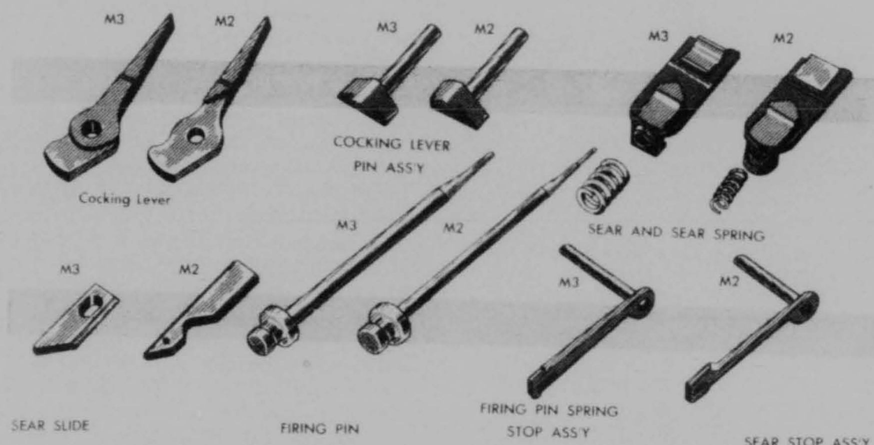

Figure 2—6. Comparison of Similar Bolt Group Parts for Guns M3 and M2.

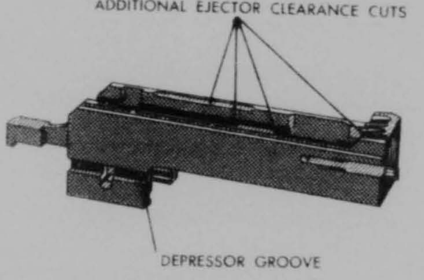

Figure 2—7. Barrel Extension Group.

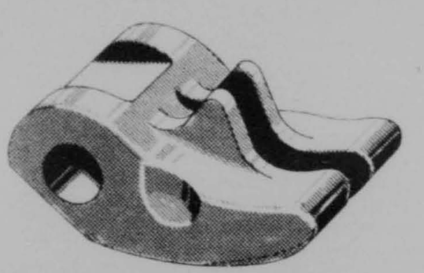

Figure 2—8. Accelerator—Dotted Lines Indicate Shape of Accelerator for Gun M2.

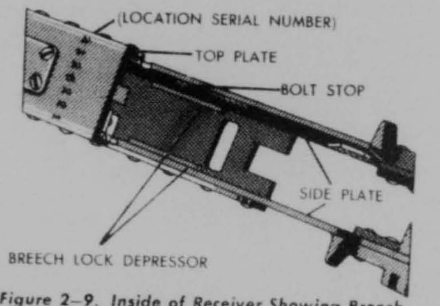

Figure 2—9. Inside of Receiver Showing Breech Lock Depressors—Top View.

The **barrel extension** (Figure 2-7) has been changed by providing additionai clearance cuts for the ejector, and the breech lock depressor slots are milled across the entire side.

A new air and washer-spring type of **barrel-buffer assembly** is used in place of an oil-buffer assembly. A barrel-buffer tube-lock assembly is similar to the oil buffer tube-lock assembly of the gun M2, but serves only to position the accelerator. There are no locking serrations on the buffer tube, nor a lug on the lock.

The **accelerator** (Figure 2-8) has been redesigned by changing the curvature of the claw end.

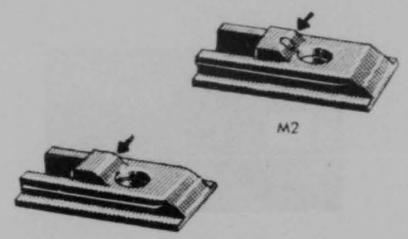

Figure 2—10. Comparison of Breech Lock Cams for Guns M3 and M2.

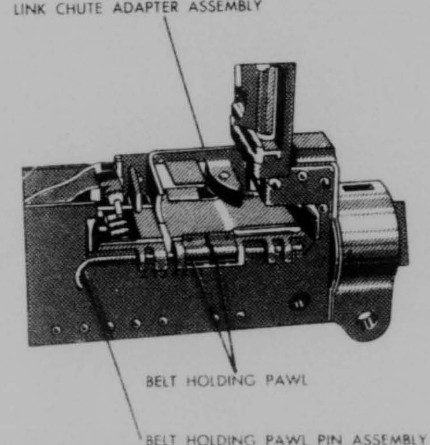

Figure 2—11. Feedway Section of Receiver—Parts Assembled for Right-Hand Feed.

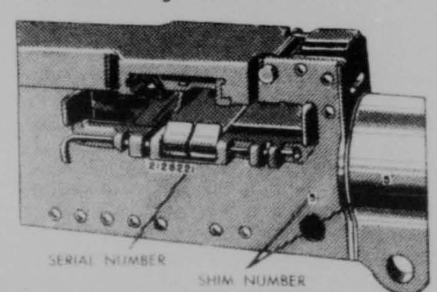

Figure 2—12. Location of Serial and Trunnion Block Shim Numbers.

The **(extractor) switch** has been made shorter than the M2 switch and the slope of the camming faces has been changed. The switch spring is slightly heavier.

The **extractor cam** has been widened, thus causing earlier rise of the extractor.

The **breech-lock depressors** are securely fastened to the side plates (Figure 2-9). On the gun M2 the depressors are attached to the oil-buffer body. The depressors have a curved camming surface formed on the front end.

The **breech lock cam** has been changed to add a radius at the top of the camming step (Figure 2-10).

A **link-chute adapter assembly** (Figure 2-11) takes the place of front and rear cartridge stops and link stripper of the gun M2. A split belt-holding pawl is used as on the gun M2.

A spring-type **recoil adapter** is used in some installations in place of the trunnion adapter.

The **trigger bar** has been made shorter at the rear end than that of the M2 gun.

Identification Information

One **serial number** is required for records concerning these weapons. The serial number is located on the right side plate just below the feedway (Figure 2-12) and on the top plate (Figure 2-9). The size of the trunnion-block shim used at manufacture is stamped on the side plate and trunnion adapter (Figure 2-12).

2. NOMENCLATURE

Backplate Group

The backplate group (Figure 2-14) is an assembly attached to the rear end of the receiver assembly. In general, the group is composed of the backplate, latch lock, and buffer components. The plate slides downward into grooves inside the receiver side plates and surrounds the outside of the side plates to prevent spreading. The backplate is held in position, when assembled, by the **latch** engaging the bottom plate of the receiver. The latch is prevented from disengaging by the transverse latch lock. Both latch and lock are spring operated.

Data pertaining to aircraft machine gun, cal. .50, M3:

a. GENERAL.

Weight of gun	64.60 lb.
Weight of equipment:	
Recoil adapter assembly	4.25 lb.
Weight of barrel	9.80 lb.
Length over-all	57.20 in.
Length of barrel	36.00 in.
Rifling:	
Length	34.14 in.
Number of grooves	8
Twist (direction)	Right-hand.
Twist (one turn in)	15.00 in.
Operation	Recoil.
Feed	Disintegrating link belt.
Capacity of feeding device	As desired.
Sights	Not furnished by Ordnance Department.
Firing pin release:	
Pressure applied to sear slide	35 lb. max.
Pressure applied to sear	23 lb. max.
[1] Belt pull	35 lb. min.
Cooling	Air
Ammunition	For complete ammunition data, see section XXIII

b. PERFORMANCE.

Rate of fire	1150-1250 rds. per minute
[2] Maximum number of rounds (in single burst) which can be fired without danger of cook-off before cooling	150 rounds
Average accuracy life of barrel	5,000 rounds

[1] The "belt pull" of the gun is an expression used to indicate the maximum belt load that can be imposed on the gun without obtaining misfeeds. It is measured by hanging a weight at the end of a belt of 10 live rounds and 2 dummy rounds by means of a cable and special ordnance equipment known as the belt feed test spring.

[2] See cook-off and barrel life data in paragraph 21c.

Figure 2—13. Tabulated Data.

THIS PAGE IS DECLASSIFIED IAW EO 13526

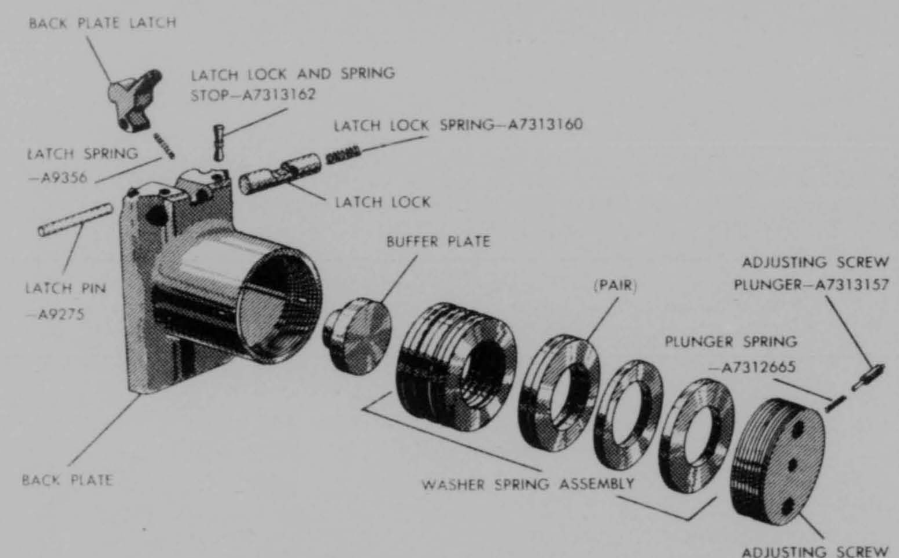

Figure 2–14. Backplate Assembly—Exploded View—Right Side and Bottom.

An integral cylinder projecting rearward from the backplate houses a buffer plate and ten cup-shaped washer springs (Belleville type) assembled in pairs and held in place by an adjusting screw which is threaded into the rear end of the cylinder. The buffer plate bears upon the washers and projects through the front face of the backplate. A spring-loaded plunger seating in the adjusting screw and a slot in the cylinder prevents the screw from backing out.

The main function of the backplate is to stop and cushion the bolt on the recoil movement. The bolt strikes the projecting buffer plate which bears upon the washer springs. These springs, which are slightly compressed at assembly, cushion the blow and store up part of the recoil energy and return it to the bolt to speed up the counterrecoil. The backplate also acts as a stop for the barrel-buffer group, and the rear end of the driving-spring rod assembly which bears in a groove in the backplate when assembled.

Bolt Group

The bolt group (Figure 2-15) contains the firing and extracting mechanisms of the gun and actuates the belt-feed mechanism in the cover. In general it is composed of the bolt assembly, sear, sear slide, cocking lever, firing-pin group, and extractor assembly, and houses the driving-spring group, when assembled. The bolt slides in ways which are cut in the barrel extension, and is locked to it, holding the cartridge in the chamber of the barrel, when firing, by the breech lock in the barrel extension. The bolt withdraws the fired cartridge from the chamber by means of the T-slot in the front end, in which the cartridge is seated when chambered.

The sear slides vertically in grooves in the rear end of the bolt, is actuated by a spring which seats on a lug on the sear and in a seat in the bolt, and is retained in the bolt by the sear slide. The sear slide is assembled in lateral grooves in the rear face of the bolt, is held in place by a retaining pin, and acts upon a lug on the sear. The purpose of the sear is to hold the firing-pin group in the cocked position when cocked by the cocking lever.

The cocking lever is pivoted vertically in a slot in the rear part of the bolt on a transverse

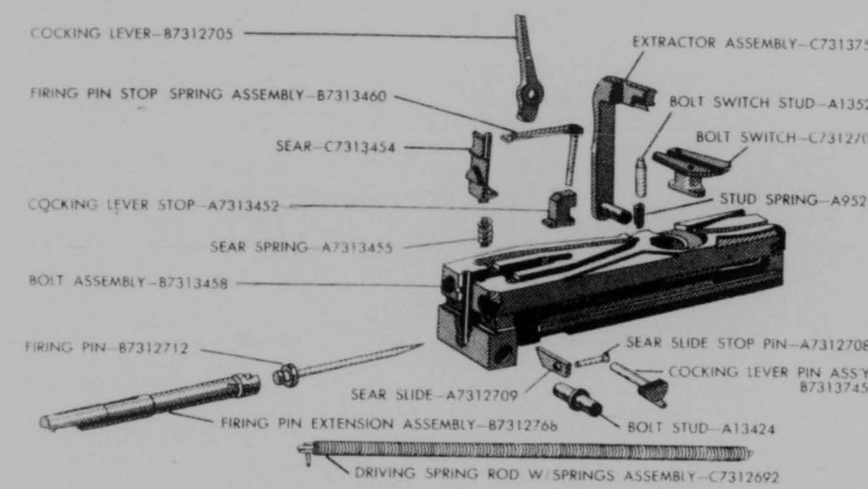

Figure 2–15. Bolt Group—Exploded View.

cocking-lever pin. A rubber stop, seated in the bolt ahead of the cocking lever, cushions the lever on its forward movement. The upper end of the lever projects above the bolt and the lower end engages in a slot in the firing-pin extension. The cocking lever cocks the firing-pin group when its upper end is cammed forward by the top-plate bracket on the top plate of the receiver, during recoil of the bolt.

The firing-pin extension, assembled to the firing pin, is housed in a longitudinal tunnel in the bolt and contains the firing-pin spring, the rear end of which bears upon a stop pin extending vertically through the bolt and a slot in the cocking lever extension, when assembled.

The extractor assembly, which contains the extractor and ejector, is pivoted in the left side of the bolt and can be assembled for either right- or left-hand feeding of ammunition. A stop lug on the bolt limits the downward movement of the extractor assembly. The extractor assembly extracts a cartridge from the belt, and guides it into the T-slot in the bolt and thence into the chamber of the barrel.

Two diagonal grooves, or ways, in the top of the bolt seat the rear end of the belt-feed lever assembly in the cover, when the cover is closed. The bolt switch seats in a circular recess in the top of the bolt and is furnished with a groove similar to the bolt grooves. The switch may be positioned on a spring-loaded stud to make either of the bolt grooves continuous. The switch is retained in the bolt by an undercut in its seating recess.

The driving-spring rod with spring assembly is housed in a longitudinal tunnel in the bolt. A shoulder at the forward end of the tunnel acts as a bearing for the springs to compress them against a shoulder on the rear end of the rod when the bolt moves rearward.

The bottom of the bolt is designed to prevent the accelerator claws from entering the transverse breech-lock notch in the bolt (Figure 2-5); this prevents jamming of the bolt. A bolt stud is assembled in a hole in the side of the bolt as a means for retracting the bolt. One end of the stud projects through a slot in the side plate, and is retained by a collar bearing upon the inside of the side plate.

The general function of the bolt group is to load and fire the gun, extract and eject the fired cartridges, and actuate the belt-feed mechanism of the gun through the medium of the belt-feed lever in the cover group. The

THIS PAGE IS DECLASSIFIED IAW EO 13526

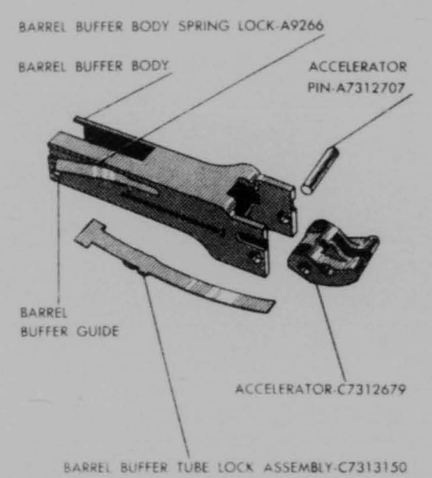

Figure 2—16. Barrel Buffer Body Group—Exploded View.

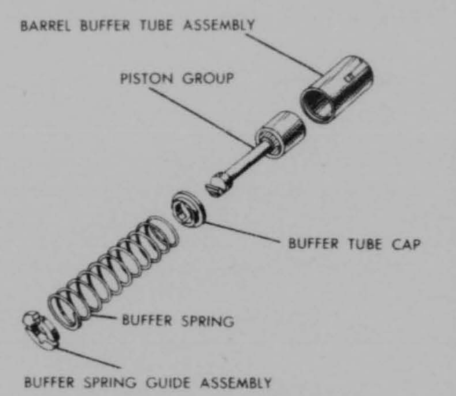

Figure 2—17. Barrel Buffer Assembly C7312663—Partly Exploded View.

driving springs act to return the bolt to the forward position at the end of the recoil movement.

Barrel-buffer Group

The barrel-buffer group (see Figure 2-16) is composed of two main group assemblies; the barrel-buffer body group assembly, which includes the accelerator, and the barrel-buffer assembly with spring and guide. When assembled the buffer assembly is housed in the body which is locked in the rear lower end of the receiver by a leaf spring lock staked in the body and bearing in a recess in the side plate. Guides fastened to the sides of the body at the rear end seat in grooves in the side plates of the receiver to hold it in position. Longitudinal grooves in the sides of the body, at the front end, seat the rear ends of the breech lock depressors fastened to the inner face of the side plates of the receiver. The depressors act as anchors for the front end of the body in addition to their function of unlocking the bolt. A longitudinal slot in the right side of the buffer body acts as a guideway for a key on the spring guide of the barrel-buffer assembly, when assembled, to prevent the piston rod from turning.

The accelerator is pivoted in the front end of the body by a transverse pin. The accelerator is acted upon by the barrel extension during recoil to speed the recoil movement of the bolt. In turn the accelerator locks the barrel extension to the buffer body until released by the bolt on the counterrecoil movement. A tube lock, assembled in the body, bears upon the bottom of the accelerator to hold it in the locked position until released by the bolt.

The barrel-buffer assembly is, in general, composed of a hollow, cylindrical body, called the "tube" (Figure 2-17), open at one end, which is closed by a threaded cap. An air port in the wall of the tube admits air for compression by the piston on the recoil movement. A piston rod, assembled through a hole in the cap, is attached at the rear end to a piston in the tube by a pin. The front end of the rod engages with the barrel extension shank when assembled. A relief valve, spring, and retainer are assembled in the rear end of the piston and held in position by ten cup-shaped washer springs upon which the rear end of the piston rod bears. An elongated pin hole in the piston rod permits the springs to be assembled under slight compression and to act as a buffer for the rod at the end of the

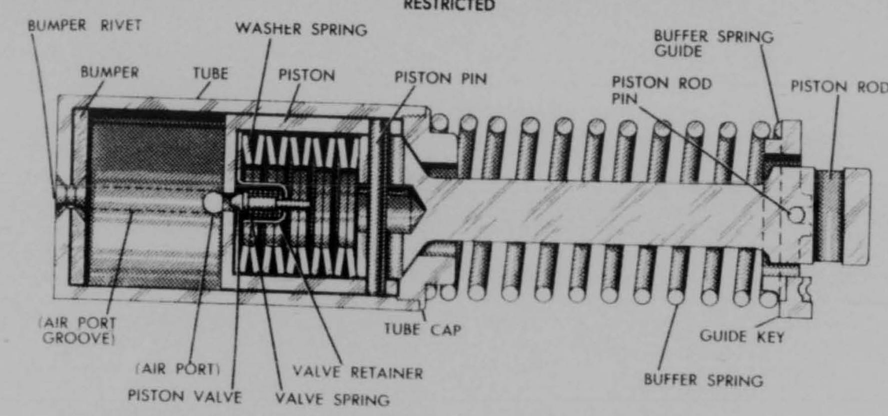

Figure 2—17A. Barrel Buffer Assembly with Piston in Forward Position—Sectional View.

recoil movement of the piston. Figure 2-17a shows a sectional view of the barrel-buffer assembly.

A coil spring is assembled on the piston rod, outside the tube, bearing upon the tube cap, and is held in position under compression by a guide. This guide is in the form of a washer, held in place by a cross pin passing through, and extending from, the forward end of the piston rod, bearing in notches in the guide, when assembled. A key in the side of the guide engaging in a slot in the buffer body, when assembled, prevents the piston from turning during operation.

The barrel-buffer group has four main functions: (1) to bring the barrel and barrel extension to rest and hold it, on the recoil movement, and to cushion the shock, (2) to transmit recoil energy of the barrel and barrel extension through the accelerator to speed up the recoil of the bolt, (3) to return the barrel and barrel extension to the forward "battery" position by means of the expanding buffer spring assisted by the accelerator acted upon by the bolt, (4) through the medium of the accelerator, to time the movements of the barrel, barrel extension, and bolt for locking of the bolt to the barrel extension during counterrecoil.

Barrel and Barrel-extension Group

The barrel is cylindrical (Figures 2-18 and 2-19), and threaded at the rear end to screw

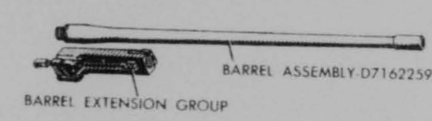

Figure 2—18. Barrel and Barrel Extension Group—Barrel Removed.

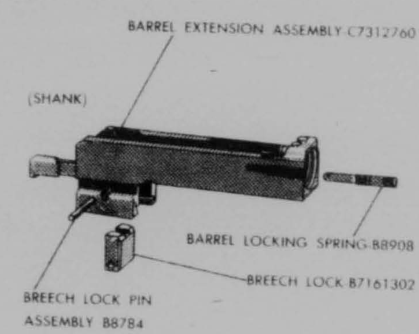

Figure 2—19. Barrel Extension Group—Exploded View.

into the barrel extension loosely enough for easy adjustment. Just forward of this thread, serrations are cut around the periphery for engagement of the barrel-locking spring which holds the barrel in adjustment, with regard to headspace, when assembled to the barrel extension. A cylindrical sleeve is fastened to the muzzle end of the barrel for en-

THIS PAGE IS DECLASSIFIED IAW EO 13526

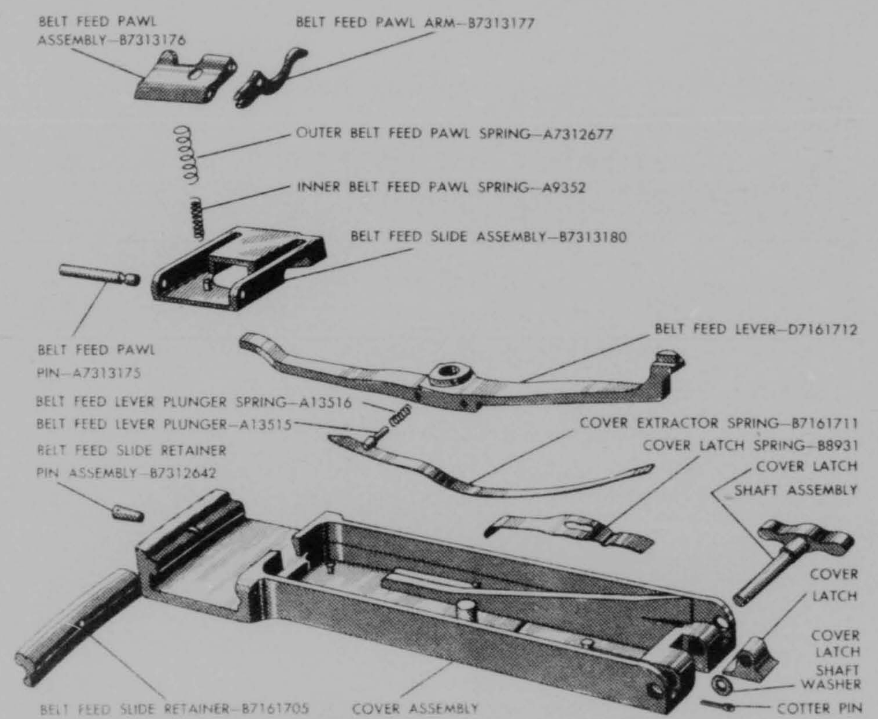

Figure 2–20. Cover Group—Exploded View.

gagement in the bearing formed by the recoil booster in the barrel jacket of the receiver group, when assembled. The bore of the barrel is chromium-plated to increase accuracy and has a special liner assembled near the breech end to increase the velocity.

The barrel extension extends to the rear of the barrel, when they are assembled. Its forward end is a formed lug, drilled and threaded, into which the barrel is screwed. Integral side members extend rearward, terminating in lugs pointing downward and carrying the breech lock. At the rear end is the barrel-extension shank, pinned in position between the side members. The shank terminates in a hook and extends rearward to engage a similar hook on the piston rod of the barrel buffer, when assembled. Grooves, cut in the side members of the barrel extension, support and form a slideway for the bolt, when assembled. Cuts in the upper inside edges of the side members, and the top of the forward portion into which the barrel is screwed, provide clearance for the extractor assembly of the bolt when assembled for either right- or left-hand feed.

The breech lock slides vertically in grooves in the rear part of the barrel extension and is retained by a pin passing laterally through the breech lock and elongated holes in the side members of the extension. The barrel-locking spring is staked in an undercut groove

in the right side of the extension, at the forward end.

The function of the barrel is to house the cartridge and direct the bullet when fired. The barrel is rifled to rotate the bullet, which helps maintain direction and prevent tumbling.

The function of the barrel-extension group is to support the rear end of the barrel and maintain its adjustment, with regard to headspace, by means of the barrel-locking spring. The extension is, in turn, supported by the breech-lock cam in the receiver. The extension also supports the bolt, forms a slideway for it during operation and provides a means for locking the bolt to the barrel during firing of the cartridge. The extension shank, engaging with the piston rod of the barrel buffer, operates the piston, compresses the buffer spring on the recoil movement, and is in turn forced forward by the expanding spring on the counterrecoil movement. The breech lock, acted upon by the breech-lock cam on the forward movement of the extension and by the breech-lock depressors on the rearward movement, locks and unlocks the bolt with respect to the barrel extension. The extension also acts upon the accelerator in the barrel-buffer body to accelerate the rearward movement of the bolt.

Cover Group

The cover group (Figure 2-20) carries the feeding mechanism of the gun, and is operated by the bolt through the medium of the belt-feed lever. The group, in general, is composed of the cover, belt-feed slide group, cover-extractor cam, cover-extractor spring, and belt-feed lever.

The cover hinges in the trunnion block, pivoting on the cover pin. It is held by a spring-loaded cover detent seated in the trunnion block and latched by the cover latch engaging under the top plate when the cover is closed. The cover-extractor cam is fastened to the left inner side of the cover. The cover-extractor spring is secured beside the cam by means of a headed stud engaging in a slot in the spring, and by an undercut in the cam. The cover latch spring, assembled to the right of the extractor spring by means of a headed stud and slot, holds the cover-extractor spring in position, and places spring pressure on the latch.

The belt-feed lever is pivoted at the middle on a stud in the cover. The forward end engages in a slot in the belt-feed slide, and a lug on the rear end engages in one of the two camming grooves in the top of the bolt when the cover is closed. A spring-loaded plunger is housed in one of two wells in the side of the lever and bears on the side plate to position the lever when the cover is open, so that the lug on the rear end will properly engage one of the two camming grooves in the bolt, for right- or left-hand feed, when the cover is closed.

The belt-feed slide group contains the feed pawl and pawl arm pivoted in the slide, which moves laterally in the guideways in the forward section of the cover and is held in place by a retainer fastened by a pin. The pawl is spring-operated by an inner and outer spring seating in the slide and pawl. The pawl arm is positioned on the pawl by a spring-loaded plunger in the pawl, and retains the pawl pin through the medium of a notch in the end of the arm seating in a groove in the pin, when assembled. The slide group and lever may be assembled for either right- or left-hand feed by positioning of parts as explained in this manual.

The function of the cover group is to pull the ammunition belt into the gun, position a cartridge in the feedway and assist the extractor of the bolt group to withdraw a cartridge from the belt, position it in the T-slot of the bolt, and guide it into the chamber of the barrel. The belt-feed slide is operated laterally by the belt-feed lever which is in turn operated by the bolt during recoil and counter-recoil. The rear end of the lever engaging in one of the two diagonal camming grooves in the bolt is moved from side to side as the bolt moves backward and forward. This causes the slide, which is engaged with the front end of the lever, to move laterally. The cover extractor spring bears upon the extractor to force it into the extractor groove of the cartridge awaiting extraction in the feedway. The cover-extractor cam forces the extractor downward against the (extractor) switch in

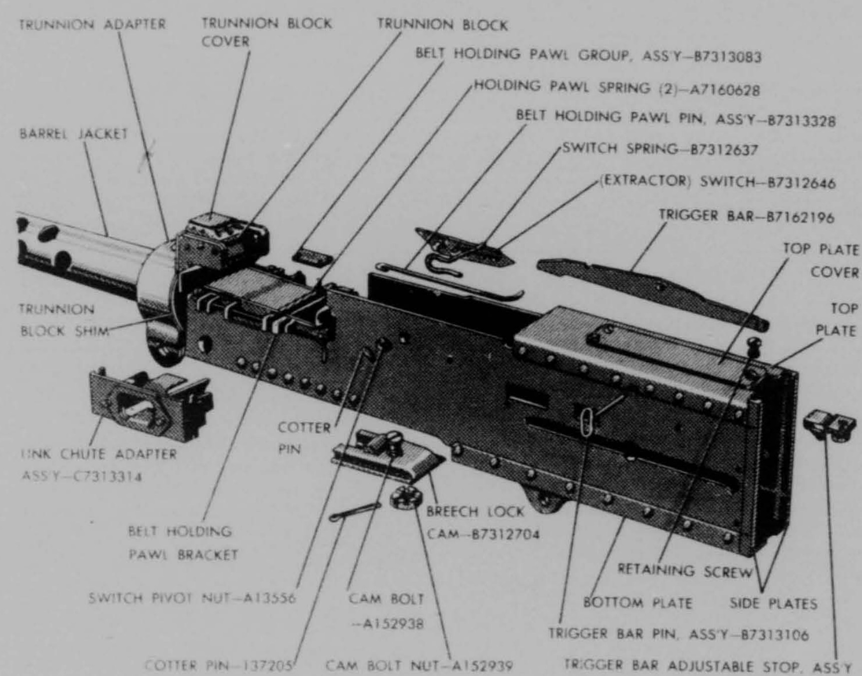

Figure 2–21. Receiver Group—Parts Removed and Shown in Relative Positions.

the receiver, to guide the cartridge into the T-slot in the bolt when extracted from the belt, during the recoil movement of the bolt. The belt-feed pawl arm prevents the feed pawl from engaging the ammunition belt and pulling another round into the feedway, should the cartridge awaiting extraction fail to be extracted; thus it prevents jamming.

Receiver and Barrel-jacket Group

The receiver group (Figure 2-21) consists of the receiver assembly, barrel jacket, and other parts assembled to them. The receiver assembly consists of the trunnion block, two side plates, a bottom plate, top plate and other parts assembled permanently to them. The trunnion block forms the basic part of the receiver assembly. The side plates are attached to the trunnion block and extend rearward. The top and bottom plates are attached to the side plates.

The barrel-jacket assembly contains the breech bearing permanently fastened to the rear end. The breech bearing screws into the trunnion block to support the jacket when assembled. A recoil booster is screwed into the front end of the jacket. The booster acts as a front barrel bearing, and contributes to an increased rate of fire by momentarily confining gas pressure at the muzzle which accelerates recoil of the barrel and barrel-extension group. The breech bearing acts only as a guide for the barrel which is supported at the rear by the barrel extension into which it threads. The barrel extension is in turn supported by the breech-lock cam in the receiver. Holes in the barrel jacket provide ventilation

to dissipate heat from the barrel when the gun is firing.

A lateral feedway for the ammunition belt is cut into the top of the trunnion block and the front-top of the side plates. At the lower edge of the feedway, right- and left-hand belt-holding pawl brackets are riveted to the side plates to support the belt-holding pawls and link-chute adapter, which are secured in the brackets by belt-holding pawl pins. The link-chute adapter contains the cartridge stops and link stripper and guide. A hole bored through the side plates and trunnion block acts as a bearing for the front-gun trunnion pin when mounting the gun in some installations. Two drilled lugs on the bottom plate act as bearings for the rear-gun trunnion pin. A lateral hole bored through the trunnion block at the top-forward end acts as a bearing for the cover pin.

A trunnion adapter, with a lug drilled to form a bearing for the front gun trunnion pin in some installations, is threaded onto the front end of the trunnion block, and held in place by a spring-loaded trunnion block lock housed in the trunnion block. Thread qualification is obtained by use of shims of varying thickness. A recoil adapter, which may be used in place of the trunnion adapter in some installations, is assembled to the trunnion block in a similar manner.

The breech lock cam is fastened to the inner face of the bottom plate by means of a lug on the cam passing through a hole in the plate and secured by a bolt and nut. The cam is grooved at the sides to form a slideway for the barrel extension which it supports. A ramp on the rear end of the cam acts to cam the breech lock upward to lock the bolt, during counterrecoil of the barrel and barrel extension.

The top-plate bracket is fastened to the under side of the top plate and forms a bearing surface which engages the upper end of the cocking lever to operate it during recoil and counterrecoil movements of the bolt. A lateral hole through the bracket and left-hand side plate forms a bearing for the trigger-bar pin which acts as a pivot for the trigger bar, when used. A bolt-latch bracket is fastened to the top plate to the right of the top-plate bracket, but in this gun serves to hold the bolt down. An adjustable trigger-bar stop assembly is fastened to the under side of the top plate to the rear of the bracket, for the purpose of limiting the upward movement of the trigger bar when acted upon by a backplate solenoid, when used. The adjustable stop is positioned on the rear trigger-bar stop (pin) riveted into the top plate, and is retained by a screw extending through the top-plate cover and top plate, and threaded into the body of the adjustable stop.

Breech lock depressors are fastened to the inner faces of the side plates (Figure 2-9). The rear end of these depressors anchor the front end of the barrel-buffer group, when assembled, and the front ends are formed into cams which engage the breech-lock pin in the barrel extension to cam down the breech lock and unlock the bolt during recoil.

The (extractor) switch is pivoted to the inside of the left-hand side plate and positioned by a threaded stud, nut, and spring. The switch, in conjunction with the cover extractor cam in the cover group, assists the extractor to position the cartridge in the T-slot of the bolt. The extractor cam riveted to the side plate, just ahead of the switch, raises the extractor near the end of the counterrecoil movement of the bolt, after the cartridge has been started into the chamber.

The purpose of the receiver group is to house the working mechanism of the gun, as well as to act as a support of the fixed parts which contribute to operation. It also acts, through the barrel jacket, to support and protect the barrel.

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION II—DISASSEMBLY AND ASSEMBLY

1. BACKPLATE GROUP

Removal

The backplate latch lock is pushed in, the backplate latch is pulled up, and the backplate slipped up out of the receiver (Figure 2-22).

Disassembly

To disassemble the backplate (Figure 2-14) the backplate is left on the receiver which will act as a fixture. The adjusting screw is loosened by depressing and holding the adjusting screw plunger with a small drift, and backing out the screw part way, using the combination wrench (Figure 2-23). The backplate is first removed and then the adjusting screw, with care being taken not to lose the plunger and spring. The washer springs and buffer plate can then be pushed out to the rear.

Caution: Plunger must be disengaged before attempting to turn screw.

Assembly

The latch-lock spring is placed in the open end of the latch lock, and the lock inserted (spring leading and center notch down) into its transverse tunnel in the backplate from the left side so that the spring-stop slots align with the vertical stop hole in the backplate. (Lock can be assembled from either side.)

The lock is held in position, and the spring stop inserted into its hole in the bottom of the backplate until it abuts the spring in the lock. Still holding the lock, the spring is compressed with a screw driver or similar tool and the stop is pushed all the way in to retain the spring. The stop should cam over the end coil of the spring and be retained by it. To allow the stop to clear the edge of the hole in the lock, the open end of the lock must protrude slightly from its tunnel.

The latch spring is placed in its seat in the latch and the latch is inserted into the backplate so that the free end of spring seats level, to the rear of the latch lock. The latch then is moved until the pin holes in latch and backplate align and the latch pin is pushed in until flush with sides of the backplate. To facilitate assembly, the latch lock is pushed in until the latch relief cut aligns with latch. When assembled, the latch and lock are operated to make sure that they function properly. When the lock is pushed all the way in, it should be possible to fully raise the thumb piece of the latch.

The buffer plate is inserted in the tube of the backplate, putting it in from the back with the small diameter forward and projecting from the front of the backplate. The ten

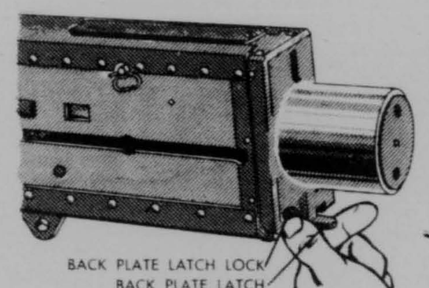

Figure 2–22. Disengaging Lock and Latch Preparatory to Removing Backplate.

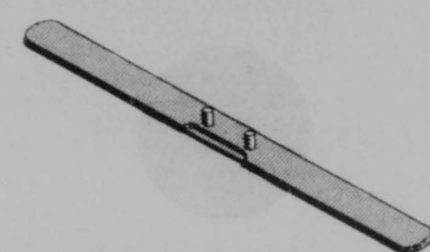

Figure 2–23. Combination Wrench, Cal. .50.

cup-shaped washer springs are inserted in pairs so that the cupped faces of each pair are facing (Figure 2-14). The adjusting screw is started and the plunger and spring inserted. The plunger and spring are depressed to allow the plunger to enter the tube, and the adjusting screw is tightened by hand, the plunger being depressed when necessary. After the adjusting screw is run up by hand it should be tightened a half to a full turn, using the combination wrench (Figure 2-23), as in disassembly, until the plunger snaps into one of the two slots in the tube to lock the screw in place. This gives an approximate torque of from forty to seventy foot-pounds. Subsequent tightening after firing is unnecessary.

Caution: The plunger must be disengaged from the slot in the buffer tube before an attempt is made to turn the adjusting screw.

Installation

The backplate is started into its grooves in the rear end of the receiver side plates. The backplate latch lock is pushed in, the latch is lifted, and the backplate assembly pushed all the way down. The latch is released and then locked. The latch must be fully engaged and the lock springs out to hold it in engagement.

2. BOLT GROUP

Removal

The backplate group is removed. The driving spring rod with springs assembly is removed by pressing forward and away from the right sideplate to disengage the retaining pin from its hole in the plate (Figure 2-25) and withdrawing assembly from the bolt. Care must be taken not to bend the rod while performing this operation. The bolt is pulled to the rear until the bolt stud is in line with the enlarged assembly hole in the center of the slot in the sideplate. The bolt stud is removed by pulling it out to the side. (See Figure 2-26.) The bolt may then be removed by sliding it to the rear.

Disassembly (Figure 2-15)

The extractor assembly is removed by rotating it upward to a vertical position (Figure 2-27) and pulling it out from the bolt. When necessary, the ejector should be removed by depressing the spring-loaded ejector-pin retainer with a small drift inserted in the retainer hole in the extractor, and pushing out the ejector pin. Care should be taken that the ejector and spring do not fly out when the pin

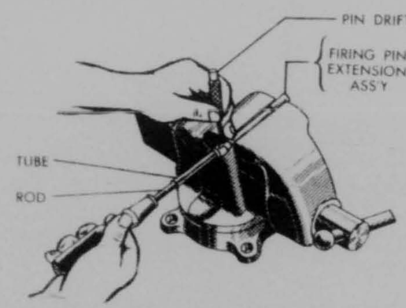

Figure 2–24. Using Firing Pin Spring Removing Tool 41-T-03098-000 (B243646).

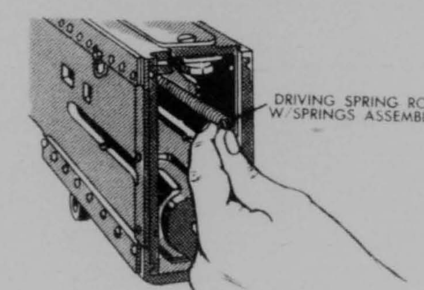

Figure 2–25. Removing Driving Spring Rod w/Springs Assembly.

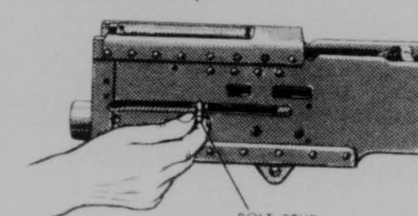

Figure 2–26. Removing Bolt Stud.

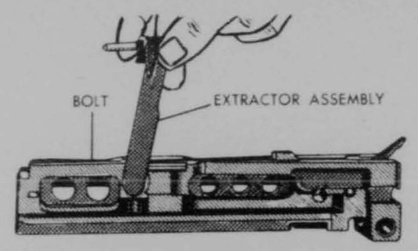

Figure 2–27. Removing Extractor Assembly from Bolt.

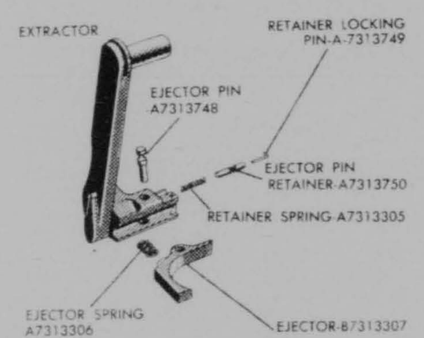

Figure 2–28. Extractor Assembly—Exploded View.

is removed. The retainer is locked in place and should not be removed. Disassembled extractor assembly is shown in Figure 2-28.

The cocking lever is rotated fully backward and the firing pin released by pushing in on the sear. The cocking-lever pin is pushed out and the cocking lever lifted out of the bolt.

Caution: No attempt should be made to release the firing pin with the cocking lever forward, as it will spring back forcibly and may cause serious injury.

The sear is pressed down, the sear-slide stop pin withdrawn from the bolt (Figure 2-29), and the sear slide removed.

Using the thin end of the cocking lever, the flat lock of the firing-pin spring-stop assembly is swung laterally out of its seating groove in the bolt (Figure 2-30), the pin is pushed upon from the under side, and the assembly withdrawn from the bolt.

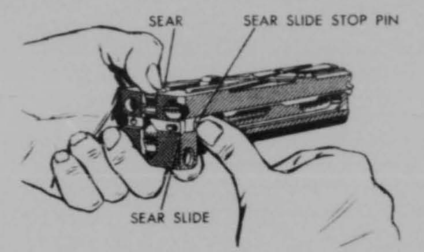

Figure 2–29. Removing Sear Slide Stop Pin.

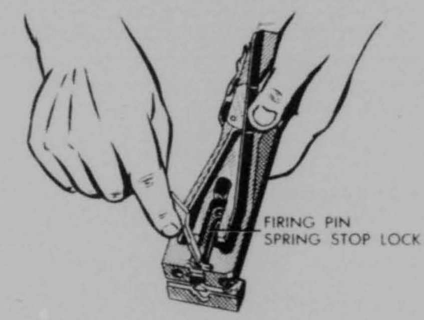

Figure 2–30. Disengaging Firing Pin Spring Stop Lock.

The sear is removed by pulling it up and out of the bolt, and the sear spring is removed.

The front end of the bolt is elevated and the firing-pin extension and firing pin allowed to slide out. The firing pin then is disengaged from the extension by sliding it laterally from the engagement groove in the extension.

The firing pin extension assembly (Figure 2-31) should not be disassembled unless necessary for cleaning or inspection of parts. To disassemble, the firing-pin spring-removing tool is used. If the tool is not available, the firing-pin spring-stop pin is driven out and the spring removed. Care should be taken to prevent the spring from flying out during the operation. To use the firing-pin spring-removing tool, the firing-pin extension assembly is clamped lightly but firmly in a vise. The head of the tool tube is engaged with the end of the extension, so that the slot in the rod straddles the pin in the extension. The rod is pressed in

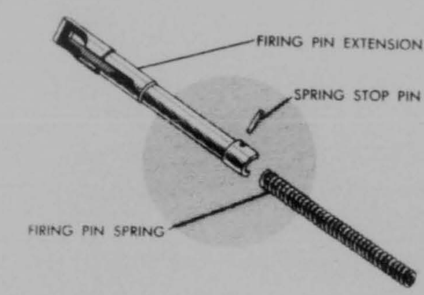

Figure 2–31. Firing Pin Extension Assembly—Exploded View.

to compress the spring, the stop pin is pushed out, and, holding tube against extension, rod is allowed to move slowly rearward in the tube, and spring to expand into the tube. (Figure 2-24)

The bolt switch is removed by depressing the spring-loaded bolt switch stud with a drift and, using the cocking lever as a tool (Figure 2-32), rotating the switch 90 degrees to disengage the interlocking tongue on the under side. The bolt switch is lifted out of the bolt and the bolt switch stud and spring removed from their seat in the bolt.

The cocking-lever stop, if necessary, is removed by prying it toward the rear from the lower left side of the bolt. A small drift is inserted through the hole for the firing-pin spring-stop assembly and the bottom of the stop is pressed down to remove it from its seat, and withdrawn from the top of the bolt.

Assembly (Figure 2-15)

The cocking-lever stop assembly is inserted into the cocking-lever slot in the top of the bolt so that the curved end is facing the front of the bolt (Figure 2-33). The stop then is pushed forward and downward against the end of the slot. Care should be taken that the stop does not interfere with proper seating of the firing-pin spring-stop assembly. The rear end of the cocking-lever stop should be flush with the bottom of the recess in the bolt.

The bolt-switch stud spring is inserted in the bolt-switch stud hole and the bolt-switch

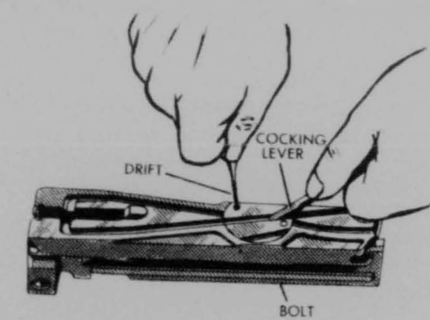

Figure 2–32. Repositioning Bolt Switch, Using Cocking Lever as Tool.

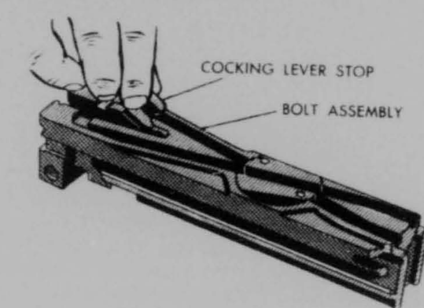

Figure 2–33. Inserting Cocking Lever Stop Into Bolt.

stud is inserted with the small diameter up.

The tongue on the bottom of the bolt switch is aligned with the groove in the bolt and insert switch. The bolt-switch stud is depressed and, using the cocking lever as a tool, the switch is rotated so that the groove marked "L" is continuous if left-hand feed is desired. ("R" for right-hand.) The bolt switch must be retained in position by the engagement of the bolt switch stud.

If the firing pin spring has been removed from the firing pin extension, the spring should be replaced and, after compressing it, secured in place by inserting the firing-pin spring-stop pin. To use the firing-pin spring-removing tool (Figure 2-27) the rod is retracted in the tube of the tool. One end of the spring is placed in the tube and the other in the firing-pin extension, the head of the tube being held over the end of the extension with the slot of the rod in position to straddle the pin holes in the extension. The spring is then compressed into the extension with the rod (Figure 2-24). The stop pin is then inserted, flush with the extension on both sides.

The firing pin and firing-pin extension assembly are engaged and inserted in the tunnel of the bolt with the notch at the rear of the firing-pin extension down. The extension is pushed all the way forward so that the tip of the firing pin protrudes from the face of the bolt.

The sear is pressed down on the spring, so that the spring is seated level on the sear, with the lug on the bottom of the sear inside the coils of the spring. The sear and sear spring are inserted into the bolt, so that the sear spring fits squarely in its seat in the rear bottom of the bolt, and so that the sear is in the vertical grooves in the rear of the bolt, with the wedge-shaped lug facing outward and pointing upward.

The sear slide is inserted into its lateral guideway in the rear end of the bolt with the pointed end leading so that the sloping cam abuts the cam lug on the sear. Then, the sear is depressed slightly and the slide pushed toward the sear lug until the elongated slot in the slide aligns with the sear-slide stop-pin hole in the bolt. The sear slide is retained in position by inserting the sear-slide stop-pin through its hole in the bolt and the slot in the slide. The stop pin should be inserted from the front so that its head faces toward the front of the bolt, and the flat side towards bolt.

Note: The square end of the side must be on the side from which the weapon is to be fired.

The firing-pin spring-stop assembly is inserted in the slot on top of the bolt. Using the wedge-shaped end of the cocking lever as a tool, the flat lock of the stop is swung into its groove in the left side of the slot. The pin of the stop assembly must lie behind the firing-pin spring and not between the coils, when assembled.

The cocking lever (Figure 2-34) is inserted into the slot in the top of the bolt with the rounded nose on the lower end of the lever to

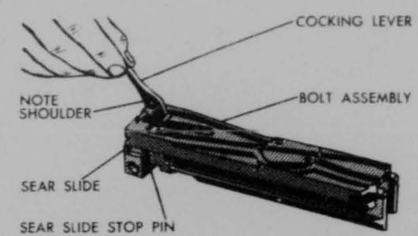

Figure 2—34. Inserting Cocking Lever Into Bolt.

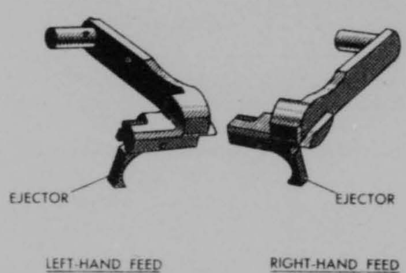

Figure 2—35. Extractor Assembly with Ejector Assembled for Left-Hand and Right-Hand Feed—Front View.

the rear and the shoulder on the side of the lever to the right; the cocking lever pin is then inserted. The head of the cocking lever pin retains the sear-slide stop pin in position; therefore, the cocking lever pin must be inserted from the side to which the sear slide is assembled.

The cocking lever is pushed all the way forward and returned fully to its rear position, and the sear slide is pushed down. A sharp metallic sound heard when the firing pin is released indicates that the firing-pin spring and other components are in good working order. The cocking lever again is pushed all the way forward for proper preparation of the bolt before assembly in the gun.

If the gun is to be assembled for left-hand feed the ejector should be assembled with the claw to the right side of the extractor (Figure 2-35) and, if assembled for right-hand feed, the ejector should be assembled with the claw to the left side of the extractor, when viewed

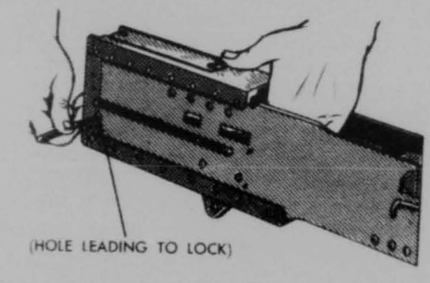

Figure 2—36. Disengaging Barrel Buffer Body Spring Lock.

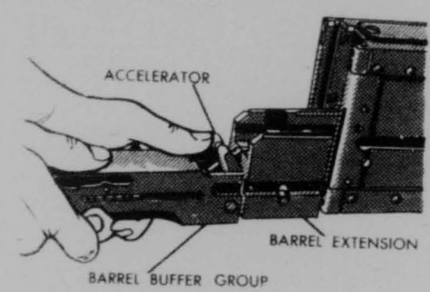

Figure 2—37. Removing Barrel Buffer Group.

from the rear. The ejector spring should always be assembled so that it is on the same side of the ejector pin as the ejector claw. Assembly is as follows:

The ejector is assembled to the extractor by inserting the ejector spring into its seating recess in the extractor and then positioning the ejector, over the spring, in its working slot.

The pin hole in the ejector is aligned with the pin hole in the extractor and the ejector pin is inserted from the rear until it abuts the retainer in the extractor. (The head of the pin must be seated in its countersink in the extractor when fully assembled.) The spring-loaded retainer is pressed in with a drift pin inserted in the retainer hole in the extractor, until the ejector pin is fully seated; the retainer then is released to lock the pin in position. The pin must be fully seated and locked. The spring action of the ejector then is checked.

With the extractor assembly in a vertical position, the pivot is inserted into the bolt as shown in Figure 2-27. As the extractor assembly is rotated forward, the flange on the bottom of the extractor must engage behind the shoulder on the bolt, thus locking it in position. The assembly should not be forced.

Installation

The barrel and barrel extension are pushed far enough to the rear so that the breech lock does not interfere with the entrance of the bolt. With the cocking lever rotated fully forward, the bolt group is inserted into the receiver, and engaged with its ways in the barrel extension. It then is pushed forward until the hole for the bolt stud is in line with the enlarged opening in the center of the slot in the side plate, the bolt stud inserted. Care should be taken when inserting the bolt so as not to trip the accelerator forward. The tip of the cocking lever must be under the top-plate bracket before pushing the bolt forward. The front end of the bolt should be lifted over the tips of the accelerator for easy assembly. The driving-spring rod with springs assembly is inserted into its hold in the bolt and the bolt pushed completely forward. The driving-spring-rod assembly is moved forward, engaging the driving-spring-rod retaining pin in its retaining slot in the right side plate, the head of the rod being pressed flat against the side plate.

Caution: The driving-spring rod with springs assembly must not be used as a lever or guide for the bolt when inserting the bolt in the receiver as this may bend the rod. The rod must be straight and the outer driving spring must not rub excessively or bind in the bolt hole.

The backplate group is installed, with the head of the driving spring rod flat against the side plate and the pin fully engaged in the hole, so that head will seat in the backplate groove.

3. BARREL-BUFFER GROUP

Removal

The backplate group and bolt group are removed.

THIS PAGE IS DECLASSIFIED IAW EO 13526

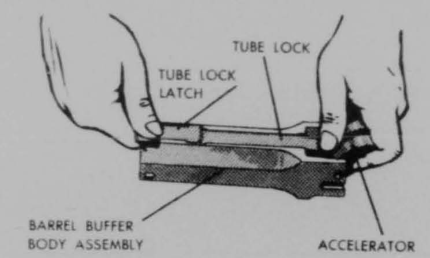

Figure 2—38. Removing Barrel Buffer Tube Lock Assembly.

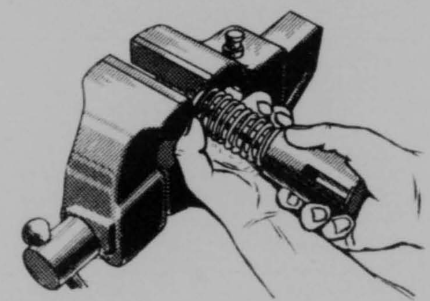

Figure 2—39. Using Vise to Remove Buffer Spring.

A drift pin is inserted in the hole near the rear of the right side plate (Figure 2-36) and the barrel-buffer-body spring lock depressed. At the same time, the barrel, barrel extension, and barrel buffer group are moved to the rear. As the barrel-buffer group emerges from the rear of the receiver it is disconnected from the barrel extension by pushing forward on the tips of the accelerator, as shown in Figure 2-37.

Then, if necessary, the barrel extension and barrel are withdrawn together.

Disassembly (Figures 2-16 and 2-17)

The barrel-buffer assembly is pushed out of the rear end of the barrel-buffer body by pressing on the end of the piston rod with the index finger.

The body is turned over and placed upside down on a bench. With a screw driver or other suitable tool, the rear end of the tube lock latch is raised out of its locking recess in the body (Figure 2-38). (A drift pin, inserted through the hole in the body under the latch, can be used to raise the latch.) With the latch thus disengaged, the tips of the accelerator are elevated and rotated slightly rearward, to move the latch out of its recess, at the same time pressing downward on the forward end of the tube lock, as shown in Figure 2-39. As the accelerator is rotated farther rearward, the tube lock assembly will be pushed out of its recess in the body. The pressure of the hand on the forward end of the lock will keep it from springing out suddenly.

The barrel-buffer-body spring lock is staked in position and should not be removed unless necessary. (It is removed by driving it out to the rear.)

With a drift pin the accelerator pin is pushed out and the accelerator removed. Figure 2-16 shows the barrel-buffer-body group with parts removed.

If a vise is available, the jaws are set about $1\frac{1}{8}$ inches apart; then, holding the barrel buffer firmly in both hands, the edges of the buffer spring guide are placed against the separated jaws of the vise (Figure 2-39). The barrel buffer tube is pressed forward to compress the buffer spring; then the buffer is given a one-quarter turn in either direction to align the piston-rod pin with the slots in the spring guide. The pressure on the tube is released slowly and the spring guide and spring removed. If no vise or other suitable support for the spring guide is available, it is possible to perform the operation as indicated in Figure 2-40.

Assembly (Figures 2-16 and 2-17)

The piston group is inserted into the barrel-buffer tube assembly. The buffer-tube cap is assembled over the piston-rod assembly and the cap screwed tightly into the buffer-tube assembly. Tube and piston should be clean and lightly lubricated.

The buffer spring is placed over the piston rod, and seated on the tube cap, the flat surface of the spring guide is placed on top of the spring with the guide key in line with the pin on the notched side of the piston rod; the

buffer spring is compressed until the ends of the pin in the piston rod pass through the slots in the guide. The piston rod then is given a one-quarter turn and the pin is allowed to seat in its notches in the guide. When assembled, the guide key must be in line with, and to the right of, the notch in the piston rod when viewed from the rear with the notch cap.

If the barrel-buffer-body spring lock has been removed, it should be forced fully into its undercut groove in the side of the barrel-buffer body with the staking notch out and leading, and body is staked into the notch.

With the barrel-buffer body bottom side up, the tube-lock assembly is positioned over the groove in the bottom of the body with the bowed side away from the body. With the flanges of the lock-body over the enlarged cut in the groove, the lock-body is depressed into the cut and slipped forward. The tube-lock assembly is pushed forward until the tube-lock latch can be depressed into the circular opening in the tube-lock groove.

The barrel-buffer body is turned top-side up, and the accelerator placed with the tips up and rounded surfaces to the front in position in the front of the body; the accelerator pin then is inserted, taking care that both ends of the pin are flush with the sides of the body.

The barrel-buffer assembly is inserted into the body, from the rear, with the key in the guide engaged in the slot in the right side of the body, and pushed all the way forward. When assembled, the notch in the piston rod should be up, and the tube lock on the body down. The air port in the buffer tube should be down, although it will function in any position.

Installation

If removed, the barrel and barrel extension are inserted into the receiver until the lower projection on the barrel extension contacts the bottom plate. The barrel buffer assembly must be pushed all the way forward in the barrel-buffer body with the notch in the piston rod up (Figure 2-41). The barrel-buffer body is held in the right hand with the index finger holding up the accelerator. With the

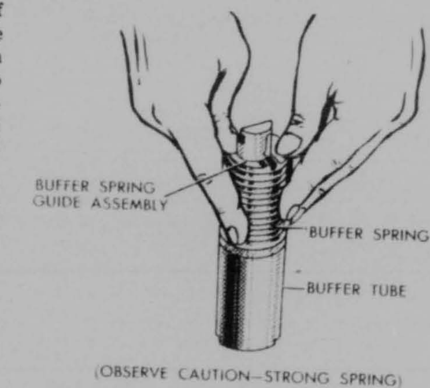

Figure 2—40. Removing Buffer Spring Without Use of View.

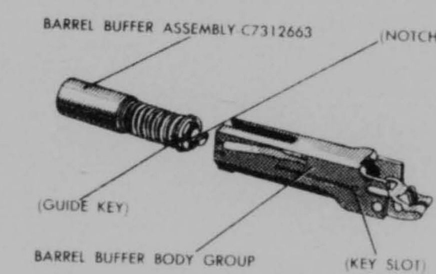

Figure 2—41. Correct Position of Barrel Buffer Assembly for Insertion Into Body.

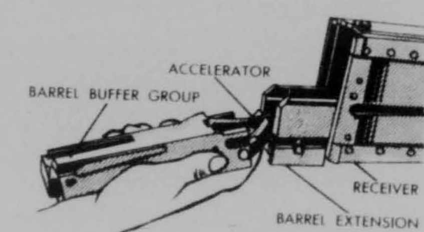

Figure 2—42. Installing Barrel Buffer Group.

rear end of the barrel buffer group slightly depressed, notch in the piston rod is engaged with the barrel-extension shank (Figure 2-42). The tips of the accelerator are engaged with the shoulders of the barrel-extension shank, and the barrel-buffer group pushed

THIS PAGE IS DECLASSIFIED IAW EO 13526

forward as far as it will go, thus rotating the accelerator upward and to the rear to lock the barrel extension to the barrel buffer group. The tips of the accelerator are pressed down to insure complete locking.

With the groups thus locked together, the rear end is raised until clear of the bottom plate. Then, engaging the breech lock depressors on the side plates with the depressor grooves in the buffer body, the groups are pushed forward until locked in position by the barrel-buffer-body spring lock snapping into its recess in the receiver. If the groups do not move forward readily, a check must be made to assure that the barrel-buffer-tube lock assembly is properly positioned in the bottom of the barrel-buffer body. The barrel-buffer guides (on rear sides of body) must enter the grooves in the receiver. The assembly must not be forced.

The bolt group and backplate group then are installed.

4. BARREL AND BARREL-EXTENSION GROUP

Removal

The following are removed in sequence: backplate group; bolt group; barrel-buffer group; barrel and barrel extension group, by pulling it out through the rear receiver.

Disassembly (Figures 2-18 and 2-19)

The barrel is removed by unscrewing it from the barrel extension.

Note: The barrel locking spring should be slightly raised to minimize wear of notches and the spring when turning the barrel. It should not be forced.

The breech-lock pin is pushed out and the breech lock removed.

The barrel-locking spring is staked in position and should not be removed unless replacement of the spring is necessary. It may be driven out by using a drift pin inserted in the small hole near the rear of the spring.

Assembly (Figures 2-18 and 2-19)

If the barrel-locking spring has been removed, it should be inserted in its recess with

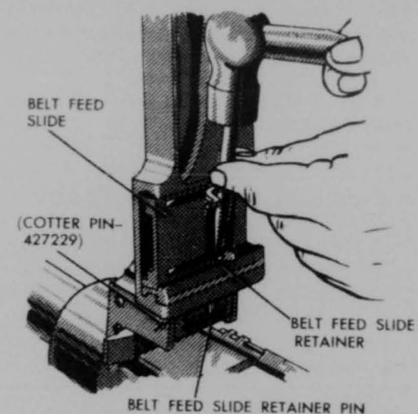

Figure 2—43. Removing Belt Feed Slide Retainer Pin.

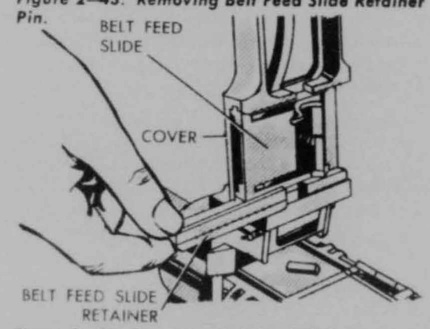

Figure 2—44. Removing Belt Feed Slide Retainer.

the protrusion inside, pushed back as far as it will go, and staked in position.

The breech lock is slipped into its slot in the barrel extension with the beveled face to the front and the notch on top. The pin is inserted so that both ends are flush with the sides of the barrel extension. The spring must be firmly seated in the pin, and retain the pin, when assembled.

The barrel is screwed into the barrel extension, and then back out eight or ten notches to facilitate assembly of the group into the gun.

Note: With the barrel screwed all the way into the extension, the recoiling parts will not go fully into battery, and difficulty may be encountered when installing the barrel, bar-

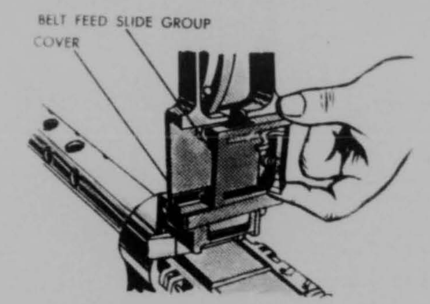

Figure 2—45. Removing Belt Feed Slide Group.

rel extension, and barrel-buffer group. No attempt should be made to operate the gun until the headspace has been adjusted and checked.

Installation

The assembled barrel and barrel-extension group are inserted into the rear end of the receiver until the lower projection on the barrel extension contacts the bottom plate. The barrel-buffer group is assembled to the barrel extension. These parts are then raised to clear the bottom plate, and pushed forward in the receiver until locked in position by the buffer-body spring lock. The bolt group and backplate group are then installed.

5. COVER GROUP

Disassembly (Figures 2-20)

With the cover raised, the belt-feed-slide retainer pin is driven out toward the hinge by inserting a drift in the half round hole appearing in the belt-feed slide retainer (Figure 2-43).

The belt-feed slide retainer is withdrawn from the cover (Figure 2-44) and the belt-feed slide group lifted out of its seat. (Figure 2-45)

The front end of belt-feed lever is aligned with the slot in the cover and the lever lifted off at the stud. Care must be taken so as not to lose the belt-feed lever plunger and spring.

The belt-feed lever plunger and spring are removed from the hole in the lever.

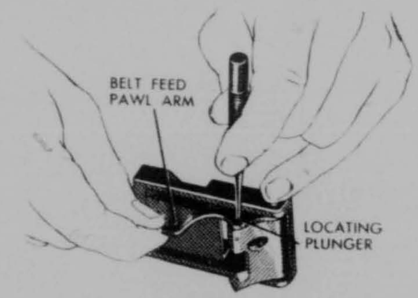

Figure 2—46. Depressing Locating Plunger to Remove Belt Feed Pawl Arm.

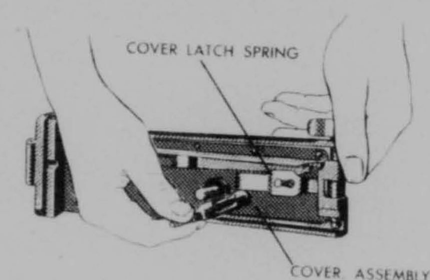

Figure 2—47. Removing Cover Latch Spring.

Using a drift pin, the belt-feed pawl-arm locating plunger (in center of arm) is depressed, and the arm slipped away from the belt-feed pawl pin to disengage it from the groove in the pin (Figure 2-46). The pawl is held down against the spring pressure, the pawl pin is pushed out and the pawl and springs removed from the slide. When it is necessary to remove the belt-feed pawl-arm locating plunger, the locking pin is driven out of the pawl and the plunger and spring removed. Care should be taken to see that the plunger does not fly out.

The end of the cover-latch spring is lifted out of the groove in the cover (Figure 2-47) and this lifted end is turned slightly so that it rests on the cover-extractor spring. The cover-latch spring is compressed by firm pressure of the thumb, and the spring slipped away from the latch and removed.

The cover-extractor spring is held with

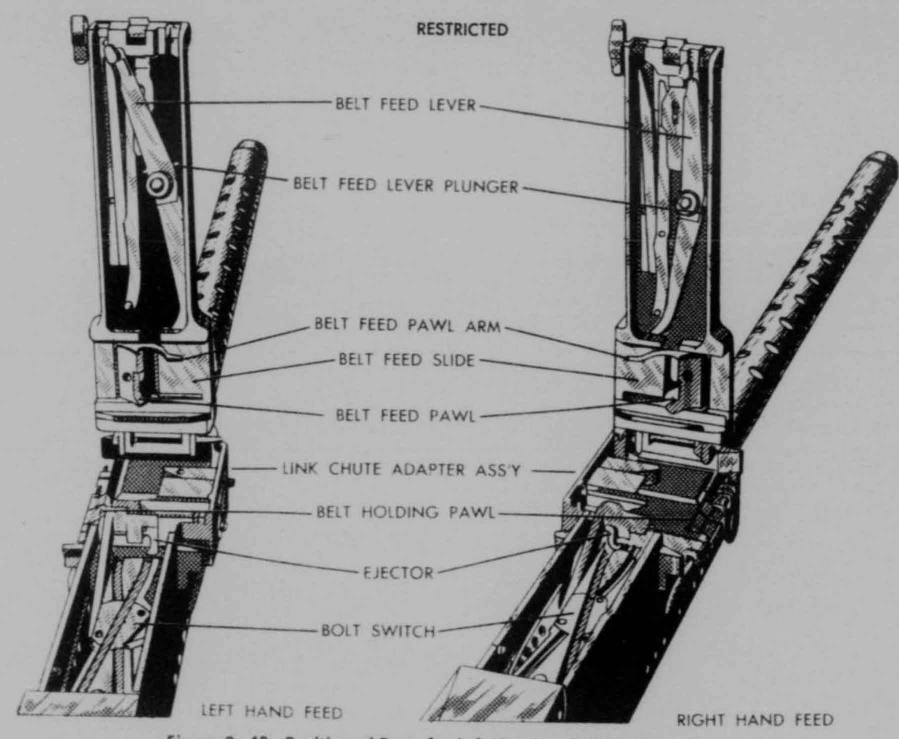

Figure 2–48. Position of Parts for Left-Hand and Right-Hand Feed.

the thumb to keep it from flying out, and the rear end of the spring is pried laterally out of its retention recess in the cover extractor cam. The spring is removed by disengaging it from the holding stud at the opposite end.

To remove the cover latch, the shaft cotter pin and washer are removed, the latch shaft is turned to the latched position, and the shaft is withdrawn from the cover.

Assembly (Figure 2-20)

To assemble the latch to the cover, the latch is placed between the shaft bosses on the under side of the cover with the keyway toward the top of the cover and with the projecting wing of the latch against the under side of the cover; the shaft may be installed from either side but, for convenience, the shaft lever should be on the opposite side from the charger or other bolt-retracting device, to provide clearance. The latch shaft assembly is inserted with the key on the shaft toward the cover. The washer is placed on the shaft and secured by inserting the cotter pin with the head toward the hinged end of the cover. The ends of the pin are bent closely against the shaft to avoid interference when latching the cover.

The cover extractor spring is installed by hooking the slotted end under the extractor-spring stud, with the curved end away from the cover. The spring is held firmly against the stud, the curved end is depressed, and engaged in the retention recess in the cover extractor cam.

The cover latch spring is placed inside the cover with the bent end against the cover and the enlarged hole over the extractor spring stud. The latch end of the spring must ride over the projecting wing of the latch, the spring must be depressed and, at the same time, the spring must slide toward the latch.

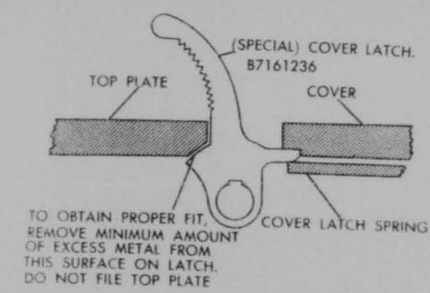

Figure 2–49. Cover and Top Plate with Special Cover Latch in Position—Sectional View.

The bent end of the spring is snapped into the lateral groove in the cover.

The belt-feed lever spring and plunger is placed in the top hole of the belt-feed lever (cover open) for left-hand feed (bottom hole for right-hand feed), as shown in Figure 2-48. The hole in the center of the lever is placed over the belt-feed-lever pivot stud in the cover and the toe of the lever is positioned in the slot in the hinge end of the cover. The lever is pressed down on the stud until seated against the cover, with the plunger bearing on the side of the cover.

If the belt-feed pawl-arm locating plunger and spring have been removed from the pawl, the spring is placed in the plunger hole in the pawl, the plunger is pressed in over the spring (large diameter leading) so that the cut in the plunger and pin hole in the pawl align; the locking pin then is inserted. The plunger must function smoothly when depressed and released, and both ends of locking pin must be below the faces of the pawl.

When assembled, the belt-feed slide group must be seated in the cover with the belt-feed pawl toward the side from which ammunition is to be fed. The feed pawl must be assembled in the slide so that the feed-pawl-arm locating plunger is toward the latch end of the cover when the slide group is seated in the cover. The feed-pawl arm must be assembled to the pawl so that the convex curve of the free end of the arm is away from the cover. This assembly will place the feed-pawl arm to the rear of the pawl, with the curve of the free end pointing down, when the cover is closed. Proper assembly for both left-hand and right-hand feed is shown in Figure 2-48. To assemble the slide group the procedure is as follows:

The small end of the outer (large) belt-feed pawl spring is seated over the spring stud in the slide, and the inner (small) spring is seated inside the outer spring. The pawl then is placed in the slide with a spring seat recess directly opposite the spring stud in the slide, so that the free ends of the springs seat squarely in the spring-seat recess in the pawl; the pawl is pressed down on the springs until the pawl holes in the slide and pawl align. The pawl pin, grooved end leading, is pushed through the slide and pawl, from the side opposite to the arm locating plunger in the pawl.

The flat of pawl arm is pressed down on the arm-locating plunger in the pawl to depress it, and the forked end of the arm is slipped toward the groove in the pawl pin until the fork seats in the groove and the locating plunger snaps through the hole in the arm.

The assembled slide group is placed in its way (groove) in the cover with the pawl end of the slide toward the side from which the gun is to be fed, engaging the end of the belt-feed lever in its seating recess in the slide. The belt feed slide retainer is slipped into its ways in the cover, the pin hole is aligned in the retainer and cover and the belt-feed slide retainer pin inserted from the bottom (cover raised). The slide is operated by moving the feed lever to see that there is no binding. With the cover closed, a check is made to see that the feed pawl is on the side from which ammunition is to be fed, and the pawl arm is to rear of the pawl convex curve of free end pointing down.

Installation

Special Cover Latch. A special cover latch (Figure 2-49) is available for use in some installations. This latch differs from the standard latch in that it has a projecting prong, so that when link jams occur, the operator may open the cover by operating the cover latch itself, without removing his gloves. (The standard latch is operated by turning the cover-latch shaft lever which is difficult to

THIS PAGE IS DECLASSIFIED IAW EO 13526

reach in some installations without the operator first removing his gloves.)

If this special latch is to be installed in place of the standard latch, a slight amount of fitting may be required. When necessary, excess metal should be removed from the latch at the point shown in Figure 2-49. (No metal should be removed from the top plate.) A minimum amount of metal should be removed, so that looseness does not exceed approximately 0.008 inch. Looseness may be measured by inserting a feeler gauge between the rear of the latch and top plate, with the cover latched. The same fitting should be done, when necessary, to a new, standard latch when assembled.

6. RECEIVER AND BARREL-JACKET GROUP

Disassembly (Figure 2-21)

The belt-holding pawls, sleeve, and springs are removed by withdrawing the belt-holding pawl pin, with care being taken not to lose the springs. If the spring in the end of the pin does not cam down freely, it should be depressed before withdrawing the pin. It should not be forced.

The link-chute adapter assembly is removed by lifting it straight up from the belt-holding pawl pin. If necessary, the pin is withdrawn as explained above.

The cover detent pawl is removed with the spring assembly by pulling the pawl up out of the trunnion block. The spring should not be removed from the pawl. If the trunnion block cover is to be removed for the installation of a sight, it can be detached by driving out the lateral pins.

To remove the (extractor) switch, the cotter pin is pulled from the switch-pivot nut, the nut is unscrewed and the switch and switch spring pulled out.

To remove the breech lock cam the cotter pin is pulled out of the breech-lock cam bolt which protrudes through the bottom plate of the receiver, and the nut is removed. The breech-lock cam bolt and cam are withdrawn from the inside of the receiver.

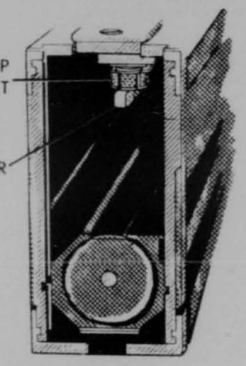

Figure 2–50. Trigger Bar Adjustable Stop Assembly, Assembled in Receiver—Rear View.

Note: The breech-lock cam should not be removed, except for replacement or when cleaning is imperative.

The trigger-bar pin assembly is removed by lifting the lock until it is perpendicular to the side plate and by rotating the pin about 90 degrees. The projection on the pin which forms a key will then pass through the keyhole in the side plate and the pin can be removed by pulling it out from the gun. When the pin is removed, the trigger bar is free. The trigger bar then is removed from inside the receiver.

To remove the trigger-bar adjustable-stop assembly from the rear of the receiver, the retaining screw is removed from the rear of the top plate and the assembly is pulled down off the rear trigger-bar stop which serves as a positioning pin. To disassemble the assembly, the adjusting nut is unscrewed and the spring removed.

The recoil booster is removed by unscrewing the two screws locking the booster to the barrel jacket and unscrewing the booster from the jacket.

When assembled, the trunnion adapter may be removed by pulling the trunnion-block lock, located in the under side of the trunnion block, to the rear and giving it a one-quarter turn so that the projecting cotter pin will hold it out of engagement with the adapter. The adapter then is unscrewed and removed together with the shim. The cotter pin in lock must not become bent or loose, or the lock cannot be retracted or held in the disengaged position.

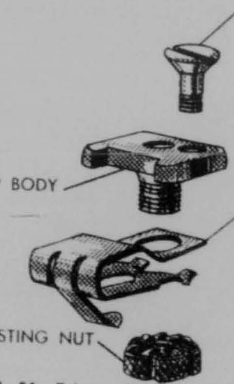

Figure 2–51. Trigger Bar Adjustable Stop Assembly—Exploded View.

The recoil adapter assembly, when used in place of the trunnion adapter, may be removed in a similar manner as described above.

Assembly (Figure 2-21)

The recoil booster is screwed into the barrel jacket until the holes in the jacket and booster are in alignment. It is inserted, tightened, and the two screws staked.

To install the trigger bar adjustable stop assembly (Figures 2-51 and 2-21) the stop body is positioned on the rear trigger-bar stop (pin) and fastened by threading the retaining screw through the top plate cover, top plate, and stop body, and stake screw (Figure 2-50). The adjusting-nut spring is seated in the body with prongs forward and down, and the nut threaded onto the body with notches up. When assembled, the end of the screw must not interfere with level seating of the spring in the body, and the prong of the spring, which cushions the trigger bar, must not be distorted.

The trigger bar is placed with the long end forward and the bowed surface upward, between the top-plate bracket and the bolt-latch bracket, and held up firmly. When positioning, the trigger bar should project approximately $\frac{5}{16}$ inch beyond the rear trigger bar stop. With the trigger bar held in that position, the lock of the trigger bar pin assembly is raised in line with the pin, the pin is inserted through the left side plate with care being taken to match the key on the pin with the keyhole in the side plate. After insertion, the lock is rotated 90 degrees until stopped by the flange of the top plate and the lock is pushed down flat against the side plate.

If the breech-lock cam has been removed or has to be replaced, it should be placed in the receiver with the cam surface up and sloping to the rear. The lower projection of the cam is placed through the hole in the bottom plate and the breech-lock cam bolt is inserted from the top. The castellated nut is screwed on the bolt with the notches (castellations) toward the bottom surface of the bottom plate, and drawn tight. The nearest castellation in the nut is lined with the cotter pin hole in the bolt and the cotter pin inserted. Prongs of the pin are spread and bent snugly around the nut. The head of the cam bolt must not project above the cam.

To install the (extractor) switch, the bent end of the switch spring is first inserted into the small hole in the switch recess in the inner face of the left side plate, with the long end of the spring outside and above the recess. The switch pivot then is started into its hole in the side plate, so that the lug on the switch is above the spring. Then, making sure the lug on the switch rides on top of the spring, the switch is rotated downward and pressed against the side plate until the spring and switch snap into the recess. The nut is threaded onto the projecting pivot and drawn up snugly, but it must not be forced. The nut is loosened slightly if necessary to line up the notches (castellations) in the nut with the hole, in the pivot. The cotter pin is inserted and the prongs bent snugly around the nut to prevent interference. The switch is checked to see that it pivots freely, snaps back into position, and that there is no unnecessary side play. Figure 2-52 shows the switch and spring in assembling position in the receiver.

The cover-detent pawl assembly is inserted spring first into its hole in the trunnion block, and pawl is seated laterally in the block. If the trunnion-block cover has been removed, it should be placed in position and the two pins inserted.

For left-hand feed, the belt-holding pawls

THIS PAGE IS DECLASSIFIED IAW EO 13526

are placed in position on the left side of the receiver and vice versa. The right-hand and left-hand pawls are placed on the belt-holding pawl sleeve, the springs are seated in the holding-pawl bracket, the assembled pawls and sleeve are placed in position over the springs so that springs seat in pawls and secured with a belt-holding pawl pin. The pin is pushed home until securely locked, and the handle is turned down.

The remaining belt-holding pawl pin is inserted securely in the opposite bracket and the link-chute adapter assembly (Figure 2-53) placed in position on the pin with the curved front stop forward. Figure 2-11 shows the belt-holding pawls and link-chute adapter installed for right-hand feed. The link-chute adapter is always installed on the opposite side of the feedway from the belt-holding pawls. When in position the curved front stop should be forward and the long end of the cartridge guide up (Figure 2-11). Position of the guide can be changed by removing the screws, withdrawing and reversing the guide, and then, replacing the screws tightly. In adapters of recent design there is only one positioning ball in the front stop of the adapter. This ball should be on top when the adapter is installed. To change position of the ball, the positioner assembly containing the ball is pushed out from the side opposite the ball, and then reseated in the opposite side of the stop.

If the trunnion adapter has been removed, it may be installed by disengaging the trunnion-block lock, and then placing the shim in position and screwing on the adapter. If, when the adapter is snugly screwed on, the hole in adapter does not align with the lock, a thicker shim is used. (Shims are numbered according to their thickness.) With shim and adapter aligned, the trunnion-block lock is given one-quarter turn and allowed to seat in the hole in the adapter. The lock must pass through the shim and must be fully seated in the adapter; the cotter pin in the lock must not be bent or broken or the lock may stick, so that it cannot be retracted.

The recoil adapter, when used in place of the trunnion adapter, may be installed in a manner similar to that described above with the exception that no shims are used.

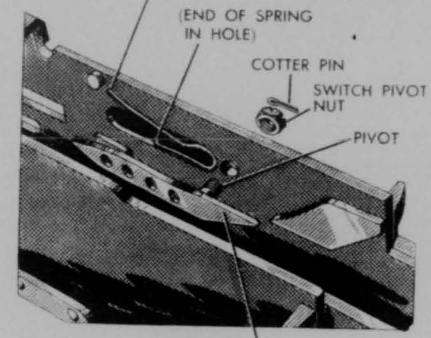

Figure 2–52. (Extractor) Switch and Switch Spring in Assembling Position.

7. CHANGING FEED

In order to change the gun from left-hand feed to right-hand feed, or vice versa, repositioning of parts must be carried out in the bolt group, cover group, and certain parts in the receiver, as shown in Figure 2-48. The following describes, in general terms, the change from left-hand feed to right-hand feed. By reversing the process, the gun may be changed from right-hand feed to left-hand feed (Figure 2-48).

Bolt Group

The bolt group is removed from the gun, the extractor assembly, and the cocking lever from the bolt.

The spring-loaded switch stud is depressed using a drift and, by means of a cocking lever or other tool (Figure 2-32), the switch is rotated until the stud engages the opposite hole. The cam groove in the bolt switch will then line up to make the groove bolt marked "R" (right) continuous. The cocking lever is then replaced in the bolt.

Note: When assembled for right-hand feed, the enlarged portion of the bolt switch is toward the rear of the bolt.

The ejector is removed from the extractor and reversed so that the claw is on the left side when viewed from the rear (Figure

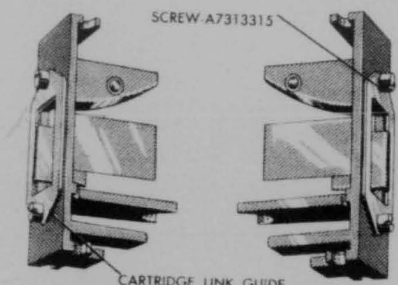

Figure 2–53. Link Chute Adapter Assembly (C7313314) Assembled for Right-Hand and Left –Feed Top View.

2-35). The ejector spring is reversed so that it is on the same side of the ejector pin as the ejector claw.

The ejector is reassembled, the extractor assembly is assembled to the bolt, and the bolt group replaced in the receiver.

Note: The square end of the sear slide must be on the side from which the weapon is to be fired. If necessary, the sear slide, sear slide stop pin, and cocking lever pin should be repositioned on the opposite side of the bolt.

Cover Group

With the cover open, the belt-feed slide retainer and the belt-feed slide group is removed from the cover.

The belt-feed lever is removed and the belt-feed lever plunger and spring transferred from the upper hole (cover open) in the belt-feed lever to the lower hole.

The belt-feed lever is reinstalled, the belt-feed slide group is reversed and replaced in its groove in the cover with the pawl end of the slide toward the right. The belt-feed slide retainer is then reinstalled.

The belt-feed pawl-arm locating plunger is depressed in the pawl (Figure 2-46) and is withdrawn.

The slide is pushed to the right and held so that the belt-feed pawl pin can be pushed out of place; the belt-feed pawl pin, belt-feed pawl, and springs are removed from the slide. Care should be taken not to lose the springs.

The belt-feed pawl is repositioned by turning it over so that the spring seat in the opposite side aligns with the stud for the belt-feed pawl springs.

The belt-feed pawl and springs are reassembled to the belt-feed slide and secured by inserting the pin from the bottom, with grooved end leading.

The belt-feed pawl arm is reversed, the locating plunger is depressed in the pawl, and the arm slipped over it so that the notch in the end of the arm engages the groove in the pawl pin and the plunger seats in the hole in the arm.

Receiver Group

The link-chute adapter is lifted from its belt-holding pawl pin, and the pin is removed from the bracket on the side plate.

The remaining belt-holding pawl pin is removed from the other bracket and the belt-holding pawls, sleeve, and springs removed.

The belt-holding pawls, sleeve, and springs are assembled to the right-hand side of the receiver.

The link-chute adapter assembly is assembled for right-hand feed and installed on the left side of the receiver, after having installed the remaining belt-holding pawl pin.

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION III—CYCLIC FUNCTIONING OF THE GUN

1. GENERAL

Cyclic functioning of the aircraft machine gun cal. .50, M3 is identical with that of the Browning aircraft machine gun, cal. .50, M2. The barrel buffer of the gun M3 takes the place of, and functions in the same general manner as, the oil buffer of the gun M2. In the barrel buffer of the gun M3 the washer springs and air compression feature take the place of the oil and valve system of the oil buffer of the gun M2.

The gun M3 may be fired by means of a top-plate solenoid acting upon the sear through the medium of a trigger bar, or by a side-plate solenoid, trigger motor or other device acting upon the sear through the medium of the sear slide. In any case, the functional operation of the gun is the same. For clarity, the illustrations in this section show the sear operated by a trigger bar.

Each time a cartridge is fired, the mechanical action within the gun involves many parts moving simultaneously or in their proper order. The action of these parts, and their relationship one to the other, can be explained more clearly if each cycle of operation is divided into various phases. These phases will be explained in the following paragraphs of this section in the order indicated in d below. Familiarity with the construction of the gun and function of its component parts and groups, as explained in sections pertaining to the groups, is necessary to a thorough understanding of the cyclic functioning of the gun as a whole. A clear understanding of the following explanations may be gained by hand operation of a gun, using dummy ammunition. Figure 2-54 shows a cutaway view of the unloaded gun with the recoiling parts in the forward or "battery" position.

For convenience and clarity, cycles of operation are divided into the following phases and explained in the order indicated.

Firing

Automatic Firing

Recoiling

Feeding

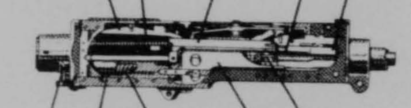

Figure 2–54. Receiver Section of Gun—Cutaway View.

Counterrecoiling

Extracting

Ejecting

Cocking

2. FIRING

When the gun has been loaded and the firing pin has been cocked, the firing pin and extension engages the sear. The firing mechanism of the gun is made ready to be fired by disengaging the sear from the firing-pin extension. In this case, the trigger bar will be rotated on its pin to depress the sear by a linkage with the top-plate solenoid when operated.

If the gun is fired by means of a top-plate solenoid and trigger bar, the firing-pin extension and firing pin is released by actuating the solenoid. When the plunger of the top-plate solenoid acts on an actuating lever assembled to the trigger-bar pin assembly, the lever presses down on the forward end of the trigger bar, causing the front end of the trigger bar to press down on the top of the sear.

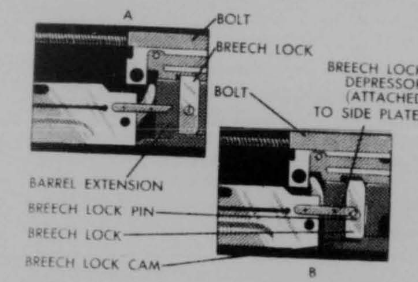

Figure 2–55. Breech Lock Locked "A" and Unlocking "B".

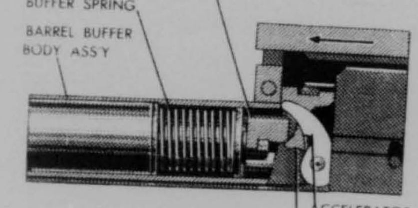

Figure 2–56. Buffer Spring Compressed and Held By Locked Barrel Extension—Bolt Still Moving Rearward.

The sear is forced downward until the notch in the sear is disengaged from the shoulder of the firing-pin extension. The firing pin and firing-pin extension are driven forward by the firing-pin spring to fire the cartridge.

If the gun is fired by means of a side-plate solenoid, the trigger motor or other device, when actuated, is forced against the sear slide. The sear slide, moving laterally, cams down the sear and the firing pin is released to fire the cartridge as explained above.

3. RECOILING

The complete cycle of the recoiling parts of the gun, which takes place as each cartridge is fired, consists of the recoil movement when certain parts move rearward, and the counter-recoil movement when the same parts move forward. At the instant the first shot is fired, the barrel, barrel extension, and the bolt, known as the "recoiling parts," are in the fully forward or "battery" position in the gun.

At this time the bolt is locked to the barrel extension and held securely against the rear of the cartridge in the chamber of the barrel by the breech lock, which extends up from the barrel extension into a notch in the under side of the bolt. The breech lock is held up by the breech-lock cam upon which it rests. "A" (Figure 2-55) figure shows bolt locked.

After the cartridge explodes and as the bullet travels out of the barrel, the force of recoil drives the recoiling parts rearward. During the first $5/8$ inch of rearward travel, the breech lock is moved off the breech-lock cam step. This permits the breech lock to be forced down out of the notch in the bolt by the breech-lock depressors engaging the breech-lock pin. This unlocks the bolt from the barrel extension. "B" (Figure 2-55) shows beginning of unlocking action.

As the recoiling parts move toward the rear, the barrel extension bears against the accelerator and rotates it rearward. The tips of the accelerator strike the lower projection on the bolt and accelerate the bolt to the rear.

The barrel and barrel extension have a total rearward travel of $1\frac{1}{8}$ inches at which time they are completely stopped by the barrel-buffer body.

During this recoil, the buffer spring in the barrel buffer is compressed by the rearward movement of the barrel extension, transmitted through the barrel extension shank to the buffer piston rod with which it is engaged. The spring is held in the compressed position by the barrel extension (Figure 2-56), locked by the claws of the accelerator which are moved against the shoulders of the barrel extension shank. The buffer spring assists the barrel-buffer piston in bringing the barrel and barrel extension to rest during the recoil movement.

During recoil, the barrel-buffer piston is forced from the forward end of the barrel-buffer tube to the rear, compressing the air confined in the tube to the rear of the piston. The piston starts rearward rapidly due to an air port or hole in the wall of the barrel-buffer tube within which it moves. The port allows

THIS PAGE IS DECLASSIFIED IAW EO 13526

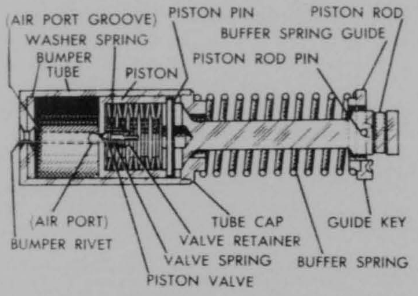

Figure 2—57. Barrel Buffer Assembly with Piston in Forward Position—Sectional View.

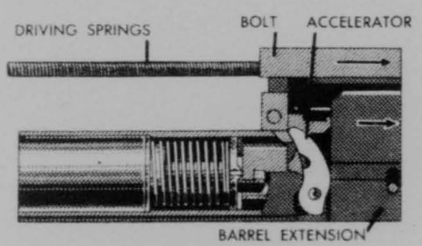

Figure 2—58. Bolt Striking Accelerator to Release Barrel Extension and Buffer Spring.

some air in the tube to escape quickly-at the start of the rearward movement of the piston. As the piston moves beyond the port, the remaining air in the tube is gradually compressed, thus forming a cushion. As the compression increases, the compressed air escapes into the piston through a spring-operated relief valve in its rear end. The escaped air then passes through the piston and out of the buffer tube through the enlarged rod hole in the tube cap. The valve regulates the flow of escaping air so that the rearward movement of the barrel extension and barrel is decelerated gradually. The opening of the relief valve is controlled by a spiral spring seated in a retainer in the piston. The retainer is held in place by ten cupped washer springs assembled in the piston, which bear upon the retainer and the rear face of the piston rod and act as a cushion for the rod at the end of the rearward movement. No terminal shock is transmitted to the buffer piston pin or piston rod due to the elongation of the pin hole in the rod. Figure 2-57 shows construction of the barrel-buffer assembly.

The bolt travels rearward for a distance of 7.2 inches plus compression of the buffer pile in the backplate. During this travel, the driving springs are compressed. The rearward movement of the bolt is finally stopped as the bolt strikes the buffer plate in the backplate. Thus, part of the recoil energy of the bolt is stored in the driving springs, and part is absorbed and stored by the cupped washer springs upon which the buffer plate bears, in the backplate tube. Any remaining recoil energy is transmitted to the recoil adapter on the gun or on the gun mountings and therefore the recoil mechanisms.

4. COUNTERRECOILING

After completion of the recoil movement, the bolt is forced forward by the energy stored in the driving springs and the compressed backplate buffer washer springs. When the bolt has moved forward about 5¾ inches, the projection on the bottom of the bolt strikes the tips of the accelerator and rotates it forward (Figure 2-58). This rotation moves the claws of the accelerator away from the shoulders of the barrel extension shank. This releases the (barrel) buffer spring. The energy stored in the spring, supplemented by the counterrecoil energy of the bolt transmitted through the accelerator, forces the barrel and barrel extension forward.

No restriction to the forward motion of the barrel and barrel extension is desired: therefore, on the forward movement the air ahead of the piston in the barrel-buffer tube is allowed to escape through the enlarged hole in the tube cap through which the piston rod passes. As the piston nears its forward position, the air port in the tube is uncovered, allowing air to enter the rear end of the tube and relieve the vacuum created by the forward movement of the piston.

Note: Air is permitted to leave and enter the port in the barrel-buffer tube through a longitudinal groove in the tube. This groove extends from the port to the rear end of the tube.

As the barrel extension moves forward, the breech lock engages the sloping ramp of the breech lock cam and is forced upward. The bolt, which has been continuing its forward motion since striking the accelerator, has at this instant reached a position where the notch in the under side of the bolt is directly above the breech lock, permitting the breech lock to enter the notch and engage the bolt. Thus the bolt is locked to the barrel extension just before the recoiling parts reach the firing position.

5. COCKING

The act of cocking the gun begins as the bolt starts to recoil immediately after firing. As the bolt moves rearward, the tip of the cocking lever, which is in the V-slot in the top plate bracket, is forced forward. Since the cocking lever pivots on the cocking lever pin, the lower end, which engages in a slot in the firing-pin extension, is forced rearward, thereby pulling the firing-pin extension and firing pin rearward and compressing the firing-pin spring against the pin of the firing-pin spring stop. The shoulder on the rear end of the firing-pin extension forces the sear downward, against its spring, and continues to travel rearward until slightly beyond the front face of the notch in the sear. The sear is then immediately forced upward by the sear spring to a position where it will engage the shoulder on the firing-pin extension when it starts moving forward again. Figure 2-59 shows position of the bolt and its components during the rearward movement.

During the forward movement of the bolt, in counterrecoil, the tip of the cocking lever again enters the V-slot in the top-plate bracket and is forced rearward. This action swings the lower end of the cocking lever forward out of engagement with the firing-pin extension which moves forward so that its shoulder is engaged and held by the sear. The cocking lever acts as a safety device to prevent the firing-pin extension and firing-pin, if released prematurely, from moving fully forward to fire the cartridge before the bolt has gone forward sufficiently for the breech lock to be engaged, and thus lock the bolt to the barrel extension. When the recoiling parts

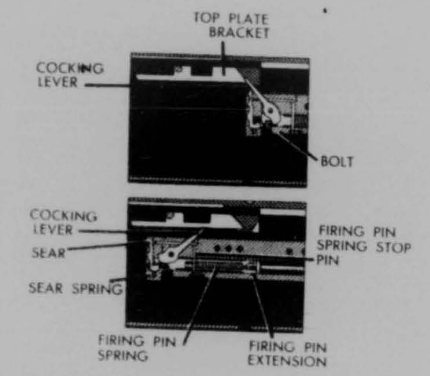

Figure 2—59. Action of Cocking Lever During Recoil.

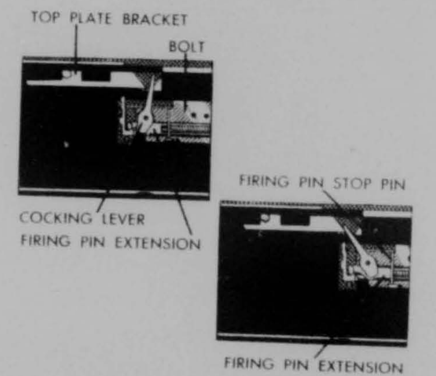

Figure 2—60. Action of Cocking Lever During Counterrecoil.

are approximately .116 inch to .120 inch from the fully forward "battery" position, depending on the "timing" of the gun, the gun is ready to fire. If, at this instant, the sear is not depressed, the recoiling parts will assume their fully forward "battery" position and the gun ceases to fire. Figure 2-60 shows the bolt and its components during the forward movement.

Automatic Firing

For automatic firing by means of a top-plate solenoid, the solenoid must be operated

THIS PAGE IS DECLASSIFIED IAW EO 13526

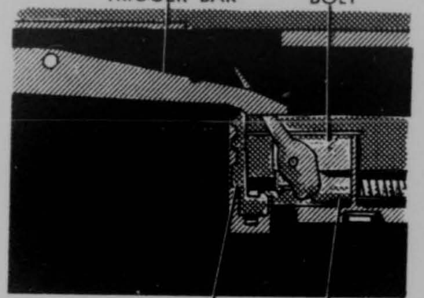

Figure 2–61. Automatic Firing—Sear Depressed by Held-Down Trigger Bar at End of Counterrecoil Movement.

so that the lever moves the end of the trigger bar downward and is then held in that position. The sear is depressed as its top is carried against the cam surface of the depressed trigger bar by the forward movement of the bolt near the end of the counterrecoil movement (Figure 2-61). The depression of the sear releases the firing-pin extension and the firing pin, thus automatically firing the next cartridge. The gun fires automatically as long as the solenoid action is maintained and until the ammunition supply is exhausted.

Automatic firing by means of a side-plate solenoid is accomplished in a similar manner. As the bolt nears the end of its counterrecoil movement, the end of the sear slide is engaged by the cam surface of the projecting solenoid plunger and is forced sideways. This lateral movement of the sear slide cams the sear downward, thus releasing the firing-pin extension and firing pin to fire the gun as outlined above.

Feeding

The belt-feed mechanism is actuated by the bolt. When the bolt is in the forward position the belt feed side is entirely within the gun. (See "A", Figure 2-62.) A lug on the rear end of the belt-feed lever rides in one of the two diagonal cam grooves in the top of the bolt. The forward end of the belt-feed lever engages in a slot in the belt-feed slide to which the belt-feed pawl and belt-feed pawl arm are attached.

When the bolt is moved rearward, the belt-feed lever is pivoted about the belt-feed lever pivot stud, and the forward end of the lever moves the slide out of the side of the gun over the ammunition belt, which is held in the gun by the belt-holding pawl.

When the bolt moves forward, the belt lever is again pivoted and moves the belt-feed slide into the gun. The belt-feed pawl attached to the slide engages a round of the ammunition belt and pulls the belt into the gun. By the time the bolt has reached its forward position, the belt-feed pawl has pulled a cartridge into the feedway to a central point directly above the chamber of the barrel and against the cartridge stops of the link chute adapter. At this position, the hook of the extractor is in engagement with the rim of the cartridge case. The belt-holding pawl has assumed a raised position behind a link of the ammunition belt to prevent the belt from falling out of the gun. (See "A", Figure 2-62.) Feeding during recoil and counterrecoil is as follows:

As the bolt recoils, the extractor withdraws the centered cartridge from the belt, and the belt-feed slide is moved out over the belt, and the belt-feed pawl pivots to ride over the link holding the next cartridge in the belt. (See "B", Figure 2-62).

At the end of the recoil movement, the travel of the belt-feed slide is sufficient to permit the belt-feed pawl to snap down behind the link holding the next cartridge in order to pull the belt into the gun. (See "C", Figure 2-62. The centered cartridge in this figure has been extracted from the belt.)

As the bolt moves forward in counterrecoil, the belt is pulled into the gun by the belt-feed pawl. The belt-holding pawl is forced downward as the belt is pulled over it. (See "D", Figure 2-26.) As the cartridge is positioned in the feedway, the belt-holding pawl snaps up behind the link holding the next cartridge to keep the belt from falling out of the gun. (See "A", Figure 2-62).

Note: If the cartridge in the feedway awaiting extraction from the belt fails to be

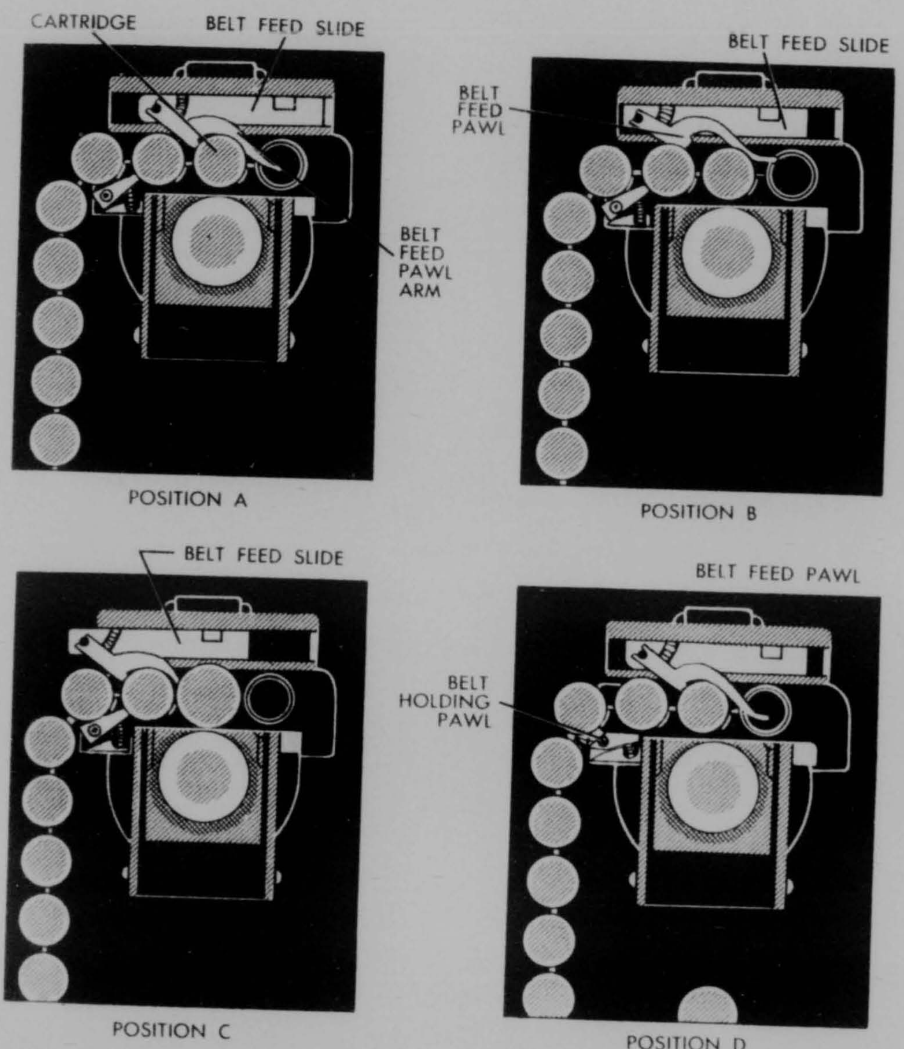

Figure 2–62. Cycle of Feeding—Showing Position of Belt Feed and Holding Pawls—Cross Section View.

extracted as the belt-feed slide starts moving out to engage and pull the belt into the gun, the belt-feed pawl arm attached to the pawl rides over this unextracted cartridge and lifts the pawl so that it cannot engage the belt. This prevents double feeding and consequent stoppage due to bent gun components.

Extracting and Ejecting

As recoil starts, a cartridge is drawn from the ammunition belt by the extractor. The empty case is withdrawn from the chamber by the T-slot in the front face of the bolt. Figure 2-63 shows a live cartridge being withdrawn from the belt by the extractor, and a fired cartridge being withdrawn from the chamber by the T-slot of the bolt, at the beginning of the recoil movement.

Note: The empty case, having been expanded by the force of the explosion, fits the chamber very tightly, and the possibility exists of tearing the case if the withdrawal is too rapid. To prevent this, and to insure slow initial withdrawal, the top front edge of the breech lock, and the front side of the notch in the bolt are beveled. Thus, before the bolt is completely unlocked, it has moved slightly away from the rear end of the barrel in a gradual manner.

As the bolt moves to the rear, the cover-extractor cam forces the extractor down, causing the cartridge to enter the T-slot in the bolt.

As the extractor is forced down, a lug on the side of the extractor rides against the top of the (extractor) switch on the side plate, causing the switch to pivot downward to the rear. Near the end of the rearward movement of the bolt, the lug on the extractor clears the end of the switch, and the switch snaps up to its normal position.

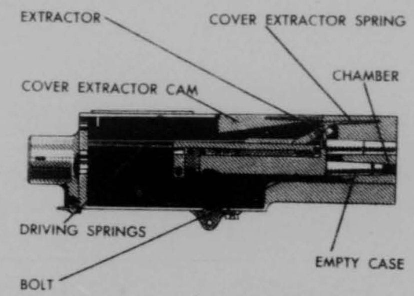

Figure 2—63. Extracting Cartridge from Ammunition Belt at Start of Recoil Movement.

On the counterrecoil movement, the extractor is forced farther down by the extractor lug riding under the (extractor) switch. This pushes the live cartridge into its correct position in the T-slot. At the same time, the live cartridge moving into place expels the empty cartridge case which has been withdrawn from the chamber. The extractor stop lug on the side of the bolt limits the downward travel of the extractor so that the cartridge, guided by the ejector, enters the chamber of the barrel. When the cartridge is partly chambered, the extractor rides up the extractor cam on the side plate, compresses the cover-extractor spring, and is forced down into the extractor groove of the next cartridge in the belt.

Note: The empty case of the last cartridge fired is forced out of the T-slot by the ejector.

SECTION IV — INSPECTION, MAINTENANCE AND REPAIR

1. GENERAL

This section contains the information needed for the performance of preventive maintenance services, scheduled lubrication, and adjustments and repair.

Cleaning and Preserving Materials

The following cleaners and preservatives are required for use with this materiel. TM 9-850 should be consulted for information additional to that contained in this manual on the use of these materials. Refer to WD Supply Catalog ORD 3, SNL K-1, for latest specifications.

Cleaner, rifle bore.

Cloth, crocus, sheets 9x11.

Cloth, wiping, cotton.

Compound, cleaning, alkaline type.

Oil, lubricating, preservative, medium.

Oil, lubricating, preservative, special.

Patches, cut, cotton flannel.

Soap, or issue.

Soda-ash.

Solvent, dry-cleaning.

Spare Parts, Tools, and Equipment

Spare Parts. A set of organizational spare parts is supplied to the using arm for field replacement of those parts most likely to become worn, broken, or otherwise unserviceable.

Tools and Equipment. Tools and equipment include items of issue required by personnel for disassembly, assembly, and cleaning and preserving of the gun. Equipment should not be used for purposes other than prescribed and, when not in use, should be properly stored in the chest and or roll provided for them.

List of Spare Parts, Tools and Equipment. Spare parts, tools, and equipment mentioned above, supplied for cal. .50 machine gun M3, are listed in WD Supply Catalog ORD 7 SNL A 67, which is the authority for requisitioning replacements.

Specially Designed Tools and Equipment

Certain tools and equipment listed in WD Supply Catalog ORD 7 SNL A 67 are specially designed for maintenance and repair operations on cal. .50 machine gun, M3. These tools and equipment are listed below for information only. This list is not to be used for requisitioning replacements.

Use of Equipment

Use of Ruptured Cartridge Case Extractor, Cal. .50, 41-E-557-50. This extractor (Figure 2-64) is designed for the purpose of extracting ruptured cartridge cases (head torn off) from the chamber of the barrel of guns equipped with Air Force chargers or like retracting devices. The use of the extractor is as follows:

The firing circuit is disconnected, the cover is raised and the gun fully unloaded. The bolt is retracted by means of the charger or other retracting device, and the ruptured cartridge extractor is placed in the T-slot of the bolt in the same manner as a cartridge so that it is held in line with the bore by the ejector of the extractor assembly of the gun. With the cover raised, it may be necessary to press the extractor assembly down by hand to align the ruptured cartridge case extractor with the bore.

When the ruptured cartridge extractor is in line with the bore and held firmly in the T-slot of the bolt, the bolt is allowed to spring forward into battery under action of the driving springs. This will force the ruptured cartridge extractor through the ruptured cartridge case and the shoulders on the extractor will spring out in front of the case.

The bolt is fully retracted by means of the

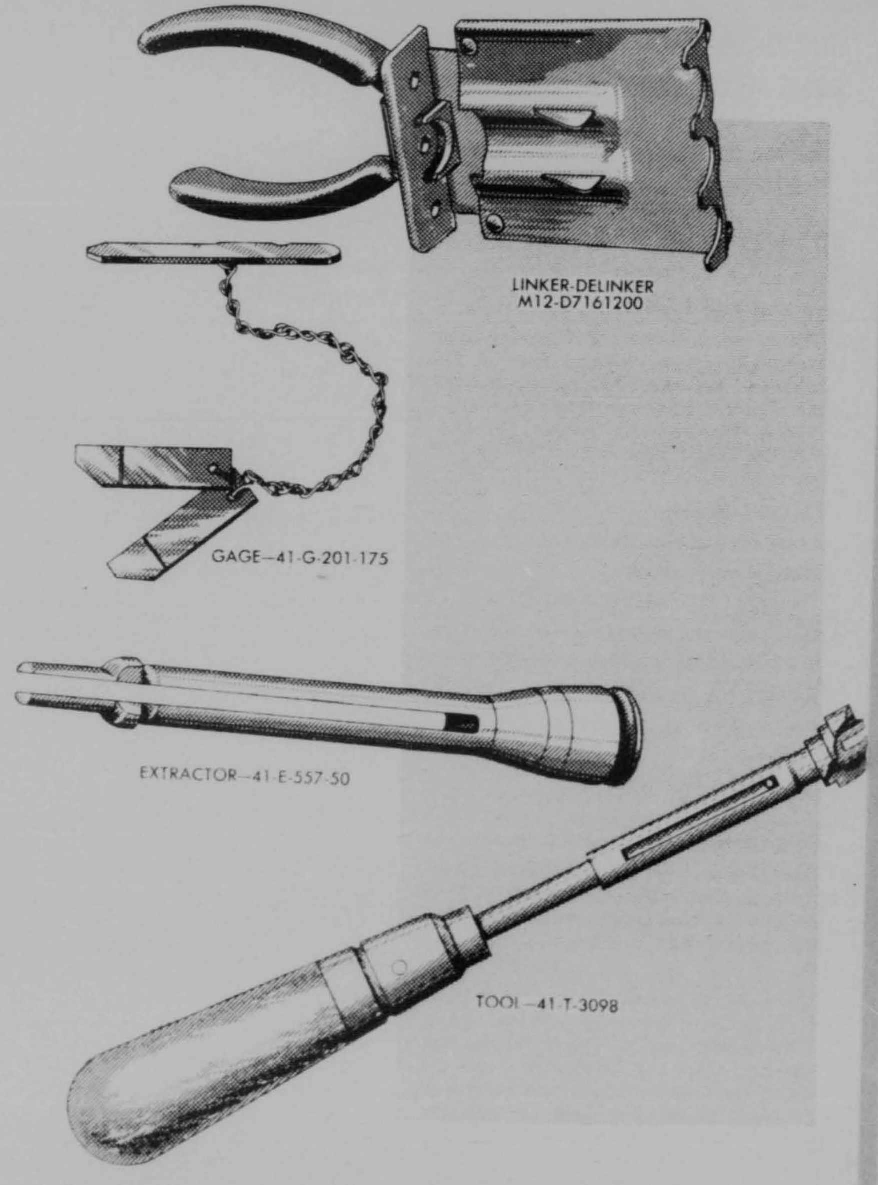

Figure 2—64. Ruptured Cartridge Extractor, Cal. .50 and Firing Pin Spring Removing Bolt.

charger or other retracting device. The ruptured case is then drawn from the chamber.

Note: If the gun is properly headspaced and timed, the ruptured cartridge extractor may be placed in the feedway, engaged with the extractor of the gun, and the cover closed. The extractor can then be fed into the T-slot like an ordinary cartridge.

Hand Cartridge Linker-delinker, Cal. .50, M12. This tool (Figure 2-65) can be used to extract a defective cartridge quickly and relink at any point in a cal. .50 metallic link belt. It will also position three cartridges. In general the tool consists of a base, slide, and handle assembly and is operated as follows:

To extract a cartridge from the link belt, the handles of the tool are spread and the extractor dog positioned (Figure 2-65) in front of the rear flange by pushing on the dog cam. The cartridge to be extracted is placed in the middle of the base with the extractor groove engaged by the extractor dog, and the rear of the link bearing upon the delinking posts, the handles are then squeezed together. The cartridge to be extracted, and the cartridge on either side, should be seated in the notches, in the front flange with the front of the links bearing upon it.

To splice two separate portions of ammunition belt, the rounds of which are held together by metallic links, a cartridge is inserted into the connecting links by hand as far as possible. The handles of the linker-delinker tool are pressed together and the extractor dog back is pressed back into its recess in the rear flange. The tool is placed under or over the cartridges so that they lie in the front-flange notches with the front of links bearing on the flange. The handles of the tool are spread as far as possible to force the cartridge fully into the links. Cartridges can be aligned in belts in a similar manner. Pivots should be lubricated occasionally, to insure smooth action, and wiped dry of excess oil.

Use of Linking-delinking Machine, Cal. .50, M7

This machine (Figure 2-66) can be used to delink and link ammunition in a cal. .50 metallic link belt. In general the machine consists of a base, handle, slide (bar) and delinker (bar), and is operated as follows:

To delink ammunition, the handle is partly raised and the belted ammunition is laid on the base with the separating pins between the cartridges and the links against the pins. The handle then is lowered until the delinker engages the extractor grooves in the cartridges, the delinker is held in position and the handle

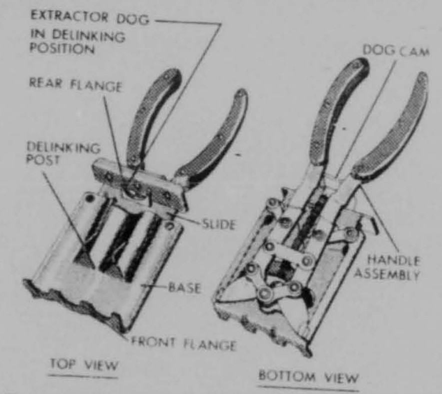

Figure 2—65. Hand Cartridge Linker-Delinker, Cal. .50 M12 (D7161200)—Showing Parts.

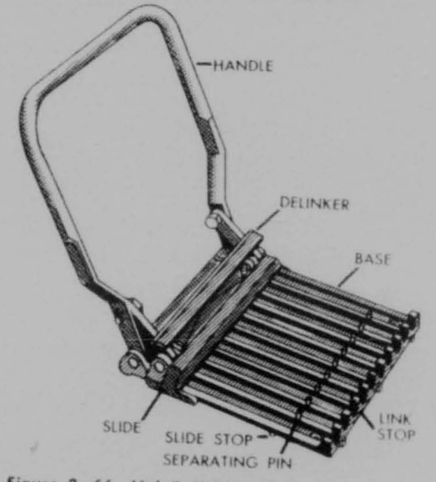

Figure 2—66. Link-Delinking Machine, Cal. .50, M7 (D7160003)—Showing Parts.

is raised. This will cause the delinker to move rearward and pull the cartridges from the links.

To link ammunition, the links are assembled and placed on the base adjacent to the U-shaped link stops, cartridges then are placed in the grooves of the base, and started into the links. With the delinker raised, the handle is lowered until the slide presses against the base of the cartridges which are then forced forward into the links. The handle is moved down until the slide is checked by the slide stops on the sides of the base. The cartridges will then be loaded to the correct depth in the links. Care should be taken to position properly that portion of the loaded belt which is adjacent to the section being loaded. Pivot pins should be cleaned and lubricated occasionally to insure smooth action and wiped dry of excess oil.

2. LUBRICATION

General Lubrication Instructions

Lubrication. To lubricate the gun prior to flight, preservative lubricating oil (special) is used. The oil prescribed insures proper functioning at all temperatures likely to be experienced during flight.

Lubrication should be accomplished carefully and sparingly. Excess oil should be wiped off. This is particularly important with regard to the bolt and rear end of the barrel of the gun in order to keep oil from getting into the chamber. Unnecessary oil or grease in the chamber of the barrel will raise the breech pressure to a hazardous point when the gun is fired and may result in a blown bolt, a ruined gun, and serious injury to personnel.

Excess oil holds grit and foreign matter blown on to it and as a result may clog the mechanism and cause a malfunction or stoppage. In any case it will cause excessive wear to the moving parts. Lubrication is best accomplished with a clean, lintless cloth saturated in the proper lubricant, wrung out, and then wiped over the surface.

Smoking of the operating mechanism of the gun when firing may indicate excessive lubrication.

Excess oil should be wiped from the bore and chamber of the barrel before firing or mounting guns for combat. Only a very light film should be used.

Note: The term "lubrication" as used in this manual applies both to the lubrication of moving, contacting surfaces to minimize friction and to covering stationary parts with an oil film to prevent rusting.

Cleaning Prior to Lubrication. Unless otherwise specified, the rifle-bore cleaner (preferred) or dry-cleaning solvent is used to clean or wash all metal parts whenever partial or total disassembly is undertaken, or when renewing the protective lubricant films on metal surfaces. The use of gasoline or benzine for cleaning is prohibited. All parts should be dried thoroughly and lubricated immediately after cleaning to prevent quick rusting.

When cleaning the bolt assembly care should be taken to insure complete removal of all oil or residue.

Points in Gun to be Lubricated

All bearing surfaces of moving parts should be lightly lubricated. In addition to the general lubrication of the gun as explained above, special attention should be given to the following points:

- Cover extractor cam.
- Cover extractor spring.
- Guideways of the belt-feed slide.
- Cocking lever.
- Belt-feed lever grooves in the bolt.
- Guideways in the barrel extension taking the bolt guides.
- Breech-lock cam guides and top.
- Switch pivot.
- Breech lock.
- Extractor pivot.
- Sear guides and slide.
- Belt-feed lever pivot stud and slide guides.
- Cleaning and lubrication of gun daily, and after firing.

3. PREVENTIVE MAINTENANCE SERVICE

Scope

Preventive maintenance service prescribed by Army Regulations is a function of using organization echelons of maintenance. This section contains important general preventive maintenance procedure, and specific maintenance procedure applying to the gun as a whole. It also contains schedules of preventive maintenance service allocated to crew and to organizational maintenance. Special maintenance of specific groups of the gun components is covered, when necessary, in sections pertaining to the groups.

General Procedures

The following general preventive maintenance should be observed in addition to the organizational maintenance schedules.

The importance of a thorough knowledge of how to clean and lubricate the machine gun cannot be over-emphasized. The kind of attention given to this weapon largely determines whether the gun will shoot accurately and function properly when needed.

Rust, dirt, grit, gummed oil, and water cause rapid deterioration of internal mechanism and outer unpainted surfaces. Particular care should be taken to keep all bearing surfaces and exposed parts clean and properly lubricated. Wiping cloths, rifle-bore cleaner, dry-cleaning solvent, and lubricants are furnished for this purpose. All traces of rust are removed from surfaces with crocus cloth, which is the coarsest abrasive to be used by the using arm for this purpose. Care should be taken not to change the shape or dimension of the part.

Loose parts should be tightened; unserviceable parts should be replaced.

Serious damage to weapons, in many cases requiring repair and replacement of component parts, has resulted from the use of water, steam, or air from a high-pressure hose used for cleaning purposes. For this reason, all personnel are cautioned to prevent water, dirt, or grit from entering functioning parts and bearing surfaces. The safest method of cleaning is prescribed in the following paragraph.

Each time a gun is disassembled for cleaning or repair, all parts should be carefully inspected for cracks, excessive wear, rust, and like defects which might cause malfunction of the gun. All parts should be thoroughly cleaned and properly lubricated before assembly.

Each time a gun is assembled, it should be given an operational check after headspace and timing have been checked and adjusted. This check consists of operating the gun by hand to see that it functions properly. When possible a belt of dummy cartridges should be fed through the gun to be sure that feeding, extraction, chambering, and ejection are properly executed by the mechanism.

When materiel is not in use, the proper covers should be used.

Spare parts, tools, and equipment should be inspected for completeness, serviceability, and interchangeability. Missing or damaged items are replaced or turned in for repair. Only tools which are provided should be used. Tools which do not fit will fail or cause damage to parts.

At least every six months a check-up is made to see that all modifications have been applied. No alteration or modification which will affect the moving parts should be made by the using personnel, except as authorized by the Ordnance Department.

4. SPECIFIC PROCEDURES

Before Firing. The bore and chamber are thoroughly cleaned of all dirt, excess oil, or grease.

Using clean wiping cloth dipped in proper oil and then wrung out, any surplus oil is wiped from the bolt, feedway, and cover assembly.

Outer surfaces of the gun are wiped with clean wiping cloth dipped in proper oil and wrung out.

After Firing—Barrel. The following cleaning procedure is followed at the end of the day's firing. If no firing is anticipated, it is to be repeated on three consecutive days thereafter.

THIS PAGE IS DECLASSIFIED IAW EO 13526

To clean bore and chamber, two clean patches are placed in the slot of the cleaning rod; the patches are saturated with rifle-bore cleaner, and moved back and forth through the barrel several times. If rust spots or foreign matter are not removed by the bore cleaner, the cleaning brush M4 is attached to the cleaning rod and the lands and grooves are scrubbed. The chamber-cleaning brush M6 should be used to clean the chamber. A light coating of rifle-bore cleaner should be allowed to remain in the bore between cleanings to prevent rust.

After the fourth cleaning following firing (if no firing is anticipated within next twenty-four hours), clean dry patches are placed in the slot of the cleaning rod and bore and chamber thoroughly dried. With clean dry patches dipped in preservative lubricating oil (special) and then wrung out, a light film of oil is applied to the bore and chamber by working the patches through the bore. Excess oil must be removed from the bore and chamber before firing.

Soap and water or soda ash solution are used after firing if rifle-bore cleaner is not available. The barrel is placed, muzzle down, in a vessel containing a solution of ½ pound of soda ash to each gallon of water. Two patches are attached to the cleaning rod, the rod is inserted in the breech end of the barrel, and moved forward and backward for about one minute, pumping the solution in and out of the bore through its entire length. If this does not remove rust or foreign matter, the lands and grooves of the bore, as well as the chamber, are scrubbed, while still wet, with the cleaning brush M4 attached to the cleaning rod. Then clean water is pumped through the bore, using clean patches. The chamber cleaning brush M6 should be used to clean the chamber. The bore and chamber are then wiped thoroughly and lubricated as prescribed above. This procedure is repeated on three consecutive days thereafter, followed by drying and lubrication as described above.

Note: If soda ash is not available, a solution of one pound of issue soap to each gallon of hot water may be used, or hot water may be used alone.

Caution: Dry-cleaning solvent should not be used because the corrosive salts from the primer composition, which cause rust, are not readily dissolved by petroleum products; they are, however, readily dissolved by water-base solutions.

After Firing—Parts Other Than Barrel. With rifle-bore cleaner or dry-cleaning solvent, the front face of the bolt and the front of the barrel extension, as well as all the cover group components which have been exposed to powder gases, are thoroughly cleaned. Dirt and foreign matter must be removed from all other parts. (After cleaning, cleaned parts should be handled with gloves as acid from hands accelerates rusting.)

Caution: Special care should be used to remove all fouling from the firing pin hole in the face of the bolt.

During firing, hard carbon gradually accumulates in the recoil booster and sometimes in the T-slot of the bolt. This carbon deposit must be carefully removed, with a scraper or crocus cloth, and the parts lubricated immediately.

All components should be thoroughly dried and a light coating of preservative lubricating oil (special) immediately applied.

Daily Service. The bore and chamber are inspected. Component parts are cleaned, wiped thoroughly dry and relubricated.

Weekly Service. If the gun has not been fired, oil film in the bore and chamber should be renewed every five days, using a single patch saturated in preservative lubricating oil (special). When operating from areas of high humidity or salt spray, and atmospheric temperatures are in excess of +32°F, in event guns are not being maintained in readiness for immediate action, preservative lubricating oil (medium) is used. In this case the medium oil must be thoroughly removed and the guns relubricated with the special oil before being placed in action. All excess oil is wiped from the bore and chamber before firing or preparing for combat, and inspected for traces of rust formation.

Care of Spare Parts and Equipment. Complete sets of spare parts, tools, and equipment should be maintained at all times, kept lubricated to prevent rusting and inspected at frequent intervals. When in actual (but not daily) use, they should be coated with preservative lubricating oil (medium). When in use, or placed in the airplane for emergency use, they should be cleaned with dry-cleaning solvent and lightly lubricated with preservative lubricating oil (special).

5. ADJUSTMENTS AND CHECKING

Headspace

Definition. The headspace of military weapons in general, with the cartridge fully seated in the chamber, is the distance between the base of the cartridge and the face of the bolt. This definition cannot be applied to aircraft machine guns due to the fact that in machine guns the distance between the face of the bolt and the base of the cartridge is controlled by the depth of the T-slot in the bolt. Therefore, in aircraft machine guns the headspace, for all practical purposes, may be defined as the distance between the rear face of the barrel and the face of the bolt which presses against the base of the cartridge.

Significance. When any cartridge is fired, the powder gases exert tremendous pressure in the chamber. This pressure forces the bullet out of the barrel; it also tends to force the cartridge case out of the chamber. The cartridge case, therefore, must be held snugly in the chamber from the time the cartridge is fired until the bullet leaves the barrel. It is held there by the forward face of the bolt pressing against the rear face of the cartridge, the bolt being locked in this position by the breech lock. The breech lock engages a recess in the bottom of the bolt and locks it firmly to the barrel extension. As the recoiling parts move into battery after recoil, the breech lock is forced upward by the breech lock cam and locks the bolt to the barrel extension just before they reach the battery position.

Tight Headspace. Improper adjustment of the parts resulting in too little headspace may cause the following malfunctions:

Failure of the recoiling parts to go completely into battery because the breech lock cannot fully enter the locking recess of the bolt.

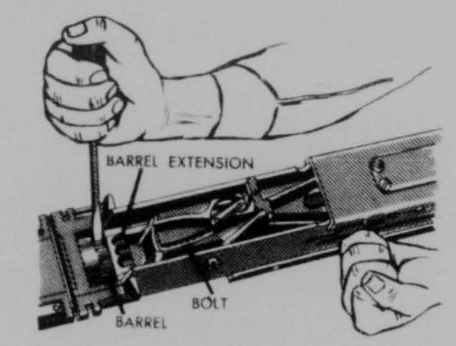

Figure 2—67. Screwing Barrel Into Barrel Extension (Link Chute Adapter Removed to Show Operation).

Failure to fire because the bolt may not go forward far enough for the sear to be released.

Sluggish fire because of binding and excessive friction between the moving parts (particularly noticeable when pulling a long ammunition belt).

Loose Headspace. Improper adjustment of parts resulting in too much headspace may cause the following malfunctions:

Rupture of the cartridge case because the barrel bolt is too far forward in the barrel extension for the face of the bolt to hold the cartridge snugly in the chamber.

Inability to obtain proper timing.

Battering of the breech lock, bolt and barrel extension because the locking surfaces of the breech lock and bolt recess are not in contact at the instant of firing. (This will soon render these parts unfit for service.)

Battered T-slot lips due to the bolt striking the barrel extension.

When and How to Adjust Headspace. The gun must be headspaced each time it is assembled. The adjustment must be made after the parts are assembled into the gun. If a gauge is not available, the following method for headspacing basic aircraft machine gun, cal. .50, M3 may be used:

The bolt is pulled back about one inch by means of the bolt handle, or other retracting device.

The barrel is screwed into the barrel ex-

THIS PAGE IS DECLASSIFIED IAW EO 13526

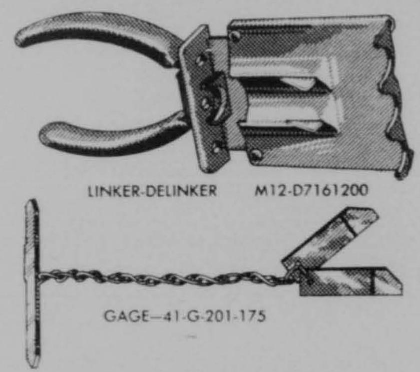

Figure 2–68. Hand Cartridge Linker-Delinker, Cal. .50 M12, and Headspace and Timing Gauge, Cal. .50.

tension by applying a screw driver to the notches on the rear end of the barrel (Figure 2-67) until the recoiling parts will not go into battery position without being forced when the bolt is released. (The recoiling parts are in battery when the barrel extension touches the trunnion block.)

Note: For ease in screwing the barrel into the barrel extension, the link-chute adapter assembly should be removed.

The barrel is screwed out of the barrel extension one notch at a time until the recoiling parts will just go into battery position when the bolt is released, but it should not be forced forward.

Note: The bolt should not be retracted more than one inch when determining the point at which the recoiling parts will just go into battery without being forced.

When this point is found, the bolt is retracted and the barrel unscrewed two more notches.

When and How to Check Headspace. The headspace should be checked each time it is adjusted, prior to test firing on the ground; after installation of the gun in an airplane, prior to each take-off of the airplane; and at any other time that there is doubt as to correctness of the headspace. Headspace gauge A351211 ("GO" and "NO-GO") is used to check the headspace of all machine guns, cal.

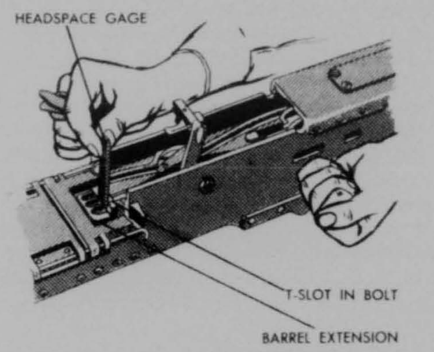

Figure 2–69. Inserting Headspace Gauge (Link Chute Adapter Removed to Show Operation).

.50. This gauge is a part of the headspace and timing gauge assembly 41-G-201-175 (Figure 2-68). To check headspace the procedure is as follows:

The gun is cocked by fully retracting the recoiling parts and allowing them to return to battery position. (This cocks the firing pin.)

The bolt is retracted until the barrel extension and trunnion block are separated approximately $\frac{1}{16}$ inch. This puts the locking surfaces of the breech lock and bolt in contact, which is the position they will assume when a cartridge is chambered.

The "go" end of the headspace gauge is inserted in the T-slot between the face of the bolt and the end of the barrel (Figure 2-69). If the gauge does not go in, the headspace is too tight; the adjustment is corrected by unscrewing the barrel, one notch at a time, checking with the gauge each time, until the gauge enters.

An attempt is made to insert the "no-go" end of the headspace gauge in the T-slot between the face of the bolt and the end of the barrel. If the "no-go" end of the gauge goes in, the headspace is too loose; the adjustment is corrected by screwing the barrel into the barrel extension one notch at a time, checking with the gauge each time, until the "no-go" end of the gauge will not enter. If the gauge does not go in and the check for tightness outlined in step mentioned above is satisfactory, the headspace is correct.

The gauge is then removed and the firing pin released.

Caution: The firing pin with the gauge in place must not be released, as this will damage the firing pin.

Note: If the headspace obtained by the method of adjustment given above is not between the "go" and "no-go" limits of the gauge, the headspace is changed to suit the gauge.

The gauge may be inserted from either the top or bottom of the gun. In the event the gauge is inserted from the bottom, the slack between the bolt and the breech lock may be taken up by inserting a screw driver in the T-slot between the face of the bolt and the end of the barrel.

Timing

Purpose of Timing Check. The purpose of a timing check is to insure that the gun is not fired too early or too late by any of the various means employed to fire the weapon. In extreme cases of early timing the gun will fire two rounds and then stop because recoil from the second round fired started before the extractor was far enough forward to engage the next cartridge in the belt. The gun must not fire earlier than 0.116 inch out of battery. On the other hand, if the gun fires too late while firing automatically, the barrel extension will strike the trunnion block as the recoiling parts move forward on the counterrecoil movement. During automatic firing, the gun must fire before the barrel extension reaches a point 0.020 inch out of battery. The procedure for making the adjustment, as well as the point at which the firing pin is released, is referred to as "timing."

When to Check Timing. Due to vibration when parts become worn, or as a result of disassembly, adjustment of the trigger bar or firing device may be disturbed. Timing should be checked whenever headspace is checked and whenever timing is in doubt. Synchronized guns need not be checked for timing unless failures to feed because of poor timing are encountered during actual firing.

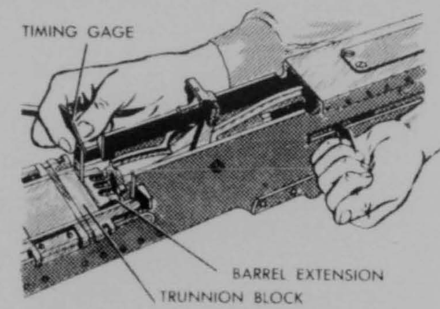

Figure 2–70. Inserting Timing Gauge (Link Chute Adapter Removed to Show Operation).

Caution: In guns equipped with trigger bars assembled for use with a top-plate solenoid, care should be taken that the trigger bar does not drag on the bolt. (In any other case, the adjustable trigger-bar stop spring always acts to hold the trigger bar up and away from the bolt.)

Timing Check to Insure That the Gun Will Not Fire Too Late. The procedure is as follows:

The headspace is checked.

The gun is cocked by fully retracting the recoiling parts and allowing them to go forward into battery.

The cover is raised and the bolt retracted slightly ($\frac{1}{4}$ inch).

The "fire" timing gauge (0.020 inch) of the gauge assembly 41-G-201-175 (Figure 2-70) is inserted between the barrel extension and the trunnion block, as shown in Figure 2-70.

The barrel extension is allowed to close slowly on the gauge.

The firing mechanism is released by operating once the solenoid or other firing device. The firing pin should release smartly. If the firing pin is not released, the solenoid protrusion or the adjustable trigger-bar stop must be adjusted until the firing pin can be released with the "fire" gauge in place.

Note: A trigger bar B7162196 is furnished with the gun M3 for use with a top-plate solenoid.

THIS PAGE IS DECLASSIFIED IAW EO 13526

To adjust the trigger bar, the backplate is removed and the trigger-bar stop adjusting nut (Figure 2-50) is turned to the right one notch at a time until the firing pin can be released with the "fire" gauge in place.

Note: To secure earlier timing the nut is turned to the right. To secure later timing the nut is turned to the left. One click (notch) of adjustment is equal to 0.004 inch change in distance between the toe of the trigger bar and the top of bolt.

Caution: Care should be taken to prevent the toe of the trigger bar from touching the top of the bolt. Clearance, which can be measured with a feeler gauge, should not be less than 0.005 inch, if possible.

Timing Check to Insure That Gun Will Not Fire Too Early. Procedure is as follows:

The "fire" timing gauge is removed, the gun is cocked, and the "no-fire" (0.116 inch) gauge of the gauge assembly 41-G-201-175 (Figure 2-68) is inserted between the barrel extension and the trunnion block.

The barrel extension is allowed to close slowly on the gauge.

The firing mechanism is released once. The firing pin should not be released.

If the firing pin is released with the "no-fire" gauge in place, the solenoid protrusion or the adjustable trigger-bar stop must be adjusted to obtain the desired results.

To adjust the trigger bar the backplate is removed and the trigger-bar stop adjusting nut (Figure 2-50) turned to the left one notch at a time until the firing pin cannot be released with the "no-fire" gauge in place.

6. MALFUNCTIONS AND CORRECTIONS

General

It is important that the gun and all its equipment be properly installed and maintained. Proper care of the gun and attention to the preventive maintenance schedules will greatly reduce the possibility of gun stoppages due to malfunctions. When trouble develops, equipment should be carefully checked before assuming that the gun itself is re-

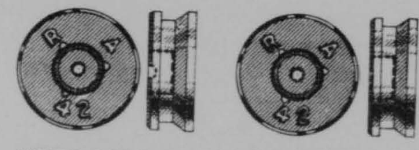

Figure 2–71. Normal and Light Indent in the Primer.

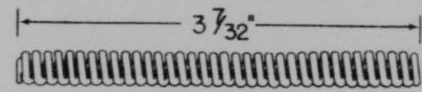

Figure 2–72. Firing Pin Spring.

sponsible for the stoppage. Excessive belt load or any of the equipment applied to the gun may cause the gun to cease firing through no fault of its own.

The first step in analyzing a malfunction is to observe carefully the position of the recoiling parts of the gun as an indication of the probable cause of the stoppage.

Before raising the cover, the feedway is inspected, whenever possible, by looking in at the side, to determine if the stoppage may be caused by misalignment due to improper loading of cartridges in the belt, short rounds, or other causes.

The bolt is held in the position at which the stoppage occurred, the cover is raised, and the gun inspected carefully. Unless the bolt is held in position when the cover is raised, the recoiling parts may spring forward toward battery position and the evidence as to the cause of the stoppage may be destroyed.

The gun should be fully unloaded and the recoiling parts moved forward and backward slowly by hand, watching for any binding or unusual friction which might have caused the stoppage.

Since most of the common malfunctions fall in one of five general categories, indicated by the position of the recoiling parts of the gun at the time of stoppage, these five categories with probable causes and remedies of the stoppages are covered in the following paragraphs of this section. On the basis of the report given by the gunner or pilot, the

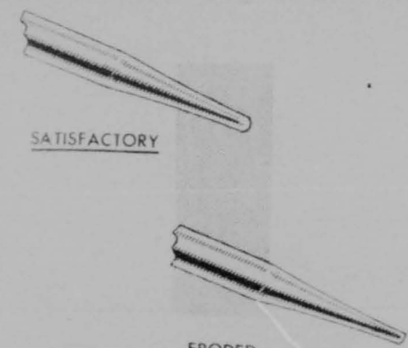

Figure 2–73. Firing Pin Showing Satisfactory and Eroded Point.

evidence available should be carefully analyzed—position of the recoiling parts when the stoppage occurred, points of friction between moving parts, etc.—and a decision made as to which of the categories the stoppage belongs. This procedure may save much time in finding the cause of the stoppage.

Gun Stops Firing in Battery Position with Live Cartridge in the Chamber

This condition is probably caused by one of the following:

Firing-pin Extension Binding in its Tunnel in Bolt. The bolt is removed from the gun and the firing-pin extension and firing pin taken out. The firing pin is dropped into its tunnel in the bolt; the striker should project approximately 1/16 inch from the face of the bolt. The bolt is then inverted; the firing pin should fall out freely. These operations are repeated with the firing-pin extension attached to the firing pin. The same freedom of movement mentioned above should be obtained. If any binding or unusual friction is discovered, the tunnel is cleaned thoroughly and, using crocus cloth or a fine grained sharpening stone, any burrs or roughness on the firing-pin extension or firing pin are removed and the parts lubricated lightly.

Caution: Abrasive should not be used on the firing-pin point. If necessary, the pin should be replaced.

Firing-pin Spring Weak or Broken. The spring may fail to drive the firing pin with sufficient force to fire the cartridge. This is indicated by a light indent in the primer (Figure 2-71). The spring is removed and the free length of the spring checked against that shown in Figure 2-72. If the spring is short, broken, or damaged, the firing-pin extension assembly must be replaced.

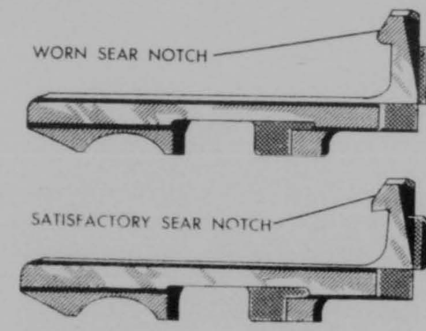

Figure 2–74. Sear Showing Satisfactory and Worn Notch.

Grease or Dirt in Firing-pin Spring. This condition is indicated by a light indent in the primer (Figure 2-71). Grease or excess oil in the firing-pin spring may congeal at low temperatures and cause failure to fire. Grease, oil and dirt must be thoroughly removed from the firing-pin spring, the firing pin and firing-pin extension, and the firing-pin tunnel in the bolt. The spring is removed, cleaned, and then lubricated.

Defective Ammunition. A defective primer, corroded ammunition, or a cartridge with the primer vent hole omitted will cause a misfire. If a normal firing-pin indent appears in the primer (Figure 2-71) and the cartridge is still unfired, it is an indication of a defective cartridge.

Firing-pin Point Worn or Broken. This condition is usually indicated by a very light indent in the primer. The tip of the firing pin may be broken off or eroded and deformed by blow-back of hot gases due to a punctured primer, as shown in the illustration at the right in Figure 2-73. The illustration on the left in Figure 2-73 shows the proper shape of the firing-pin point. Punctured primers are usually caused by a firing pin with excessive

THIS PAGE IS DECLASSIFIED IAW EO 13526

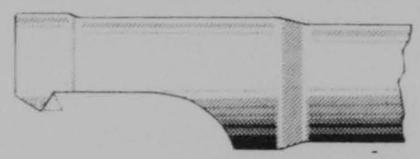

Figure 2–75. Firing Pin Extension Showing Worn Notch, Dotted Line Indicates Satisfactory Notch.

protrusion or a sharp point, or by hard brass in the primer. An enlarged firing-pin hole in the face of the bolt may also lead to pierced primers.

Worn Sear Notch. Wear on the sear notch, as shown in the right-hand illustration on Figure 2-74, may cause failure of the sear to engage the shoulder of the firing-pin extension properly. This may result in "failure to fire" or possible "uncontrolled fire." The proper shape of the sear notch is shown at the left in Figure 2-74. If badly worn, the notch will permit the firing-pin extension to ride forward with the cocking lever and result in failure to fire. If not too badly worn, the sear may hold the firing-pin extension rearward momentarily but not securely. This may result in a "run-away gun." A worn notch can also be the cause of light primer indents.

Worn Sear-engaging Notch of Firing-pin Extension. If the sear-engaging notch of the firing-pin extension is worn as shown in Figure 2-75, it may result in failure to fire or possibly "uncontrolled fire," because the shoulder may fail to engage the sear notch properly. The correct shape of the engaging shoulder of the firing-pin extension is indicated by the dotted line in Figure 2-75. A worn shoulder can also be the cause of light primer indents.

Weak Sear Spring. If the sear spring is weak or broken, it may fail to force the sear upward in time to engage the shoulder of the firing-pin extension. If weakness of the spring is suspected, the free length of the spring should be checked by laying the spring on the illustration in Figure 2-76, which shows the exact minimum free length of the spring. If the spring is shorter than the illustration, it should be replaced.

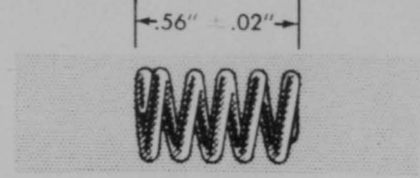

Figure 2–76. Sear Spring.

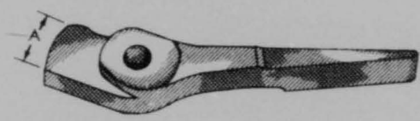

Figure 2–77. Cocking Lever ("A" Indicates Area Subject to Wear).

Broken or Worn Cocking Lever. If the cocking lever is broken it will fail to cock the gun. If the cocking lever is worn at the area indicated at "A" on Figure 2-77, it may fail to force the firing pin far enough rearward to engage the sear.

Gun Stops Firing in Battery Position with No Cartridge in Chamber

This condition is probably caused by one of the following:

Bent or Worn Belt-feed Lever. This may be caused by an excessive belt load such as is encountered when the free flow of the ammunition belt is impeded for any reason such as the misalignment of the ammunition feed chutes with the gun. A careful check should be made for such misalignment, particularly at the points where the base of the cartridge could catch and stop movement of the belt. The belt-feed lever may also be bent or broken if the belt-feed pawl arm has been broken and has thus permitted attempted double feeding when a cartridge has not been extracted from the belt.

Long Ammunition Belt Imposed Excessively Heavy Feeding Load. The force required to pull the belt into the gun must not be greater than thirty-five pounds without the aid of a booster. A check should be made for twisted belt chutes out of line, etc.

Belt-holding Pawl Springs Weak or Broken. If these springs are weak or broken, the belt

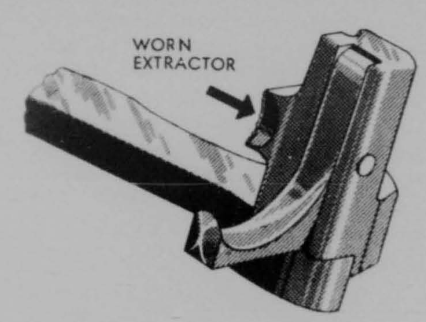

Figure 2–78. Worn Extractor.

links will slip back over the belt-holding pawl and the belt will not be properly positioned in the feedway. Grease or dirt in the spring recesses may also cause improper operation of the pawls.

Belt-feed Pawl Springs Weak or Broken. If these springs are weak or broken, the pawl will fail to engage the belt link firmly and a failure to feed may result.

Extractor May be Bent, Broken, or Deformed so that it Does Not Fit and Securely Engage Extractor Groove of Cartridge. Wear at the area indicated (Figure 2-78) may cause failure to extract the cartridge from the belt. A worn extractor should be replaced with an extractor assembly.

Gun Stops Firing with Recoiling Parts Out of Battery Position

This condition may be caused by any of the following:

Backplate Buffer Springs Broken. Broken backplate buffer springs may cause the gun to fail to complete the counterrecoil stroke, causing serious damage. Ordnance maintenance will replace broken springs since this item is not furnished to organizations. A light film of oil must be maintained on each spring.

Headspace Too Tight. A damaged or weak barrel-locking spring will cause the headspace to change. The headspace is checked and, if found incorrect, a check is made of barrel-locking spring for fracture, weakness, and worn projection. The headspace is then readjusted and checked.

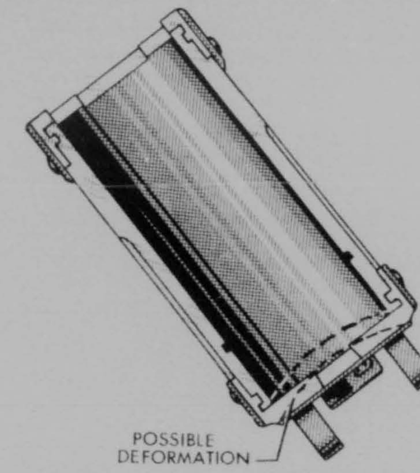

Figure 2–79. Receiver—Rear View (Dotted Lines Indicate Possible Deformation (Exaggerated) of Bottom Plate).

Bolt Binds Between Side Plates. If the gun is improperly mounted, the side plate may be twisted to such an extent that the bolt or barrel extension will bind and cause a stoppage. In such cases, the mounting of the gun should be checked.

Bolt Binds Against Top Plate Bracket. If the bottom plate is not flat, the bolt will be forced up against the top-plate bracket, and may cause the bolt to stop all the way to the rear when operating under full belt load. If the mounting bolts through the rear mounting lugs are drawn too tightly, the bottom plate may be sprung upward as indicated by the exaggerated white dotted line in Figure 2-79, causing the bolt to bind against the bracket.

Bolt Stud Binding in Slot of Side Plate. If such binding occurs, the bolt is likely to stop all the way to the rear when operating under full load. The edge of the side-plate slot should be stoned slightly to eliminate interference. If the stud section of the bolt handle or bolt stud is too long, the gun will not function properly because the stud will extend too far into the bolt and prevent movement of the sear. If the stud is too long, it will also force the collar out too firmly against the side plate.

THIS PAGE IS DECLASSIFIED IAW EO 13526

causing it to bind and catch in the slot. The distance from the retaining collar to the end of the stud inserted in the bolt should not be more than 0.585 inch.

Breech Lock Cam Excessively Tight. This will cause a binding between the guides of the breech lock cam and the barrel extension.

Firing-pin Hole Enlarged or Recoil Plate Not Flush with Face of Bolt. If the firing-pin hole in the recoil plate is enlarged, the firing pin will not be properly supported and the firing pin will be deformed. If the recoil plate is not flush with the face of the bolt, the primer will not be properly supported at the time of the explosion and the metal of the primer may be forced backward beyond the base of the cartridge, forming what is known as an "extruded primer." The projecting surface of the primer will cause the empty case to bind in the T-slot so that ejection cannot take place. On counterrecoil, the front end of the case will strike the barrel or barrel extension and cause the recoiling parts to stop out of battery position. Replacement of the bolt assembly will correct this condition.

Ruptured Cartridge Case in Chamber. A ruptured cartridge case which has not been extracted will stick in the chamber and prevent chambering of the following live cartridge. The ruptured cartridge case is removed, using the ruptured-cartridge extractor. Chamber and bore should then be thoroughly cleaned, and headspace and timing of the gun checked.

Side-plate Switch Does Not Complete Cycle in Time. A weak switch spring, or an installation on the aircraft which imparts vibratory motion to the switch, may cause the switch not always to complete its cycle in time. In this case, the extractor will ride the top of the switch during counterrecoil and the stoppage will occur in an "out-of-battery" position. The switch spring should be checked for proper strength and for vibration in installation.

Double Feeds. When feeding from the right-hand side, double feeds may occur with the present feed pawl because the pawl catches on the ears of the link. This stoppage may be recognized by the presence of distorted cartridge cases and broken links in the feedway. Condition of feed pawl should be examined and the unit replaced if necessary.

Gun Fires Two Rounds and Stops in Battery Position with No Cartridge in Chamber

If this condition continues after repeated chargings, it is probably due to early timing. With early timing, the gun is fired and recoil starts before the extractor has gone forward far enough to engage the cartridge in the feedway; therefore, the gun fires only the cartridge which was charged into chamber and that cartridge engaged by the extractor before firing started. The timing should be checked.

7. STORAGE AND SHIPMENT

General

Preparation of the materiel for domestic shipment will be the same as that prescribed for limited storage and/or standby storage.

Instructions for limited storage and/or standby storage include receiving inspection, preferred storage, preparation of materiel for storage, necessary inspections and servicing to insure safe storage and methods of removing from limited storage.

Instructions for domestic shipment include preparation of materiel for shipment, boxing and boxing data, and loading materiel in boxcars.

Materials required for preparation of materiel for storage and shipment throughout this section in addition to those listed previously.

Barrier, waterproof.

Compound, rust preventive, light.

Compound, rust preventive, medium.

Tape, adhesive, non-hygroscopic, O. D.

Wrapping, greaseproof.

Instructions for Limited Storage

General. When materiel is out of use, it must be turned over to ordnance personnel, or placed in a limited storage status for period not to exceed ninety days.

Note: Storage of materiel for periods in excess of ninety days normally will be handled by ordnance personnel only.

Receiving Inspection. Immediately upon receipt of materiel for storage, it must be inspected for missing or broken parts. If missing or broken parts cannot be replaced or repaired prior to placing the materiel in storage, a tag must be attached specifying the repairs needed; a written report of these items must be made to the officer in charge of the materiel.

Preferred Storage. The preferred type of storage is in closed, dry warehouses or sheds. When outdoor storage is necessary, materiel must be boxed and the storage site selected and arranged as prescribed in SB 9-47.

Preparation. All materiel received for domestic or overseas shipment should not be reprocessed for storage unless the inspections preparatory to or during storage reveal it necessary.

Cleaning. Alkaline solutions deteriorate phosphate finishes rapidly, and therefore are not to be used when degreasing materiel having a phosphate finish. Prior to cleaning, materiel is disassembled. The bore, all parts of the mechanism, and the exterior parts must be thoroughly cleaned and made free of foreign matter, using one or more of the following cleaning methods:

Rifle-bore Cleaner. Rifle-bore cleaner is preferred for degreasing materiel. Maximum cleaning efficiency will be obtained when used undiluted. When necessary to conserve the supply it may be diluted up to 50 per cent with water, provided prevailing temperatures are above +32°F.

Dry-cleaning Solvent. Dry-cleaning solvent may be used instead of rifle-bore cleaner as it does not harm phosphate finishes, dries rapidly, is noncorrosive, and has a fast degreasing action.

Vapor Degreasers. Vapor degreasers using trichlorenthylene are suitable for cleaning all materiel. Materiel cleaned in vapor degreasers must be immediately dipped in preservative lubricating oil (special) after the degreasing process. The natural dark color of phosphate finishes will be restored when oiled.

Hot Water Solutions. The efficiency of hot water solutions is accelerated to a greater extent by raising the temperatures of the solutions than by increasing the amount of materials in solution. Maximum results are obtained with a temperature of +180°F to +200°F.

Note: When hot water solutions are used, materiel must be thoroughly rinsed immediately in clear hot water to remove all traces of the solution which may promote deterioration of the finish.

For phosphate finishes, any one of the following materials may be used in the proportions shown, added to each gallon of water:

Borax .... 6 to 10 oz.

Issue soap .... Not more than 2 oz.

For nonphosphate finishes, any one of the following materials may be used in the proportion shown, added to each gallon of water.

Borax .... 1/2 to 1 lb.

Soda-ash .... 1/2 to 1 lb.

Castile or other available soap .... 1/4 lb.

Alkaline cleaning compound ...... 1/3 lb.

Drying. Dry all parts thoroughly with a lintless wiping cloth or dry compressed air, if available, and handle carefully to avoid contact with bare hands.

Caution: Unless special filters or moisture traps are used, compressed air will contain moisture and must not be used.

Application of Preservatives. Immediately after cleaning and drying, the gun is dipped in a hot bath of rust preventive compound (medium or light). The gun then is immersed at a 45-degree angle to avoid air bubbles in the barrel and receiver. The gun is allowed to remain in the bath until it reaches the same temperature as the bath. The gun is removed from the bath and the rust preventive compound allowed to set.

The gun is wrapped with type I or type II, grade C greaseproof wrapping at all places where it contacts the shipping box, bracing or cushioning.

The prepared gun is then placed in the shipping box as described previously. In addition to contents identification, the type of preservative applied (e.g., preserved with USA 121 Compound, Rust Preventive, medium) will be stenciled on the ends of the containers.

Inspections. A visual inspection must be made periodically to determine general condition. If corrosion is found on any part, the rust spots must be removed and the part cleaned and treated with the prescribed preservative.

Removal From Limited Storage. Materiel to be shipped should not be deprocessed unless inspection reveals that it is necessary to reprocess the materiel for shipment.

When it has been ascertained that materiel is to be placed into immediate service, any items noted, by a tag attached to materiel, as requiring repairs must be given a complete inspection, plus any repairs which are indicated by this inspection. Materiel is reprocessed as prescribed above and the prescribed lubrication applied.

Instructions for Domestic Shipment

General. If the materiel to be shipped will reach its destination within the scope of the limited storage period, it need not be reprocessed upon removal from storage, unless inspection reveals it is necessary.

Preparation. For the preparation of materiel for domestic shipment, see previous paragraph on preparation.

Shipping Container. Construction of the shipping container for the machine guns must be in accordance with TM 9-2854. The essential data necessary in the determination of storage space and shipping requirements is listed below:

	Unboxed	Boxed
Length (O. D. ft.)	4.78	5.30
Width (O. D. ft.)	0.41	0.66
Height (O. D. ft.)	0.57	0.84
Weight (lb.)	65	97
Volume (cu. ft.)	—	2.9
Ship ton	—	0.072

Loading Materiel in Boxcars. For the methods used in loading and bracing boxed items for rail shipment, refer to TM 9-2854.

CHAPTER 3—ROCKET LAUNCHERS

1. GENERAL

Existing aircraft rockets of the fin-stabilized type are too large to house and launch in sufficient numbers from within the airframes of present-day, high-speed, fighter-type airplanes. Such rockets, of necessity, are externally mounted beneath the wings or fuselage. In the past, fixed posts, pods, or pylons were used to support these rockets externally (Figure 3-1). These launchers remained attached to the airplane even after rocket firing and created considerable drag through the entire flight of the aircraft. Also, no provisions were made for jettisoning the rocket load in flight in the event of failure to fire or other emergency. The advent of faster airplanes demanded decreased drag and emergency means of ridding the aircraft of its external, drag-inducing load.

Retractable Post-flush-mount

The retractable post-flush-mount rocket launcher is designed to provide suitable means for carrying externally, launching, and jettisoning finned-type aircraft rockets from high-speed airplanes and to leave the airplane contour as clean as possible after expending the rockets. This is accomplished by causing the protruding rocket supports to retract fully into the airplane wing or fuselage automatically after firing or jettisoning the rockets. In addition, special design of the launcher and certain external components of the rocket make it possible to suspend two rockets from each launcher, a method called "double shot" or tier mounting, by attaching one rocket to another (Figures 3-3, 3 and 4).

2. PRINCIPAL COMPONENTS

The front post is retractable automatically, after firing or jettisoning of the rocket, to a position flush with the normal contour of the wing or fuselage. It must be capable of being withdrawn by hand or ordinary screwdriver from its retracted position to its extended position where it can be locked prior to loading without the insertion of extra or loose parts. It is imperative that no special tools or equipment be required to extend and lock the posts. The front post, which is required to have a

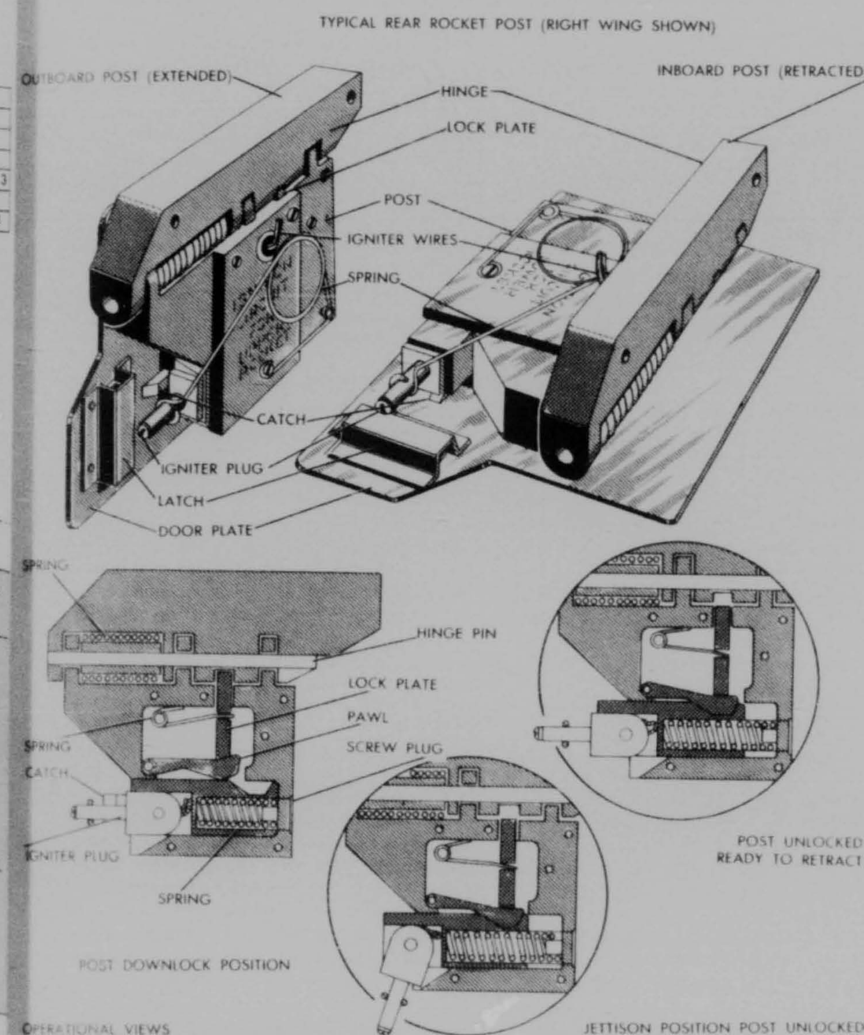

Figure 3–7. Operational Views.

THIS PAGE IS DECLASSIFIED IAW EO 13526

diameter or fore-and-aft dimension of 1.5 inches, must receive the support pin of the rocket-lug band and must be capable of withstanding the full vertical loads, the forward shear-wire load, and the aft air and acceleration loads imposed on the rocket in ground and air maneuvering (Figures 3-5 and 3-6). At the rear, the rocket is supported by sockets in the aft extremities of the two uppermost fins which receive the rear pivotal support plugs. These plugs, mounted on small fittings which retract, after rocket firing or jettisoning, into the under surface of the wing or fuselage, contain a central insulated contact and an outer shell which is positively grounded to the airplane frame. Thus these rear mounting plugs provide both support and electrical connections to the rocket. Since the rocket is not completely constrained in a lateral plane by the front lug band, but is free to rotate about the lug-band pin as a center, twisting moments arising from side loads must be absorbed by the two rear support plugs. Also, the rear supports are required to bear a portion of the vertical loads imposed by the rockets, if the lug band is not positioned exactly at the rocket center of gravity. During jettisoning, the lug band is released from the front post and the rocket swings downward, pivoting about the rear support plug, quickly developing sufficient centrifugal force to move away from the rear support plugs. Hence, these rear plugs must be capable of pivoting downward from their normal horizontal position. Normally, they are retained in their horizontal or firing position by a strong spring, or detent, or by a shear wire (.064-inch diameter standard bomb-arming wire) to prevent their moving about during loading of the rockets. The rear must be capable of being extended to the firing position and locked prior to loading without the use of loose parts or special tools. Upon firing or jettisoning of the rockets, the mounts retract automatically to their flush positions (Figure 3-7). The four rocket-stabilizing fins form a portion of both the launching and ignition systems. Identical sockets are incorporated in the outward rear corners of each of the fins. These sockets slide onto the rear support plugs to provide rear suspension for the rockets. They also contain insulated, spring-loaded, contact pins which provide electrical circuits from the airplane support plugs engaged in the two upper fins to similar sockets in the two lower fins. The fin sockets are internally-wired to diagonally opposite fin sockets so that selective fin positioning on the aircraft launchers is not required. A single steel-lug band, incorporating a rearward protruding support pin at its upper edge, is located near the center of gravity of the rocket. The horizontal $\frac{3}{8}$-inch diameter support pin, engaging in a hole in the lower end of the retractable front post, provides the forward rocket support. The pin is designed to protrude behind the front post when fully inserted and exposes a horizontal shear-wire hole through the pin just aft of the post. A suitable shear wire (.102-inch diameter hard brass) is soldered at one end to the lug-band pin block and is easily removed for insertion into the shear wire hole after loading the rocket on the launcher. The lug band is clamped tightly about the rocket at the proper rear support plug-to-front post dimension and prevents movement of the rocket on the launcher. The rockets are fired electrically by the pilot through the bombing button on top of the control stick in a sequence and interval determined by a rocket firing control box or intervalometer. The rocket nose fuses are controlled by arming solenoids located inside the wing skin just forward of the front posts, or inside the posts themselves. The solenoids are controlled by a fuse-selecting switch located in the cockpit.

3. ROCKET LOADING

The retractable-post rocket launcher incorporates shortened mounts and improved sway bracing. Previous mounts were generally $\frac{1}{2}$ inch to 1 inch longer and sway brace points of the standard 5-inch HVAR lug band are spaced $2\frac{1}{4}$ inches apart. With the flush-mount launcher, the top rocket is suspended closer to the wind and fin sockets, by which the rear of the rocket is suspended. The rockets are spaced 10.34 inches apart. This improved mounting lends itself well to the double-shot or tier method of carrying rockets. In this arrangement, one rocket is suspended from the launcher mounts as described in the preceding paragraph and another round, staggered forward of the upper round slightly, is suspended from, and parallel to, the upper round. Identical fins and lug bands are used on both rounds. The lug-band pin for the lower round engages in a block attached beneath the upper round lug band and is secured by means of a shear wire. Fins of the lower rocket interlock at the rear with fins of the upper rocket to complete the support of the lower round.

Prior to loading the rocket, the front post and rear mounts are extended and locked. The rocket, with the front lug-band correctly spaced and tightly clamped, is raised and the lug-band pin inserted into the hole at the lower end of the inboard front post. As the projectile is slid rearward on the front post, the upper-fin sockets are guided onto the rear-support plugs and engaged simultaneously. After determining that the lug-band pin is fully engaged and that the rear support plugs are bottomed in the fin sockets, the shear wire attached to the lug-band block is inserted immediately into the shear-wire hole and both ends bent down to prevent its loss in flight. If double-shot loading is used, another rocket, with different lug-band spacing to accommodate the fin and lug-band spacing of the upper round, is slid into position beneath the upper

Figure 3—8. Type A-2 Control Projector Release.

THIS PAGE IS DECLASSIFIED IAW EO 13526

rocket. The lug-band pin of the lower rocket is engaged in the block located beneath the upper lug band and notches in the upper and lower fins are interlocked and engaged to provide rear support for the lower round. After ascertaining that the lug-band pin and both fin slots are fully engaged, the shear wire is removed from the lower rocket lug-band block, inserted through the shear-wire hole in the pin, and both ends bent down.

If air-arming nose fuses, MK 149, are used on the 5-inch HVAR, .064-inch diameter standard bomb-arming wires are to be inserted in the fuse as noted on the fuse tag, the arming wire swivel loops are inserted into the arming solenoids, and the wires cut to length.

Just before take-off, the rocket igniter plugs from the rockets are inserted into the proper fin sockets of the upper round as shown on the fin "decals." The upper round is plugged into the left socket, the lower round into the right socket of lower fins of the upper round (looking forward). It is imperative that these wiring connections be observed, since all aircraft designed with this type of launcher are to be wired to provide successful firing circuits in this order. Improper connection will result in the upper round firing first, with the lower round attached. The thrust line of the top round, being located considerably above the combined center of gravity of the two rounds, produces a large over-turning movement and results in a sharply curved downward flight of the two rockets and possible damage to the aircraft.

4. ROCKET FIRING

To fire the rockets, the pilot must turn the projector release control or intervalometer selector switch from **"off"** to **"single"** or **"auto"** (Figure 3-8). If in **"single"** position, the intervalometer will fire one rocket each time the button is depressed, in the sequence established by the aircraft rocket wiring. If in **"auto"** position, rockets will be fired successively at 1/10-second intervals as long as the firing button is held depressed. Upon depressing the firing button, a rocket-firing circuit is energized to ignite an electric squib inside the rocket. This in turn ignites the rocket propellent. A forward thrust is produced which results in shearing the rocket retaining shear wire and the rocket is launched from the airplane. If both nose- and base-fuses are used in the rocket head, before firing the rockets the pilot selects which fuse shall function on impact by placing the fuse-arming selector switch in the **"inst"** or **"delay"** position. When the switch is in **"inst"** position, the fuse-arming solenoids are energized and retain the nose-fuse arming wires, allowing the nose fuses to arm upon firing of the rockets and producing instantaneous detonation upon impact. When the switch is placed in the **"delay"** position, the arming solenoids are not energized, the nose-fuse arming wires are released with the rockets and the nose fuses fail to arm, thereby allowing the base fuse (.015 second delay) to function on impact (Figure 3-9). Since the base fuse is armed by motor pressure during rocket burning, the rockets can be jettisoned in the **"safe"** condition if the nose-arming fuse wires are released with the rockets (arming selector switch in **"delay"**). (Figure 3-10).

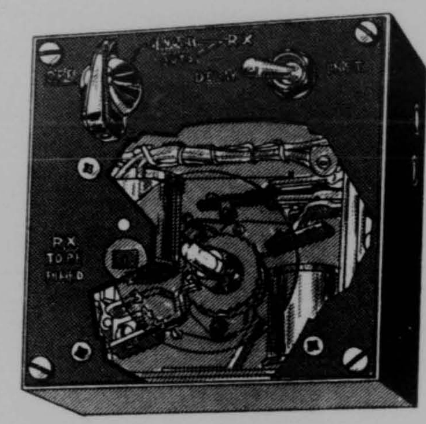

Figure 3—9. Type A-2 Control; Projector Release.

5. ELECTRICAL EQUIPMENT

The Type A-2 Projector Release Control, Specification No. 24973 (Figure 3-8), contains

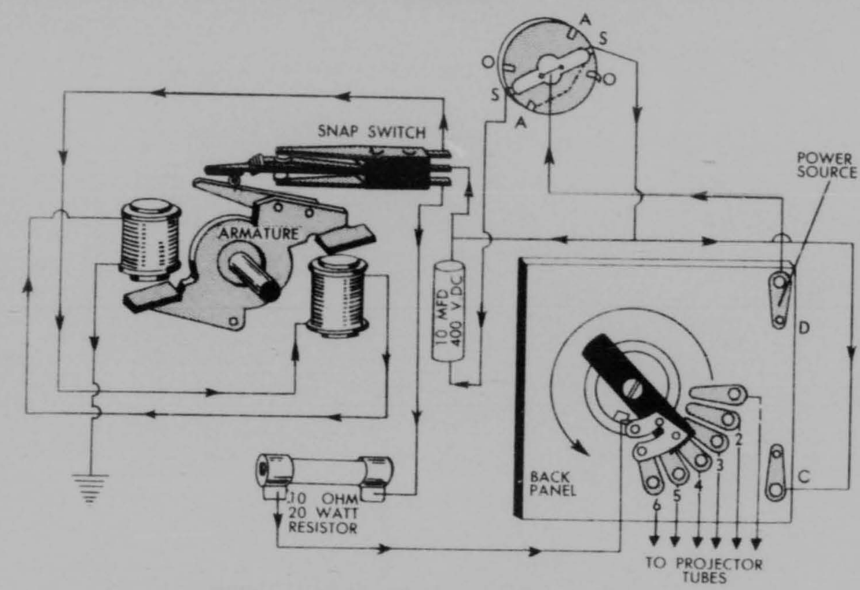

Figure 3—10. Cutaway View—Control; Projector Release.

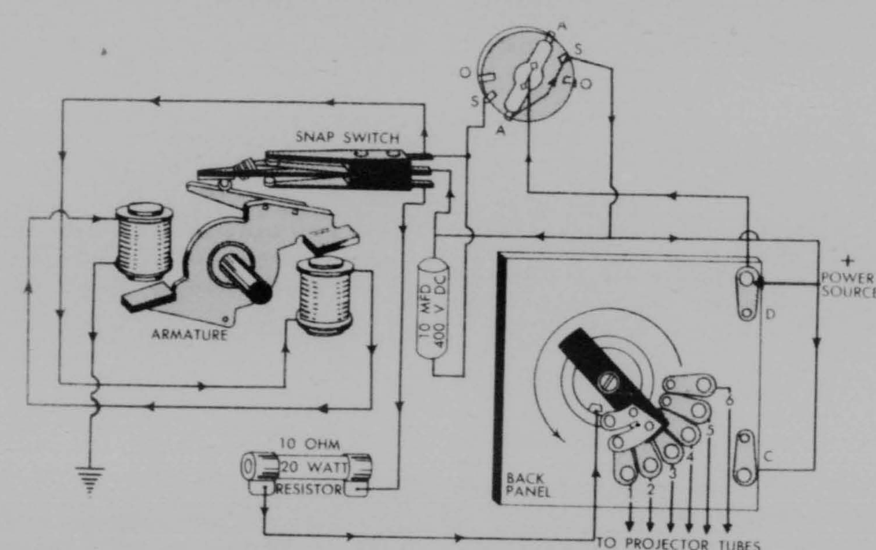

Figure 3—11. Schematic Diagram—Single Actuation.

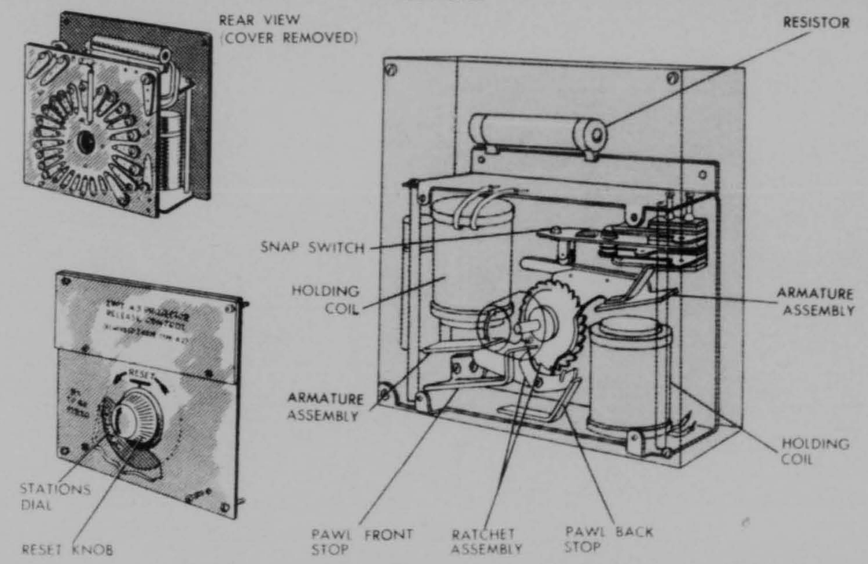

Figure 3—12. Schematic Diagram—Automatic Actuation.

a 24-volt, timed-relay stepper or intervalometer which provides electrical circuits to successive rockets (Figure 3-11). When actuated by the bomb-release button atop the control stick, the control will deliver to the rocket circuit indicated in the circular window on the control panel dial, a firing impulse each time the button is depressed (selector switch in **"single"** position) or impulses in train or ripple at the rate of one every 1/10 second as long as the button remains depressed (selector switch in **"auto"** position). The **"inst—delay"** fuse-arming selector switch located at the upper right of the control box panel will energize all arming solenoids simultaneously when in the **"inst"** position. The electrical supply for this circuit must be adequately protected by a circuit breaker of a size determined by the total number of AN-A-2 arming solenoids employed in the installation (Figure 3-12). The ANA-2 solenoid requires .25 to .50 amperes of 28 volts. The Type A-2 control is housed in a metal box 4¼" x 4¼" x 2¼" and has a total weight of 2.2 pounds. The control must be located adjacent to the pilot in such a position that he may readily set the dial indicator and switches on the panel. Its face must be visible without the pilot having to move from a normal sitting position, and must be easily operable by the hand which normally operates the engine-throttle control. The Type A-3 Projector Release Control, Specification No. 24975, is a modification of the Type A-2 in which the selector switch and fuse-arming switch have been removed and placed as shown on Drawing "Armament Control Panel", Air Force Drawing No. 4704432. Its operation is similar to that of the Type A-2 and its location requirements are identical. The wiring diagram for the Type A-3 control is shown on Air Force Drawing No. 45A5750. Its size is 4 11/16" x 3½" x 2½" and its weight is 1.5 pounds. The Type AN-A-2 Bomb Arming Control, 24-volt, is required, one for each rocket carried. Its weight is approximately .23 pound. It is located flush in the wing skin forward of the mounts, or in the mounts themselves. Care must be taken to provide housings around the solenoids and fairings about the slots to facilitate introduction and extraction of the arming-wire loop.

Aircraft Wiring

A single wire system with ground return is used between the cockpit control box and wing terminal strips for the front and rear launcher mounts. The wire must be No. 18 gauge or larger, adequately insulated, numbered, and supported throughout its length (according to Specification No. AN-J-C-48). From each of the rear support plugs, both hot and ground wires must be adequately protected from rocket blast, if exposed, and must lead to terminal blocks in each wing. Fuse-arming solenoids, when their support brackets are properly grounded, require only a single supply wire. All wire, terminals, and rear support plugs or their fittings must be properly and permanently numbered in accordance with wiring diagrams furnished. Rocket-firing circuits are wired and numbered, preferably in the following order; for number of rockets = n:

No. 1 Lower left outboard
No. 2 Lower right outboard
No. 3 Upper left outboard
No. 4 Upper right outboard
No. 5 Next inboard lower left
No. 6 Next inboard lower right
No. 7 Next inboard upper left
No. 8 Next inboard upper right
. . . .
. . . .
. . . .
No. n-3 Lower left inboard
No. n-2 Lower right inboard
No. n-1 Upper left inboard
No. n Upper right inboard

This method clears rockets from each launcher as soon as possible so that the airplane is maintained at its lowest drag configuration. The method also allows partial rocket loads to be carried and still be fired in uninterrupted sequence. It may be generally stated that a given number of rockets carried in double-shot, or two-per-launcher, will result in less total drag than the same number of rockets carried on individual launchers. That is, four rockets carried double on two launchers will result in less drag than four rockets loaded singly on four launchers.

Rocket Circuit Checking

Prior to each rocket-firing mission, a thorough ground check is required of the intervalometer, rocket-firing circuits, rocket fuse-arming circuits, and rocket-jettisoning circuits. If ground-safety cutout switches are incorporated in the rocket circuits, they must be capable of being overridden by a manual ground-check switch to enable the circuit checks to be made.

The jettisoning circuits are checked by extending the front posts and, individually or collectively, placing a screw driver, spare lug band, or other suitable pin through the lug-band-pin support tongs. If the jettison switch is operated in the cockpit while a downward load of approximately twenty-five pounds is exerted on the test pins, all pins should be released instantly.

Fuse-arming circuits can be checked by turning on the **battery switch, master armament switch,** if used, and the **fuse-arming switch** to **"inst"**. A click should be heard simultaneously from all arming solenoids as the solenoids are energized. Positive check of solenoid operation is made by attempting to insert a coin, screw driver, or arming-wire loop into the solenoid opening. If the plunger is properly extended by solenoid actuation, it will be impossible to insert the blade past the spring-loaded button. The fuse-arming switch should then be returned to the **"delay"** or **"off"** position.

Complete rocket-firing circuits can be checked only with rockets installed on all launchers, since the fins themselves incorporate a portion of the firing circuits. Before loading the rockets, a positive check must be made in the cockpit to insure that all switches are **"off."** Rocket loading should proceed from inboard to outboard on each wing to facilitate access to launchers and rockets. If double rounds are to be carried on each launcher, corresponding lower rockets should be mounted immediately after each upper rocket is installed and the shear wires inserted. All rockets loaded on aircraft prior to circuit checking must have their igniter plugs and cables completely enclosed inside the metal, cup-shaped, rear shipping cap which has been tapped into place in the nozzle shroud ring firmly enough to prevent its falling out during rocket handling and loading. **It is mandatory that this precaution be taken to prevent accidental insertion of a rocket igniter plug during the firing circuit check.** A tester, Electric Circuit, Type B-2, incorporating multiple-indicator light circuits is clipped to the wing trailing edge and the tester plugs inserted into the lower fin sockets of the upper rounds. If available, two tester units are used to allow checking of all rocket-firing circuits simultaneously. After the numbered tester plugs have been inserted into the corresponding firing circuits, the area fore and aft of the airplane must be cleared of personnel and the cockpit switches turned on to check rocket firing circuits. With the intervalometer in **"single"** position and the dial set to No. 1, the circuit-tester lights should indicate firing circuits available alternately at each wing, outboard to inboard, one indication each time the button atop the control stick is depressed. The intervalometer should then be set to **"auto"**, the dial returned to No. 1, and the firing button depressed, allowing the intervalometer to click around in "automatic" or "ripple" fire. All cockpit switches should then be turned off and the ground-safety override switch released to the normal or cutout condition. Shipping caps may be removed and igniter wired from the rockets clipped firmly behind the rockets and fins by means of the trailing edge metal tube. It is extremely important that any excess cable or "slack" be firmly positioned behind the rockets out of the airstream and rocket-blast region.

A rigid routine involving a minimum of personnel must be observed during all checking and plugging in operations to avoid confusion, delay, and accident. Before plugging in, the armorer should make visual check with the pilot to insure all rocket circuits are **"off."** The rockets are to be plugged in immediately prior to take-off only, and when the rockets are pointed toward a safe and uninhabited area. Plugging in commences at either outboard station and proceeds completely across all launcher stations, the armorer passing under the fuselage or around the nose after he plugs in the inboard position on one side and then proceeds to the inboard position of the opposite side. Plugging in should be accomplished at arm's length, the armorer standing well to one side of the rocket being plugged in, never standing or passing to the rear or front of any rocket previously plugged in. The igniter plug is inserted firmly as far as possible with the metal wings or finger tabs approximately 30 degrees counterclockwise from parallel to the rocket-fin blades, then twisted clockwise into locking grooves of sockets until the plug wings are parallel to the rocket-fin blades. If any doubt exists as to the plug being properly installed, a vigorous rearward pull on the plug (not the cable) will unseat the plug if it is not locked into place. The armorer, as he is plugging in the rockets, must again check to see that the lower round is being plugged into the right-fin socket and the upper round into the left-fin socket of the upper round. Immediately upon completion of the plugging in, the armorer gives the pilot a visual signal to that effect.

6. ROCKET JETTISONING

Provisions should be made in the front posts of these launchers for jettisoning the round by releasing the rocket lug band. Upon release of the forward end, the rocket swings downward and pivots about the rear support plugs as a pivot until the rocket slides off the plugs and falls free. The downward angle at which this release occurs is from 30 to 90 degrees, depending on the aircraft velocity at jettisoning. Hence, the rear support plug must be capable of a 90-degree swing downward from the normal launching position and should be spring-loaded upward so as to return to the launching or firing position before rear mount retraction is complete. To facilitate rocket loading, the rear support plugs should be held in the launching position by means of a shear pin or spring detent which will resist a 20- to 30-pound downward load at the forward tip of the plug.

The mechanism to accomplish jettisoning in the front posts must be as simple and foolproof as possible and incorporate a fine adjustment to compensate for wear and to facilitate maintenance. The jettisoning operation must involve no loss of parts and require no recurring repair to the launchers. Visual or mechanical means are provided to indicate the safe or "locked" position of the jettisoning mechanism prior to loading rockets. It is required that both front and rear mounts retract automatically after rocket jettisoning has been accomplished.

Jettisoning of the rockets is controlled electrically from the cockpit. Two methods for jettisoning are required in combination with similar emergency jettisoning or salvo of bombs and external fuel tanks. For ridding the aircraft or rockets, bombs, and fuel tanks in flight a "bomb-and-rocket-salvo" switch is provided in the cockpit, which, when operated, will result in the simultaneous actuation of all rocket, bomb, and external fuel-tank jettison or release circuits. To provide another important safety feature, it is possible to setup or preselect, prior to take-off, individual jettisoning or release circuits for rockets, bombs, and external fuel tanks so that the pilot at any time during the take-off may effect emergency release of all droppable armament and fuel loads by pressing the bomb button atop the control stick. Once the airplane has completed take-off, the various preselected circuits are switched off and the normal jettison or firing circuits employed thereafter.

If the rockets are mounted with their centerlines less than sixty inches above the ground level when the airplane is in taxiing or take-off attitude, a landing-gear cutout switch must be incorporated in the rocket jettisoning circuits to prevent possible damage to the aircraft. Such damage may result from the rockets swinging downward and striking the ground before the rocket fins have left the rear posts or from rockets ricocheting back up into the wings or flaps after falling free and striking the ground. If required, this switch interrupts the jettisoning circuits until the airplane has attained sufficient altitude to prevent such damage. Both firing and jettisoning circuits, if interrupted by a ground-safety switch, must include a manual, momentary "on" or "flagged" overriding switch for use in ground check of the circuits.

7. LOCATION OF MOUNTS

The launcher mounts are so positioned and of such length as to provide a minimum of ½-inch clearance to the lower wing or fuselage skin as the rocket moves forward along its flight path. A ¾-inch minimum clearance must be provided from the rocket head, motor and fins (in their firing position and along their flight paths), to the airplane flaps, control surfaces, landing gear and lights, external guns, bombs, fuel, smoke or chemical tanks or adjacent rockets.

A minimum ground clearance of six inches is provided between the fins of the lowest rocket and the ground level under any combination or adjustment of rockets, any combination of airplane struts fully compressed and tires deflated, and any normal change in attitude during take-off. If the double-shot arrangement (tier launching) is prohibited at any mount by this restriction, "decals" or other permanent markings are used on the mount affected.

The rocket-fin-to-lug-band spacing is here defined as the distance, measured parallel to the rocket centerline, from the rear face of the lug-band block to the rear face of the fin sockets. The fore and aft spacing of the front and rear posts on the aircraft provide for a minimum fin-and-lug band spacing of 32 to 48 inches and the maximum dimension that can be used and not place the big band on the war head of the rocket. The distance between front and rear posts must be equal at all rocket stations within plus or minus .062 inch.

The centerlines of the rockets must be parallel to the line of flight or "velocity vector" within ± 1 degree under the following conditions: 85 per cent maximum speed 3250 feet standard-pressure altitude, normal crew, full ammunition and oil load, ½ fuel load, ½ external rocket load, no bombs.

Centerlines of the rockets and their respective front posts must be in the same planes, these planes to be parallel to each other and vertical, or perpendicular to the wing dihedral angle up to a maximum of 10 degrees to the vertical. At angles greater than 10 degrees from the vertical, binding and distortion may be encountered in the rear posts during jettisoning.

The rockets must not interfere with normal operation of the approved machine gun installation. Also, AMC approval must be obtained for any design in which the installation

18. BODY

Figure 3—13. Projector Release Control.

of a full complement of rockets results in displacement or interference with the normal use of other external stores such as bombs and fuel tanks.

8. ROCKET BLAST PRESSURES

Only meager information is available concerning the magnitude and extent of the blast pressures surrounding rockets when fired from aircraft in flight. The following information was obtained from ground firing experiments by launching 5-inch HVAR at 70 degrees from aircraft wing launchers:

Peak positive (away from rocket centerline) pressure normal to a wing surface six inches above rocket centerline at various lateral distances from the vertical plane through the rocket fired:

Lateral distance in feet	0	1	2	3	4
Pressure in lbs./sq. inch	15	10	5.2	3.5	Negligible

Peak negative (toward rocket centerline) pressures occurring during rocket firing are approximately 1/4 to 1/3 the above positive pressures.

The duration of periodic pressure fluctuations appears to be on the order of 30 milliseconds and pressure fluctuations are principally of 420 C.P.S. frequency.

9. BLAST PROTECTION

The airplane skin, structure, and control surfaces in areas adjacent to the path of the rocket blast must be capable of withstanding repeated rocket firings without sustaining immediate or progressive failure. (See AF Specification No. 34014, Gun and Rocket Installation; Engineering Armament Acceptance Test of.) Tests must be conducted to determine blast resistance under any of the conditions listed below. All blast firing tests are made with full-scale installations on actual airplane structures and by firing such rocket projectiles as are being considered for the installation at their upper temperature limits. Test results must be submitted to, or obtained by, the AMC before approval can be given for any of the following installations:

Rockets are mounted with their centerlines less than eight inches from conventional metal skin-and stiffener wing structure. (Areas offering inadequate blast resistance must be reinforced by increasing the skin thickness and/or internal supporting structure.)

Rockets mounted with their centerlines (extended) less than twenty-four inches from any fabric covered wing, fuselage, or control surfaces, until extensive tests have been conducted and test results submitted and approved.

Rockets mounted under or forward of any aileron or other control surfaces, until adequate ground, flight, and air firing tests have been conducted and approved by the AMC for production installations.

10. ROCKET PROJECTILES

Two types of rocket projectiles are to be considered in the design of flush-mount launchers, the 5-inch HVAR and the 5-inch T-200 rocket. Both rockets are equipped with T-38 Modification Kit—Rocket Aircraft 5-inch, which consists mainly of the flush-mount-type fin assembly and lug band as described above in paragraphs 3 and 4. The rockets generally consist of three main components (Figure 3-13). In the H.E., or armor piercing head, the motor contains the propellent and the venturi nozzles. The fin assembly of four fins is spaced 90 degrees apart and clamped about the aft end of the rocket. A high-speed jet issues rearward from the burning propellent and a forward thrust forces the projectile forward, shearing the retaining wire and propelling the rocket along its trajectory. Pertinent data for the two applicable rockets are:

		TENTATIVE
Designation	5-inch HVAR	5-inch T-200
Drawing No.	H25013294	48A4262
Weight of round	140 pounds	170 pounds
Overall length	69 inches	120 inches
Motor diameter	5 inches	5 inches
Fin circle diameter	15.75 inches	15.75 inches
C.G. from nose	34.5 inches	50.0 inches

Due to the increase in length and extreme shift in center of gravity of the T-200 as compared to the standard rocket, 5-inch HVAR, it is not considered feasible to carry the T-200 rocket in the double-shot or tier arrangement.

The mass flow, which is indicative of the exhaust blast pressures of the T-200 rocket, is approximately 20 per cent less than that of the 5-inch HVAR.

11. STRUCTURAL REQUIREMENTS

The strength of the rocket mounts and their supporting structure is governed by the weight and mounting dimensions of the various combinations of rockets employed. The installation is investigated for all three conditions of loading, one 5-inch HVAR, double-shot (two) 5-inch HVAR, and one T-200 rocket per launcher. The installation is designed for the following conditions:

Vertical Loads. Front and rear mounts, and the structure to which they are attached, are designed for the maximum ultimate vertical-load factors, positive and negative, of the airplane. These loads are assumed to act at the combined center of gravity of the single and double rounds, the resultant loads being distributed proportionately to the front and rear mounts:

Fore, Aft and Side Loads. The mounts are designed to withstand an ultimate side-load factor of 2.25 and an ultimate fore and aft load of 3 acting at the combined center of gravity of the double rounds.

Release Load. In addition to the above loads, but not acting simultaneously with them, a design release load of 2,000 pounds acting forward at the upper lug-band support pin must be sustained by the front post in its extended or firing position due to the required force for shearing the retaining wire upon launching of the rocket.

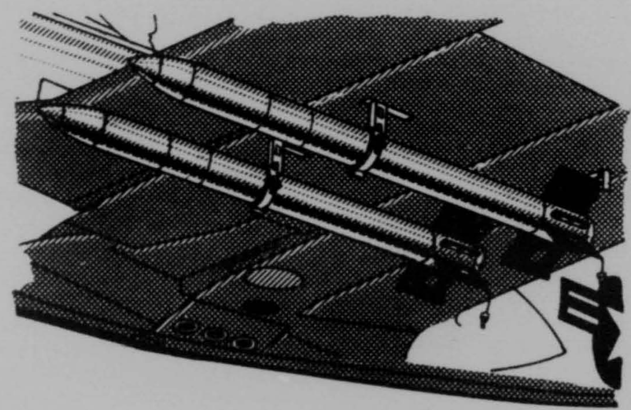
12. JETTISONING CONDITIONS

The pilot must be capable of jettisoning rockets electrically from all stations simultaneously under the following flight conditions:

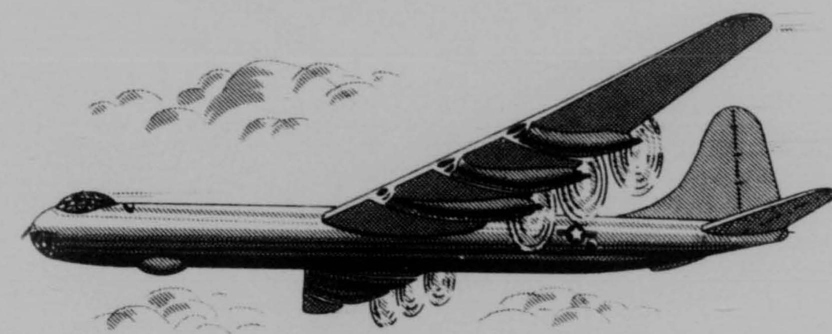
2 "G" pullout.

Level flight at cruising speed.

THIS PAGE IS DECLASSIFIED IAW EO 13526



CHAPTER 4—BOMBING ACCESSORIES



SECTION I—BOMBING SYSTEM UNITS

1. INTRODUCTION

There is no question as to the most effective method of pouring destruction into an enemy's industry, supply points, transportation systems, and other points vital to his pursuance of offensive or defensive action. The "winged artillery" or bombing aircraft clearly does everything that ground artillery can do, except that it can operate over vastly greater areas with more highly concentrated effect.

The United States Air Forces first airplane, a Wright Flyer, wasn't capable of carrying and dropping our smallest present-day bombs. The total weight of bombs dropped on London during World War I by the German Zeppelins and Gothas did not equal that carried by four fully-loaded B-29 Superfortresses. Early efforts at aerial bombing were crude. Early bombing efforts consisted of tossing out five-gallon cans filled with explosives and fused by an ordinary wick-type fuse, throwing out steel darts, and ordinary artillery shells. Gradually, however, the pear-shaped and streamlined bombs equipped with mechanical fuses and vane-type fins were developed. As the aircraft and bombs were improved, brackets or supports for carrying these bombs on the airplane's wings and fuselage had to be developed. In the planning and experimental stages, certain characteristics of bombing systems were desired. Engineers, in designing these systems, worked on the basis that the bomb load should be carried safely, considering such factors as stress and strain on the airplane, and prevention of arming until dropped or released.

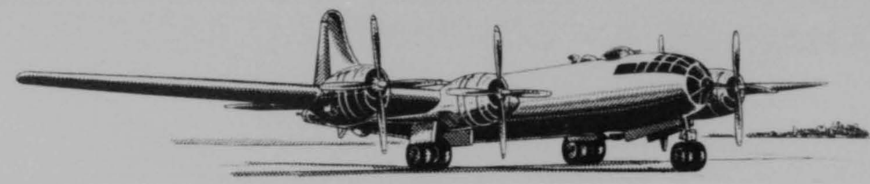
Another obvious requirement was that there should be complete and flexible control over the release of the bombs, in that they might be dropped singly or in groups (sticks or trains) with a preselected interval between each bomb.

In emergencies such as take-off trouble or crash landings, it was necessary to have a means of dumping or jettisoning the entire bomb load in an unarmed or "safe" condition.

2. BOMB TRAINS AND CONTROL OF BOMB RELEASE

General

A bombing system is predicated on the "bomb train" or group. This is essentially a



group of bomb-rack release units mounted on one or more bomb racks. These release units, in one group or in train, are connected electrically in series much as beads are strung. A release impulse is sent to a bomb train and the first bomb is released. To release subsequent bombs the impulses must enter the first release unit to reach the second; then it must enter the first, and then the second release unit to reach the third, and so forth. Usually one entire bomb train will be located on a single bomb rack, and there will be two or more separate bomb trains and consequently two or more separate bomb racks in an aircraft. However, early model North American Mitchell bombers had only a single bomb train while the Boeing Superfortresses use four bomb trains divided, on occasion, between as many as twelve separate bomb racks.

Rack Selector Relay

Since the balance point (center of gravity) of an airplane is in the area of attachment of the wings to the fuselage (wing root), designers of bombing planes attempt to distribute the bomb load evenly within this area. After loading the bombs they must be released or dropped in an even distribution from the various bomb racks in order to maintain balanced flight characteristics. A unit which automatically distributes the bomb-release impulse between bomb racks is the "rack selector relay."

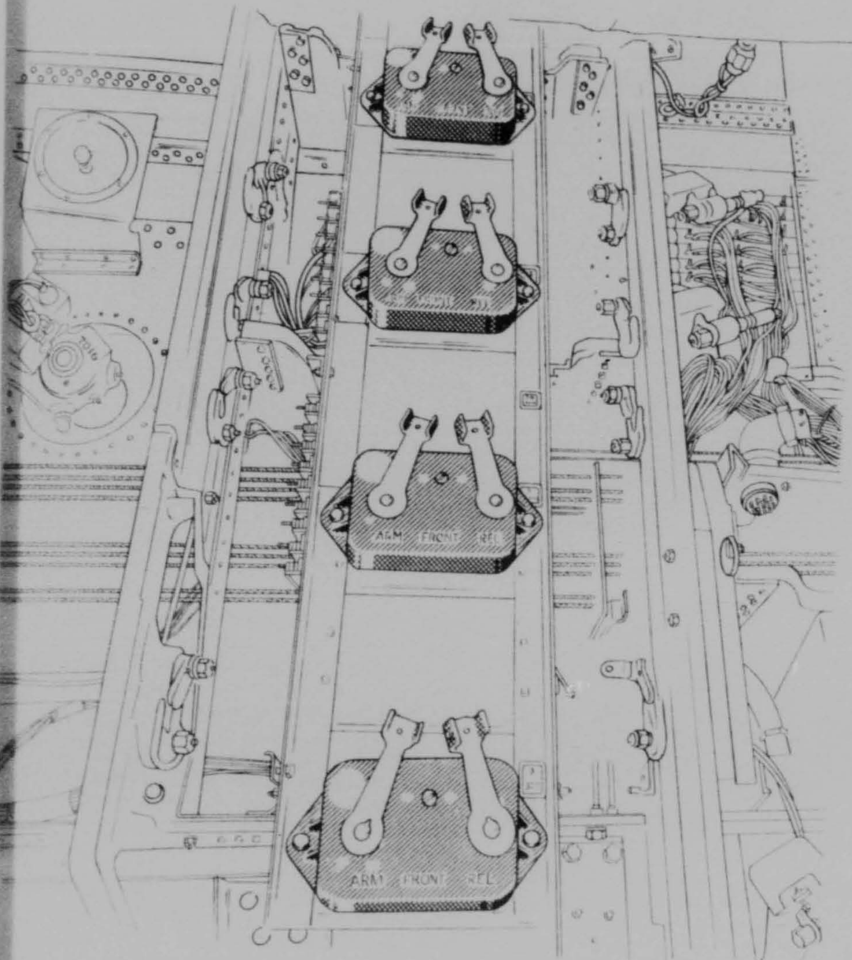
Interval Control Unit

The unit used to control the number of bombs released with each bomb-release impulse, and the interval spacing between each of the bombs so released is generally called a "bomb-release interval-control unit" or "intervalometer." Although there are two principal types of these, the function of both is essentially the same. This unit delivers the bomb-release impulses to the rack selector relays. These in turn distribute the impulses evenly between the various bomb trains or groups. The bomb-release impulse is initiated by closure of the bombardier's bomb-release switch.

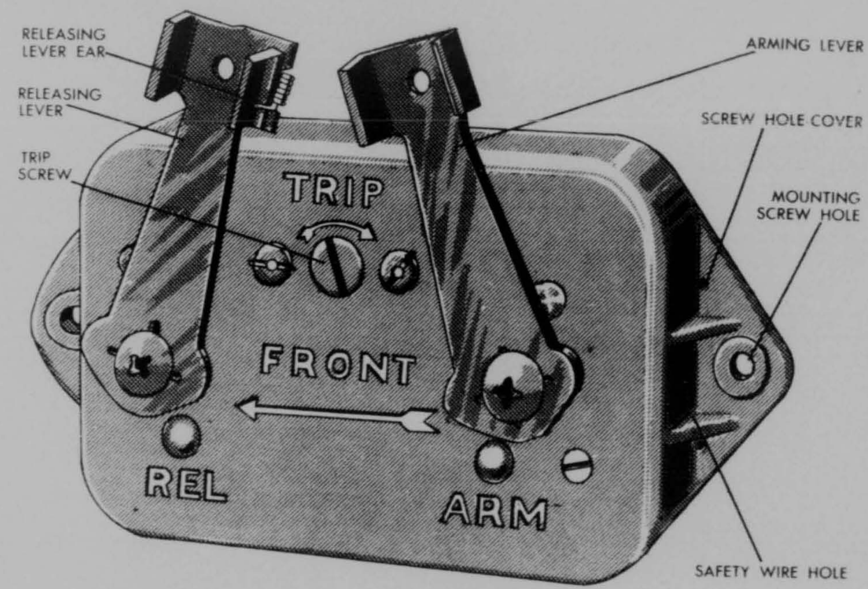
3. DESCRIPTION OF BOMBING SYSTEM UNITS AND SYSTEM OPERATION

General

Bomb racks are of two general types: internal and external, so designated from the manner in which they are carried by the airplane. Racks which are attached to the outside of the fuselage or to the underside of the wings of an airplane are known as "external bomb racks." Those which are attached to the inside of the fuselage and which carry the bombs entirely within a compartment in the fuselage are known as "internal bomb racks." Bomb racks are further classified as to type or model and carrying capacity. In order that the operation of releasing a bomb, and the consequent sudden decrease in load, may not disturb the steady horizontal flight of the airplane, the center of gravity of each bomb of the bomb load must be as close to the center of gravity of the airplane as possible. With an internal rack, this condition may be satisfactorily obtained since the distance of the bombs from the center line of the fuselage is not great when compared with the distance to the control surfaces of the wings. The center of gravity of the various sizes of bombs does not differ materially, and it is therefore possible to locate the bomb rack correctly in relation to the fore and aft center of gravity of the airplane. When some types of external racks are mounted on the wings, the balance of the aircraft is not always easy to retain.



SECTION II—BOMB RACKS

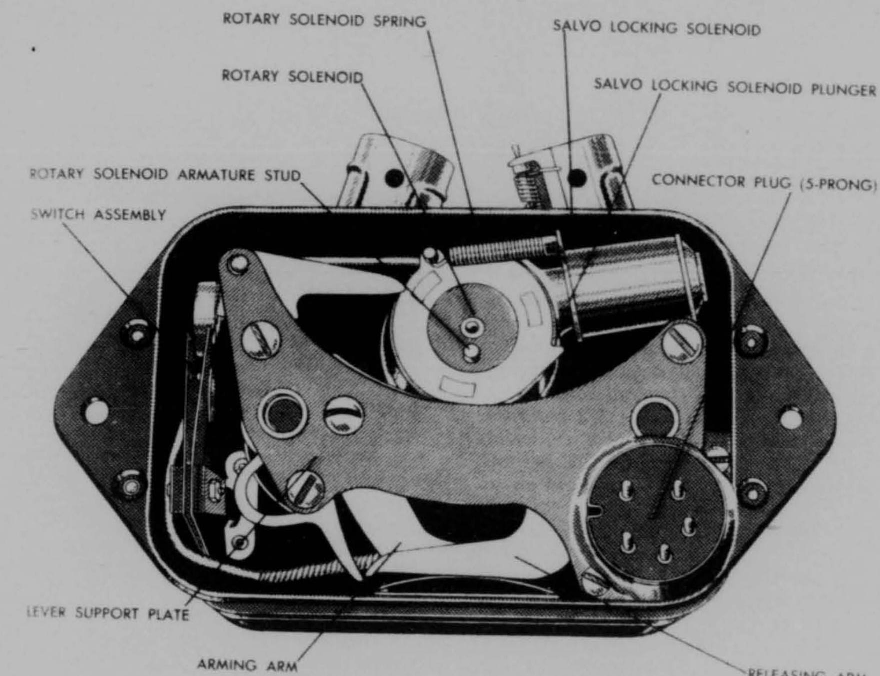


1. BOMB-RACK RELEASE UNITS

Bomb-rack release units (usually called "releases") are of two types: The first, type A-4, is used on all electrical bomb-release systems; it is being replaced by the second, type A-5, because the bombs are salvoed when the indicator lights are turned on and the bomb-release switch is pressed.

2. THE A-5 BOMB-RACK RELEASE UNIT

The component parts include an arming lever and a release lever, a rotary solenoid to trip the levers, a salvo-locking solenoid for dropping bombs unarmed, a releasing arm, an arming arm, a combination transfer and indicator light switch, a switch operating arm, a shock plate, a trip screw, and internal wiring terminating in a five-prong electric plug. All parts are assembled in a die-cast aluminum case with a dustproof cover for the back. A drilled flange at either end of the case permits bolting the unit to the rack. The five-prong plug connects with a socket on the bomb rack to provide an electrical connection. The release lever is provided with a hinged ear to facilitate local manual release which may be accomplished by prying the release lever of the shackle out of engagement with the release lever of the release unit, dropping the bomb "safe". A slotted manual trip screw, located on the face of the release unit, provides for local manual release. Bombs dropped by this means are in an armed condition, and the internal switches are moved into the same position they would have assumed if the release had been actuated in the normal manner. If the release is tripped manually, the trip screw should always be returned to its original position, or it will be impossible to cock the release. Closing the "salvo" switch energizes the rotary solenoid and the salvo's solenoid, causing the release lever to fall and



the arming lever to remain cocked. Bombs released in this manner will fall "safe". In operation, the bomb release impulse enters the release unit through electrical pin No. 2 and energizes the rotary solenoid. Then the rotary solenoid is energized, the solenoid armature plate rotates, disengaging the solenoid armature stud from the releasing arm and the arming arm. The releasing arm is disengaged slightly ahead of the arming arm. The above action causes the arming lever and the release lever to be tripped, resulting in the bomb being dropped in an armed condition. After the release has been tripped and the electrical impulse terminated, action of the switch operating arm causes the internal switching arrangement to assume a position that will close the circuit to the next unit. The rotary solenoid returns to its normal position, and the circuit to the indicator light and salvo solenoid is opened. One cycle of electrical operation has been completed. Manual operation is accomplished by turning the trip screw on the front of the release in the direction indicated. Function of the release is exactly the same as described for electrical release. When the salvo switch is closed, the rotary solenoid and the salvo solenoid are energized. Energizing the salvo solenoid causes the salvo-locking solenoid plunger to be thrust outward in a position to oppose the movement of the rotary solenoid at the point where the arming arm would be tripped. As the rotary solenoid is activated, the releasing arm is disengaged from the rotary solenoid armature stud, allowing the release lever to trip. Since further rotation of the rotary solenoid is prevented by the action of the salvo-locking solenoid plunger, the arming arm maintains engagement with the rotary solenoid armature stud and the bomb is dropped in the "safe" condition.

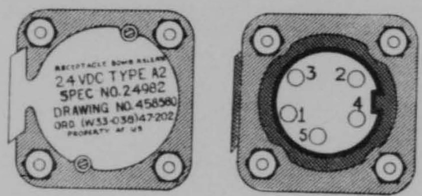


Figure 4–1. Receptacle Bomb Release Type A2.

3. BOMB RELEASE UNIT RECEPTACLES

Bolted to the bomb racks at each bomb station is a "bomb release unit receptacle" which serves the bomb-rack release unit in the same manner that a wall plug does on an electrical home appliance. The standard receptacle at present is the type A-2. The A-2 receptacle has five socket terminals which are legibly marked 1, 2, 3, 4 and 5 (Figure 4-1). Between terminals 2 and 3 there is a contact switch which is normally closed when there is no bomb release plugged into the receptacle. The contact switch between terminals 2 and 3 is a "skip-over" switch which permits current to flow to the next station if a bomb release is not installed in the receptacle. The installation of a bomb release at the receptacle allows the contacts between terminals 2 and 3 to be broken by the action of the prongs pushing against the spring assembly. Breaking this contact does not permit any current to flow from terminal 2 of the receptacle to the next station, unless the installed bomb release is tripped. The contact of the "skip-over" switch remains unbroken when there is no release installed, allowing current entering terminal 2 to be short-circuited to terminal 3 and flow to the next station.

4. BOMB SHACKLES

The bomb shackles act as links between the bomb and the bomb rack. These are provided in a variety of types for use with a variety of bomb sizes. Since the principle of operation of most bomb shackles is the same, the type B-7 bomb shackle (Figure 4-2) will be discussed in detail as representative of all types. The B-7 shackle (Figure 4-3) consists of a frame (provided with two carrying loops at

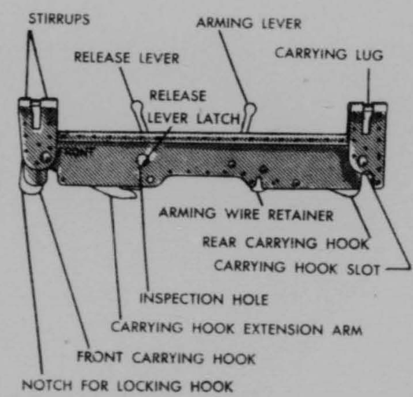

Figure 4–2. Bomb Shackle B-7.

the top for attachment to the shackle-carrying hooks of the bomb rack), carrying, releasing, and arming mechanisms. Two carrying hooks, pivoted in the lower part of the frame and spaced to engage the carrying lugs of the demolition bombs, are connected at their upper ends by the carrying-hook link. Attached to the carrying-hook link, near the front, is the sear. The latch mounted inside the front provides an engaging surface for the sear and trigger. The latch, pivoted at one end with a pin, is free to move up and down at the other end. With the sear engaged with a latch, the trigger is mounted in a position to engage the latch and prevent it from moving down to disengage the sear. The latch spring, positioned below the latch, moves the latch up in position for engagement of the trigger. The trigger arm projects through a slot in the top of the link and is positioned between the lugs of the tripping lever on the bomb rack. The trigger spring holds the trigger engaged with the latch. To close the

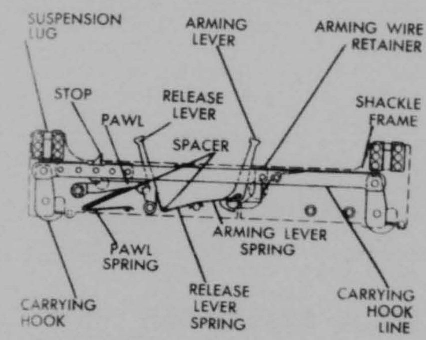

Figure 4–3. Detail of Bomb Shackle Type B-7.

carrying hook: as the link is moved forward, the latch moves up to engage the sear; the trigger then engages the latch, preventing the latch from being disengaged from the sear. Bomb release is accomplished by moving the trigger arm to the rear. Near the pin that positions the trigger to the frame is an engaging surface. As the trigger arm is moved to the rear to clear the latch, the weight of the bomb on the carrying hooks forces the sear (which is attached to the carrying-hook link) and latch to disengage, permitting the carrying hooks to open. The arming mechanism consists of the arming-wire retainer (pivoted in the carrying-hook link and held in position to retain the arming wire by a spring) and the arming hook. This mechanism is located inside the frame to the rear of the trigger. The arming hook is pivoted on the opposite side of the arming-wire slot from the arming-wire retainer. The arming-hook assembly has a hook at the lower end and an arm at the upper end. The arm extends through an elongated slot in the carrying-hook link, and is positioned between the lugs of the arming lever of the bomb release. The arming hook is held in the safe position by the arming-hook spring. The loop of the arming wire is placed in the slot above the retainer. When a bomb is dropped "safe", only the release lever is tripped. As the trigger is moved to release the carrying-hook link, the arming-wire loop and the wire fall with the bomb. To drop the bomb "armed" the release lever and the arming lever are

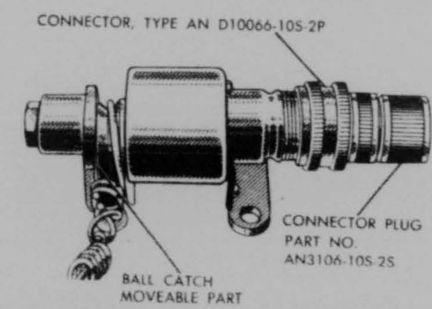

Figure 4–4. AN-A2 Bomb Arming Control Unit.

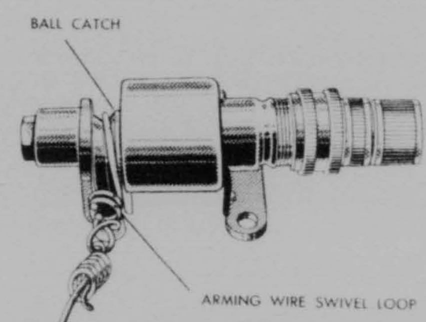

Figure 4–5. AN-A2 Bomb Arming Control Unit.

tripped. Tripping the arming lever moves the arm of the arming hook forward (by action of the arming lever of the release), and the arming hook is pivoted to the rear through the loop of the arming wire and under the retainer. When the bomb is released, the retainer moves to the rear as before, but the arming hook holds the arming wire in the shackle and prevents it from falling with the bomb. The arming wire, being held by the shackle, pulls the wire from the fuse and the bomb drops "armed".

5. BOMB ARMING CONTROL UNITS

The preferred arming unit is the A-2 (Figure 4-4). There is one of these arming units for each main bomb station, with the entire group of units electrically connected in parallel to each other. A bomb-arming control switch on the bombardier's control panel turns all these units on or off simultaneously. One of the bomb arming wire swivel loops (Figure 4-5) (always the nose fuse) is inserted into the arming-unit ball-catch. If the bomb is now dropped while the arming switch is "off," the arming-wire swivel loop simply pulls out of the ball-catch without arming the particular fuse controlled by that wire. However, if the bomb is dropped with the arming switch turned "on," the solenoid within the arming unit case is energized, locking the ball-catch. Therefore, the arming wire is held by the arming unit, and pulling out of the bomb fuse, arms the bomb. By use of the bomb-arming control system, the bombardier can not only select which bombs will be nose-armed but also whether or not the bombs will be released armed in salvo.

SECTION III — BOMBING SYSTEM CONTROLS AND INDICATORS

1. RACK SELECTOR RELAYS

The rack-selector relays (Figure 4-6) are needed when more than one bomb train or bomb group is used, as their purpose is to distribute the bomb-release impulses evenly between the bomb trains so as to maintain a balanced bomb load.

General

Each single-rack selector relay has two separate release circuits and can therefore operate two separate bomb trains, or bomb racks. Thus, four bomb trains would require two rack-selector relays, and six trains would require three rack-selector relays. Electrical connection is made to the bomb-rack selector by a nine-contact screw-type of pin, a female connector plug that is not furnished with this instrument. Electrical connections to the male connector plug should be as described in the paragraphs which follow.

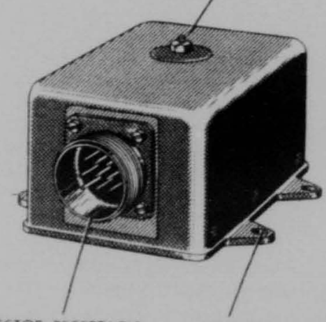

Figure 4–6. RS-2 Rack Selector.

Pin A is attached to a common circuit between all of the bomb-rack selectors in the circuit. It is not utilized if only one bomb rack selector is used.

Pin B is attached to the positive DC power source. A bomb group selector switch in this circuit will control output pin E.

Pin C is attached to the positive DC power source. A bomb-group selector switch in this circuit will control output pin F.

Pin D is the "impulse input" pin. It is attached to the bomb-release interval control or to pin H of the previous bomb-rack selector unit in the circuit.

Pin E is the first "impulse output" pin. It is attached to the desired bomb-rack release unit or series-wired group of release units.

Pin F is the second "impulse output" pin. It is attached to the desired bomb-rack release unit or group of release units.

Pin G is not used.

Pin H is attached to pin D of the next bomb-rack selector in the circuit. It is not used on the last bomb-rack selector in a circuit, nor when only one bomb-rack selector is in the circuit.

Pin J, electrical ground, is negative (—) and is made through the mounting bosses.

Function and Operation

Operation of the RS-2 rack selector is based upon a "feeler current" with the release impulses being transmitted to the group selector from the bomb-release control unit. This "feeler current" in reality is searching for a ground or path through which the circuit may be completed. When the circuit is completed through the cocked release, the proper relays in the selector close, thus providing a path for the firing impulse which releases the bomb after the firing button is depressed by the bombardier. The bomb-rack selector is an electrical device consisting of interconnected relays which will automatically transfer the bomb-release electrical impulse alternately between two circuits. Two bomb-release selectors, which are wired in series, will distribute the impulse between four circuits and three selectors, between six circuits, etc. Three bomb-rack selectors in series will transfer the bomb release impulse to circuits 1, 2, 3, 4, 5 and 6; 1, 2, 3, 4 and 5, and 1, 2, etc. Each circuit may be connected to any group of series-connected bomb-rack release mechanisms. The selector is so designed that if an output circuit from either pin E or pin F is not completed to ground (through an unreleased bomb-rack release mechanism), the circuit will automatically be excluded from the bomb "train". This allows uneven loading of bomb racks or bays, without any impulse failures in the bomb "train", and in each succeeding "train" which includes that bomb. By the inclusion of a manually operated bomb-group selector switch in each circuit, it is possible to direct the impulses into any one or more of the circuits the bombardier may desire. Should a bomb fail to release, the particular bomb rack should be excluded from succeeding bomb "trains" by means of the bomb-group selector switch, in order to eliminate an impulse failure in the train. After a "train" of bombs has been released, the first impulse in the next "train" may be directed into circuit number 1 (or the first closed bomb-group selector switch) by momentarily breaking the positive AC power source to all bomb release controls by closing the bomb-bay doors. Many different circuit combinations are possible in which RS-2 rack selector may be connected into the electrical bomb-release circuit. Each circuit has certain peculiarities which affect the operation and the sequence of release of the rack selectors. In general, the following procedure should be observed in order to insure proper release order: The first bomb-release interval-control impulse is sent to the first circuit in which the bomb-group selector switch is closed, and the second impulse to the second circuit, and so forth.

All bomb-group selector switches are thrown to the "off" position when cocking the bomb-shackle release mechanism.

Bomb-bay doors must be closed after the bomb-shackle release mechanisms have been cocked and bombs have been loaded.

Bomb-group selector switches to the circuit in which the release of bombs is desired are closed.

Bomb-bay doors are opened.

Bomb-release switch (bomb-sight or control switch in bomb-release interval-control circuit) are closed when in proper position to hit target.

Bomb-bay doors are closed after "train" of bombs has been released.

2. BOMB RELEASE INTERVAL CONTROL UNIT

General

The bomb-release interval-control unit (Figure 4-7) or "intervalometer" is mounted on the bombardier's control panel in most airplanes. These units employ relays and capacitors in controlling the interval between release impulses.

Train Selector Switch

The "train selector" switch is a two-posi-

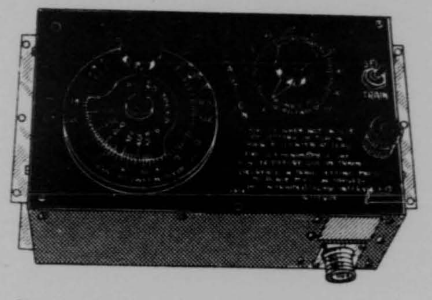

Figure 4–7. Bomb Interval Control.

tion toggle switch, located above the pilot light. When the toggle switch is in the "select" position, bombs may be released one at a time by depressing the bomb-release switch once for each bomb dropped. When the switch is in the train position, bombs may be released "in train" by depressing the bomb release switch once.

Counter Switch

The "counter" switch controls a number of bombs to be released in train. The dial is graduated from "0" to "50". The desired number of bombs to be released in train must be selected before the bomb release switch is closed. When the control dial reaches the "0" position, the release of bombs is stopped automatically due to the action of an internal switch arrangement. If, however, the selector switch is in the "select" position, bombs may be released after the dial reaches "0" by continuing to close the firing switch. It is possible to interrupt the "train release" of bombs at any time by manually turning the counter dial back to the "0" position. It is also possible to drop more than the selected number of bombs, or more than 50 bombs, by manually retaining the dial at any position above "0".

Interval Selector Dial

The interval selector dial indicates the distance in feet between the bombs on impact. The dial is operated by a knob at the bottom of the dial. Twenty-one settings are provided to enable the operator to select the desired spacing of bombs at the desired ground speed.

Pilot Light

The pilot light is illuminated when the "select train" switch is in the "select" position. When the "select train" switch is at the "train" position, and the counter dial at "0", the pilot light will be out. Current will not pass through the bomb-release interval control.

Releasing Bombs "In Train"

In order to release bombs "in train", the procedure is as follows:

The "train selector" switch is set on "train".

At least one minute prior to operation of the instrument, the counter switch is placed at the desired number of bombs to be dropped in the train.

The "interval selector" dial is set at the position which will give the desired spacing between bombs at the ground speed at which the airplane is expected to be traveling when the "train" is released.

This instrument is ready for operation at this point. Other allied operations, such as opening the bomb-bay doors and turning on the rack-selector switches, must be performed before releasing any bombs. For dropping one bomb at a time the "train selector" switch is put on "sel" position.

3. BOMBING SYSTEM CONTROL AND SAFETY SWITCHES (Figure 4-8)

General

A bomb-release switch of the push-button style is used. On closure the switch sends a spurt of electricity into the A terminal of the bomb release interval control unit, which results in an impulse going out from this interval control and into the rack-selector relay. Bomb-release switches, in cases of light bombers, are located in the pilot's compartment, as well as in the bombardier's compartment. But in the larger bombers this switch is logically located close to the bombardier's control stand.

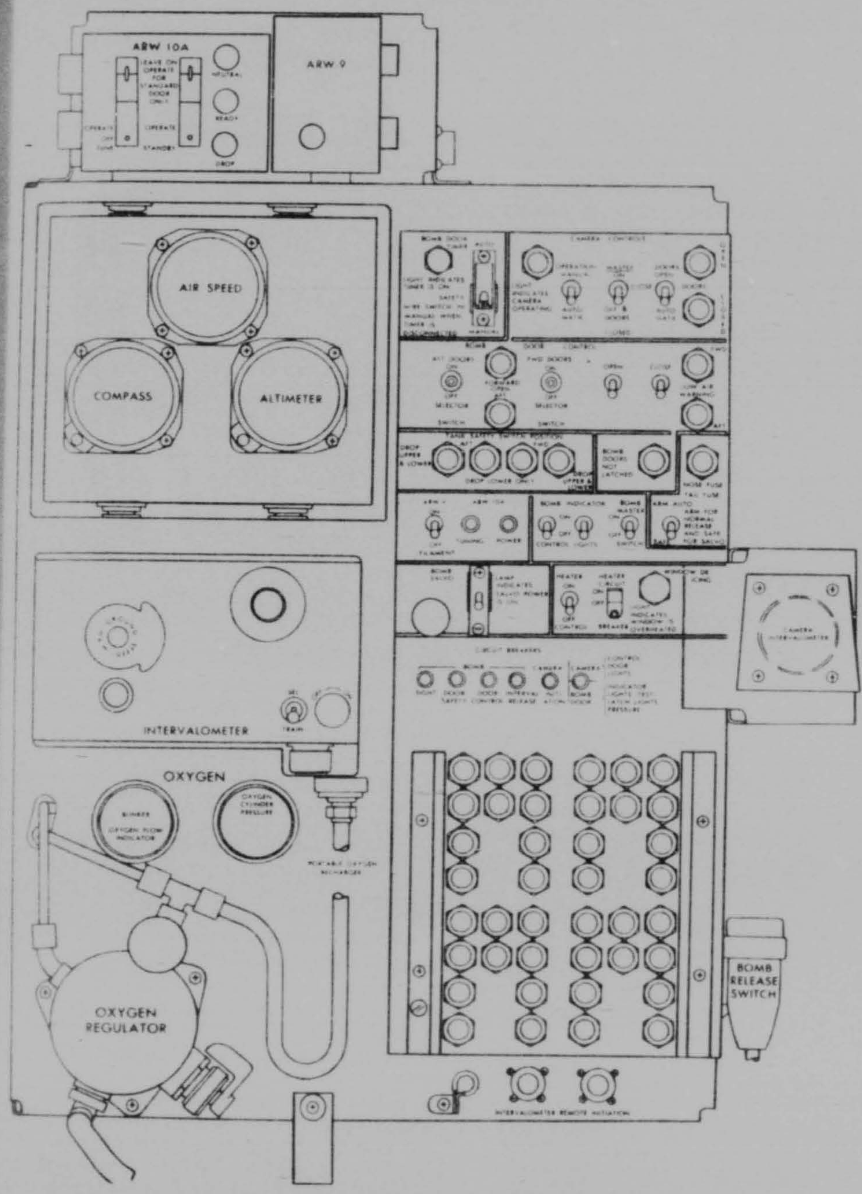

Figure 4–8. Bombardier's Control Panel.

Rack-selector Switches

Rack-selector (group selector) switches operated by controlling the "feeler current" into the rack-selector relays. These switches are located on the bombardier's control panel and give control over which bomb groups or trains will be released. One of these switches in the "off" position prevents releasing any bombs from that particular bomb train since the feeler current is prevented from closing the relays in the rack-selector relay for that release circuit.

Bomb-door Safety Switches

Bomb-door safety switches, like rack-selector switches, control the feeler current into the rack-selector relays. These switches are opened and closed by the movement of the bomb-bay doors. As the doors come fully open these switches close, thereby letting the feeler current close the relays to the bomb-release circuits. With bomb doors closed these safety switches shut off the feeler current and thus prevent closing of the relays to the bomb trains. Since the purpose of these safety switches is to prevent release of internal or bomb-bay bombs while the bomb doors are closed, it is logical that they are unnecessary on release circuits going to wing and other external racks.

Salvo Safety Switches

Salvo safety switches are operated in the same manner as bomb door safety switches. However, these prevent current reaching and energizing the salvo time-delay relays on the bomb-bay release circuits, thus preventing salvo releases of internal bombs until the bomb doors are fully opened.

Fuel-tank Safety Switches

Fuel-tank safety switches generally are located on the salvo time-delay relay unit in the bomb bay in the near vicinity of the bomb racks. These function to open and close the release circuits between the rack-selector relays and the first station in each bomb train. If one of these switches is opened ("off" position) no release impulse can be sent to that particular bomb train. The principal purpose

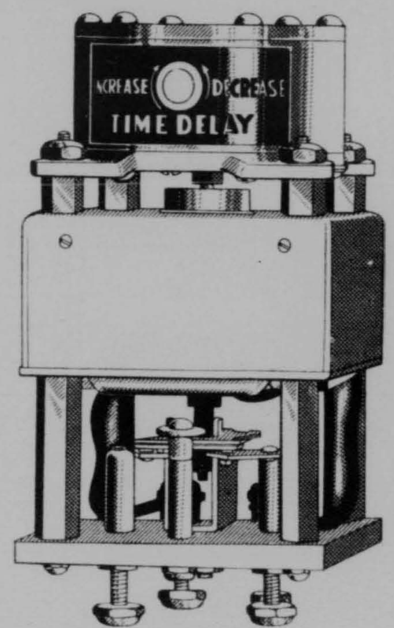

Figure 4–9. Agastat NC-28A.

of fuel-tank safety switches is to prevent accidental release of bomb-bay fuel tanks which are sometimes suspended from bomb racks by means of bomb shackles. However, they serve also as a safety measure in bomb loading, since these switches in the "off" position prevent any dropping of bombs while ground personnel are engaged in bomb hoisting.

Bomb-formation Light System

The bomb-formation light system is used on most bombing planes, and serves to warn trailing aircraft in the same formation or group that (1) the particular airplane's bomb doors are open and (2) when bombs are actually being released from that airplane. This serves not only to reduce chances of the trailing aircraft crowding the bomber during the bombing operation, but also serves as a guide to bombardiers in trailing aircraft who often depend on the lead bombardier (in the airplane leading the group) for determining the

time of bomb release.

A time-delay relay called an AGASTAT relay (Figure 4-9) controls the signaling from this system. The time-delay relay controls the white-to-red color change of the bomb-formation light below the rudder and to the rear of the fin. The light is connected in parallel with the bomb-door signal light and is illuminated when the bomb doors are fully open. A red filter controlled by the time-delay relay changes the light from white to red. The light switch on the bombardier's control panel has "bright", "dim" and "off" positions. The resistor which dims the light is in the bombardier's fuse panel. The time-delay relay is a quick-closing, delayed-opening type of relay, and is operated by impulses received from the bomb interval release, regardless of whether the bombs are being dropped in train or selective. Each impulse energizes the relay coil, causing the core to make an instantaneous and complete stroke downward, compressing a spring and causing the snap action switch to close the circuit. This energizes the bomb-formation-light solenoid which thrusts the red cylindrical filter in place around the light, where it remains as long as the solenoid is energized. When the pulse from the interval release ceases, de-energizing the coil in the time-delay relay, compression force from the spring is transmitted through the spindle to a diaphragm in the timing head. The diaphragm contains a flapper valve which allows air to be drawn in readily on the downward stroke; but on the upward stroke the air must escape through an orifice adjusted by the timing knob on the side of the relay. The orifice has been set to provide five seconds delay at sea level. When the diaphragm moves upward to a certain point, a lever trips the flapper valve, allowing the remainder of the air to escape instantly. The contacts snap to their original position, de-energizing the bomb-formation-light solenoid and allowing a spring to return the red filter to its original position. If the delay is energized again before the five seconds elapse, the core immediately travels downward, starting a complete new five-second delay. This keeps the light red while bombs are being dropped in train and allows it to become white five seconds after the last bomb has been released.

Miscellaneous Indicator Lights

Bomb-station Indicator Lights. These are used to indicate to the bombardier which bomb stations are cocked (and therefore loaded, since a release unit is not left cocked unless it is to be loaded). These indicator lights complete circuit to ground through the No. 5 pin or connection of the respective bomb rack release units. Since the No. 5 pins connect to ground only when the release units are cocked, the indicator light for a station can light on the "on" position of the "station check" switch only if that release unit is cocked. A "test" position is provided on the indicator-light switch for testing the light bulbs themselves. Thus, if a particular station light does not glow on "station check" an uncocked bomb station is indicated.

Bomb-door Indicator Lights

These are used to notify the bombardier (and, in the case of light bombers, the pilot also) when the bomb-bay doors are open. The current to these lights is controlled by switches operated by the bomb-bay doors, as are the bomb-door safety switches. When the bomb doors open fully the switch or switches close the circuit from electrical power to these indicator lights. As the doors close, these lights go out, since the switches open the circuit to power.

Bomb-release Indicator Light

This is usually located on the bombardier's control panel although the pilot's compartment may also have one. This light is connected to the B or output circuit of the bomb release interval control so that the light blinks or flashes with every bomb release interval impulse, thus serving as a check on the operation of the release circuit.

4. BOMB BAY DOOR OPERATION

General

Bomb door operation may be by means of:

Hydraulic pressure
Electrical power
Compressed air (pneumatic)
Mechanical linkage

Pneumatic System

While all four forms are used, the newest and best system appears to be the compressed air or pneumatic system. To a large extent, the mechanical operation of bomb doors seems to prevail for emergency-door operation failure of the normal door system. The pneumatic bomb-door system as used on the B-29 Superfortress will be discussed here. (The B-29 uses two bomb bays and two sets of bomb-bay doors.) The two sets of bomb doors each have their own pneumatic actuating system interconnected only by controls and pressure line. The forward bomb-bay installation consists of controls, a compressor, accumulator, air-pressure regulator valve, distribution valve, door actuators, and emergency opening springs. The rear installation is almost identical to the forward installation but does not include the springs which are used to open the forward doors in an emergency. The interconnecting pressure line allows one compressor to charge both systems in case one of the compressors is inoperative. To make this possible, the shut-off valve in the forward bomb bay must be open.

The system has both electrical and manual controls. Electrical controls are at both the bombardier's and pilot's station. They consist of two momentary switches, at each location, one for closing and one for opening the doors. The bombardier also has a selector switch which allows him to open the rear doors only. Salvo switches at the bombardier's, pilot's and right-hand gunner's stations also operate the bomb doors electrically when the bombs are salvoed. Manual control is provided for emergency operation of the bomb doors and consists of two release handles and two closing handles. The closing handles are not on all airplanes. One of the release handles is on the pilot's control stand and the other is on the left side of the forward bomb-bay cross walk. Both of the closing handles are in the bomb bays. One is located on the right side of the forward bomb bay cross walk and its operation closes the forward doors. The other is on the right-hand catwalk in the forward section of the rear bomb bay, and its operation closes the rear doors. Before the emergency-control handles in the bomb bays can be operated their protecting covers must be removed. It is necessary to close the forward doors first when using the closing handle.

During ground operation the bomb doors are normally operated by the "open" and "close" switches at the bombardier's or pilot's station. When the switch is held in the "open" position, a time-delay relay allows the solenoid-operated distribution valve to admit a small amount of air to the lower end of the bomb-door actuators. This pressure forces the actuator piston down against its cushioning air and opens the doors. To close the bomb doors, the "close" switch is held in place.

If the pneumatic system fails and no air pressure is available, either the pilot's emergency release handle or the release handle on the forward bomb-bay cross walk can be pulled to open the doors. The emergency release opens the latches on the forward bomb doors and the emergency springs force the doors open. Then air wedges on the aft ends of the doors, forcing them to the full open position. When the forward doors are approximately 70 degrees open, a cable which is attached to the left-hand forward door mechanically releases the aft-door latches, so that the built-up positive air pressure in the rear bomb bay (due to the opening of the forward doors) forces the aft doors open. Air wedges then force them to the full open position. In case of electrical system failure, if sufficient air pressure is stored in the accumulator, pulling of the release handles will allow air pressure to open the doors.

Micro switches on the door hinges turn on warning lights at the bombardier's station when the doors are open. Also warning lights are illuminated at the bombardier's and pilot's station when the latches are open.

During a bomb run, normal opening of the bomb doors is controlled by the bombsight. When the bomb door "open" switch at the pilot's or bombardier's station is actuated, the bombsight time-delay relay is not involved. The same thing occurs when the bombardier's or pilot's salvo switch is closed, except that no selection of doors is provided. The crew's salvo switch bypasses the relays entirely and allows the current to go directly to the distribution valve opening solenoids. The closing

switches bypass the relays also and allow the current to go directly to the closing solenoids.

5. UNIFIED BOMB RELEASE SYSTEM
(Figure 4-10)

Normal Release

On normal release of bombs the release impulse enters the bomb release interval control unit at terminal A. This results in an impulse going out from this unit through terminal B, blinking the bomb-release indicator light, energizing the time-delay relay (AGASTAT) of the bomb formation light system, and going on into terminal D of the rack selector relay. An impulse then comes out of E or F (depending on which of these two release circuits is set to "fire" next) of the rack-selector relay and passes through the normal-position contact points of the salvo time-delay relay, and from there through the fuel-tank safety switch and into the No. 2 pin or contact of the first cocked bomb-rack release unit in that particular bomb train. Since No. 2 pin on a cocked bomb-rack release unit connects with that unit's release solenoid, the release trips. If all rack-selector switches are closed or "on", successive release impulses would leave the rack selector relays alternately out, terminal E, then F, etc., and if two rack-selector relays are present, the release order would be E of the first rack-selector relay, then F of this same relay followed by E of the second rack selector relay, and then F of this last relay.

Salvo Release

On emergency or salvo release, closing any one of the three salvo switches would result in the following sequence of events:

Salvo warning lights would glow.

Door-opening solenoids would start the bomb doors opening.

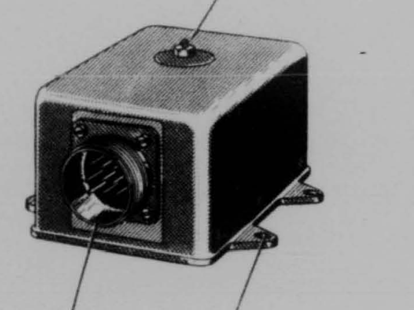

Figure 4—10. Unified Bomb Release System—Type A-5 Release Units.

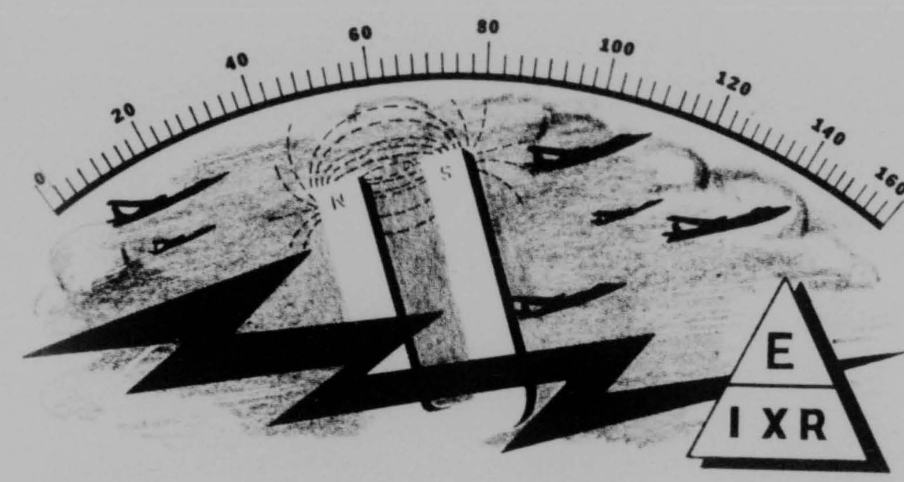
Bomb-salvo relay would close.

After the bomb-salvo relay is closed **electrical power would immediately go through the No. 1 pins of the release units,** energizing the salvo-locking solenoids in the releases.

When the bomb-bay doors have reached "full open" position, **current would flow through the coils of the salvo time-delay relays,** snapping these relays closed to the "salvo" position. This would allow the current from the closed bomb-salvo relay to flow through the fuel-tank safety switches and into the release solenoids of the release units.

The release units would then trip, with only the release levers tripping (since the salvo-locking solenoids are already energized), **thus dropping the bombs "safe".** However, had the bomb-arming control switch been "on" at the time of salvo release, the bombs would have been armed by these units.

CHAPTER 5—AC THEORY AND ELECTRONICS



SECTION I—ALTERNATING CURRENT

1. ELECTRICITY

Electricity is a fundamental quantity in nature, consisting of electrons and protons at rest or in motion. Electricity at rest has an electric field that possesses potential energy and can exert force, as in electrically charged pith balls. Electricity in motion has both electric and magnetic fields which possess potential energy and can exert force, as in an electric motor. Electricity in motion ordinarily consists of a movement of electrons through a conductor or through space.

Electricity may be generated by contact of dissimilar materials, thermo-electric action, chemical action, friction, or by electro-magnetic induction.

A conductor of electricity is a substance containing an abundance of free electrons through which electrons (current) flow freely.

An insulator or nonconductor of electricity is a substance containing relatively few free electrons, through which electron (current) flow is very limited.

It is necessary that we have conductors and insulators so that electricity may be guided or channeled where it can perform useful work.

2. ALTERNATING CURRENT

Alternating current is an electric current that is continually varying in value and reversing its direction of flow at regular intervals. Each repetition, from zero to a maximum in one direction and then to a maximum in the other direction and back to zero, is called a cycle. (Figure 5-1A.)

Direct Current

Direct current is an unidirectional current

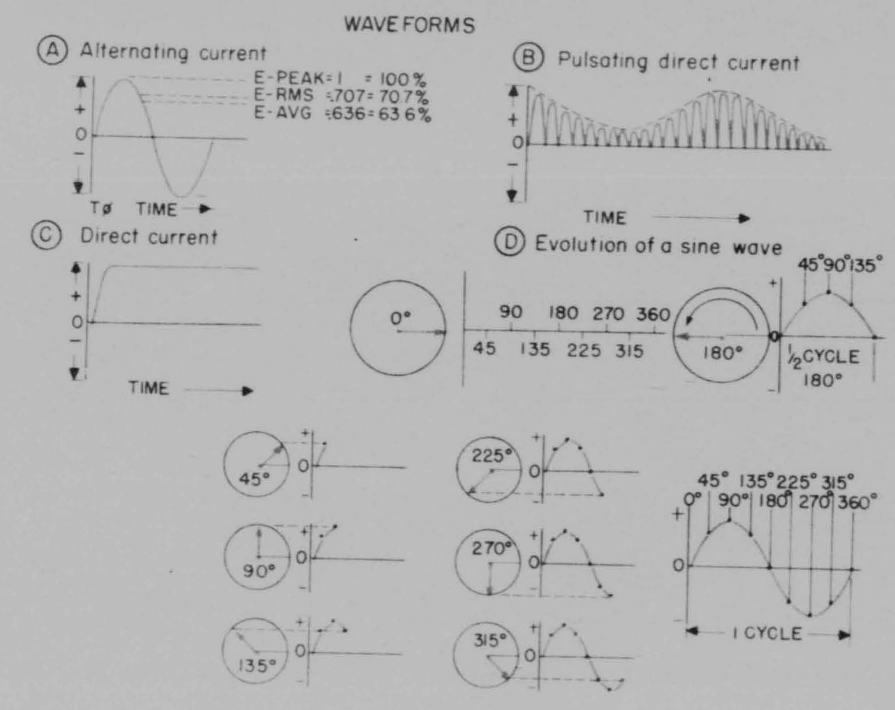


Figure 5—1. Waveforms.

(flowing in one direction at all times) in which the value is essentially constant. It is also called a continuous current. (Figure 5-1C.)

Pulsating Direct Current

A pulsating direct current is a current that is changing in value at regular intervals or irregular intervals but has the same direction at all times. Pulsating direct current is encountered in telephone use and in radio microphone circuits. Pulsating direct current may be produced by a carbon microphone whose resistance varies the direct current by the sound waves that impinge upon the carbon crystals, converting the voice or sound into pulsating direct current. (Figure 5-1B.)

3. ALTERNATORS

An alternator is an electric generator which generates an alternating current when its rotor or stator is rotated by a motor, an engine, or other prime mover. An alternating current may also be produced in a vacuum tube oscillator circuit. A simple AC generator may be constructed of a permanent magnet with a north and south pole (or with an electro-magnet that is excited by a direct current so as to set up a north and south pole), a single turn of wire placed between the north and south poles of the magnet on a shaft which may be rotated, two slip rings which are insulated from ground and from each other connected to the ends c' this single turn coil, and two sliding contact brushes to take

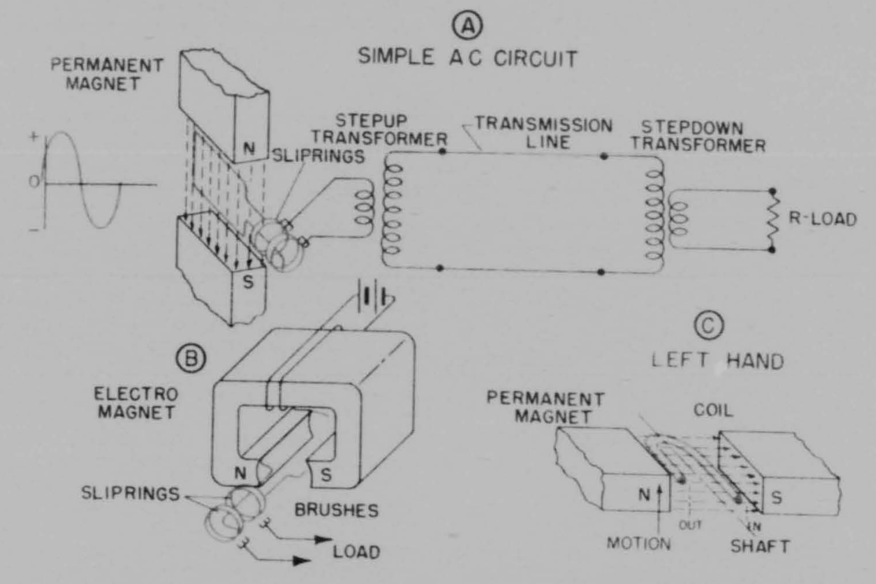

Figure 5—2. Simple Alternator, Step-up Transformer, Transmission Line, Step-down Transformer and Load.

the alternating current from the slip rings to the transmission lines and load circuit. (Figure 5-2A.)

Consider the simple generator in Figure 5-2A being turned by a prime mover in a clockwise position. If the first finger, thumb, and forefinger of the left hand are held at right angles to each other, and the first finger is pointed in a direction of the magnetic lines of force from the north to the south pole and the thumb is pointed in the direction of rotation of the single turn coil, the forefinger will point in the direction of the instantaneous current flow.

Current flow in a generator or motor is considered to flow from positive to negative. Electron flow in a vacuum tube is considered to flow from the more negative cathode to the more positive plate. It will be noted that these two theorems are in direct opposition and it will be necessary to bear this in mind when considering the current flow in motors and generators and electron flow in vacuum tube circuits.

4. DEFINITION OF TERMS OF ELECTRIC AND MAGNETIC QUANTITIES IN A SIMPLE ALTERNATING-CURRENT CIRCUIT CONSISTING OF A SIMPLE-ALTERNATOR SOURCE, A TRANSMISSION LINE, AND A LOAD (Figure 5-2A)

The alternator is an electro-mechanical device which converts mechanical energy into electrical energy; the transformer is an electrical device which steps up the voltage so that we may transfer it efficiently over long distances by a transmission line; the transmission line is the circuit which carries the electricity to the load. The load is the equipment or device which is placed or connected in the electrical circuit to absorb the power and convert it into the desired and useful form of work.

5. VOLTAGE

Voltage is the term most often used to mean electro-motive force, potential, potential difference, or voltage drop and to designate the electric pressure existing between two points which is capable of producing a flow of current when a load circuit is connected between the two points.

The instantaneous voltage produced in an alternating current generator is equal to the sine of the angle at which the conductor is passing through the lines of flux, hence the waveform of the voltage so produced follows a sine wave. When the conductor is passing through the lines of force at right angles, the voltage is maximum. If the peak value of the sine wave voltage is considered to be one or 100 per cent, the root mean square or the effective value of this voltage is considered to be .707 or 70.7 per cent of this value. The average value is considered to be .636 or 63.6 per cent of the peak value. A "RMS" volt or root mean square volt is the effective voltage. (Figure 5-1A.)

6. ELECTRIC CURRENT

An electric current is the rate of transfer of electricity. The practical unit of current is the ampere, which is a transfer of one coulomb per second.

7. CYCLE

A cycle is one complete sequence of variations in an alternating current, including a rise to maximum in one direction, a return to zero, a rise to maximum in the opposite direction, and a return to zero.

8. FREQUENCY

The frequency is the number of the cycles occurring in one second. Frequencies most commonly encountered in electric power are in the order of 25 cycles per second to 2400 cycles per second.

Audio-frequencies are those frequencies which the human ear can hear or respond to and are in the order of 20 cycles per second to 20,000 cycles per second.

The radio frequency spectrum extends from approximately 15,000 cycles per second to over 300,000,000,000 cycles per second. The radio frequency spectrum is further subdivided as follows: in very low frequencies abbreviated (VLF) 10,000 cycles per second to 30,000 cycles per second; low frequencies, abbreviated (LF) 30,000 cycles per second to 300,000 cycles per second; medium frequencies, abbreviated (MF) 300,000 cycles per second to 3,000,000 cycles per second; high frequencies, abbreviated (HF) 3,000,000 cycles per second to 30,000,000 cycles per second; very high frequencies abbreviated (VHF) 30,000,000 cycles per second to 300,000,000 cycles per second; ultra high frequency abbreviated (UHF) 300,000,000 cycles per second to 3,000,000,000 cycles per second; super high frequencies, abbreviated (SHF) 3,000,000,000 cycles per second to 30,000,000,000 cycles per second. Above approximately 100 megacycles per second or 100,000,000 cycles per second is known as the quasi optical region and radio waves at these frequencies behave in a manner similar to light waves.

The angular velocity of these sine waves frequencies is 2 pi radians per cycle. There are 57.3 degrees per radian.

9. PHASE

Phase is a quantity that specifies a particular stage of progress in any recurring operation such as a vibration or an alternating current. Phase is often expressed as an angle or part of a cycle in which case the complete cycle of operation is equal to 360 degrees (one complete rotation). When two alternating quantities pass through corresponding zero values at the same time they are said to be in phase.

The phase angle is the phase difference between corresponding stages of progress of two cyclic operations (such as between the applied voltage and the current in an inductive alternating current circuit). Expressed as an angle the terms "lag" and "lead" are used to specify which of the two quantities is first in time. The angle is expressed in degrees (one cycle equals 360 degrees or in radians, one cycle equals 6.28 or 2 pi radians).

If the voltage and current pass through their maximum and zero quantities at the

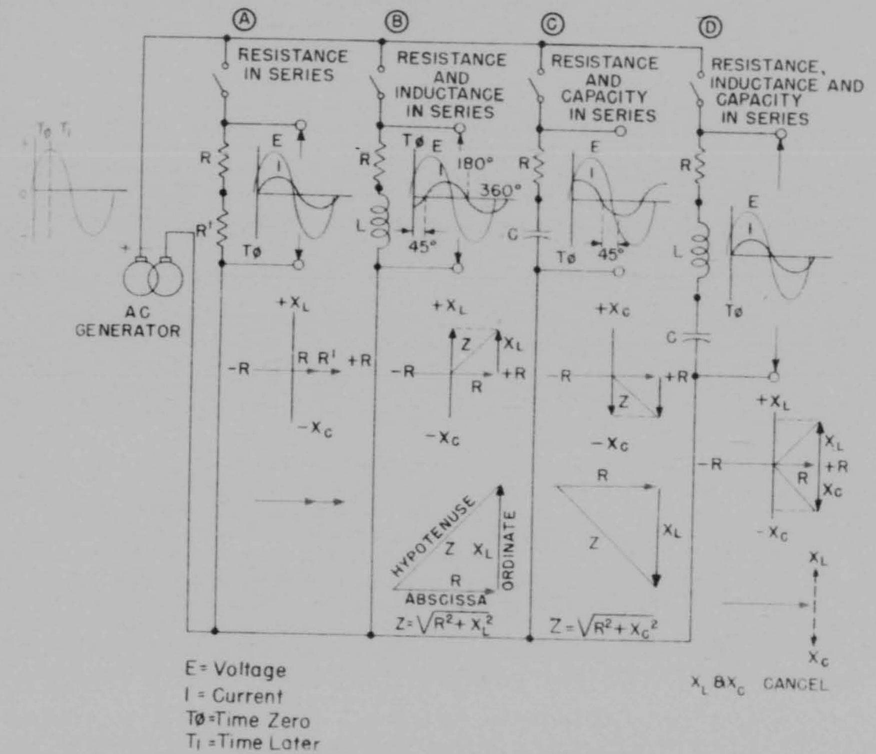

Figure 5–3. Series AC Circuits Containing Resistance, Inductance and Capacity.

same time they are said to be in phase. If the voltage and current pass through their maximum and zero at different times they are said to be out of phase. If the current leads the voltage by 90 degrees as in a capacitive circuit or if the current lags the voltage by 90 degrees, as in an inductive circuit, the circuit is said to be "reactive" and no work is done. If the voltage and current waves occur in time phase, work is performed in the load circuit, i.e., lighting a lamp, or turning a motor. The power factor of an AC circuit is equal to the cosine of the angle of the lead or lag of the current from the voltage in degrees. If the voltage and current are in phase the power factor is said to be "100 per cent."

10. RESISTANCES IN SERIES IN AN AC CIRCUIT

Resistances in a series AC circuit add arithmetically as in a DC circuit. Resistances in parallel in an AC circuit are equal to the reciprocal of the sum of the reciprocals of each resistance as in a DC circuit. (Figure 5-3A.)

11. INDUCTANCE

Inductance is that property of an electric circuit or two neighboring circuits which determine how much electro-motive force will be induced in one of the electro-motive cir-

THIS PAGE IS DECLASSIFIED IAW EO 13526

cuits by change of current in either of them. Inductance is measured in "henrys" and designated by the letter "L."

Self-inductance is that property of an electric circuit which determines, for a given rate of change in current in the circuit, the electromotive force induced in the same circuit. Self-inductance is measured in "henrys" and designated by letter "L."

Mutual-inductance is the common property of two associated electric circuits determining, for a given rate of change of current in one of the circuits, the amount of electromotive force induced in the other. Mutual inductance is measured in "henrys" and is designated by the letter "M."

Inductive reactance is that type of reactance which is due to the inductance of the circuit or coil. It is measured in ohms, designated by X_L, and is equal to the inductance in Henrys multiplied by 2 pi times the frequency in cycles.

$$X_L = 2\pi fL.$$

The mechanical analogy of an inductance is similar to the compression of a spring, in other words, the inductance tends to cause the current to be pushed behind or lag behind the voltage. (Figure 5-3B.)

12. CAPACITANCE

Capacity is the electrical size of a capacitor, determining the amount of electrical energy which can be stored in it by a given voltage at an amount of alternating current which will flow at a given frequency. The basic unit of capacitance is a "farad". It is the value which will pass a current of one ampere when the voltage across the capacitor is changing at the rate of one volt per second. The farad is too large a unit for radio and electrical work, hence, micro-farad (one millionth of a farad) and micro-micro-farad (one millionth of a micro-farad) are commonly used. Capacitance exists when two conductors are separated by an insulating material commonly known as a di-electric.

Capacity in farads in series AC circuit is equal to the reciprocal of the sum of the reciprocals.

Capacitance in an AC circuit in parallel is equal to the arithmetic sum of all of the capacitors in parallel.

Capacitive reactance is that type of reactance which is due to the capacitance of a capacitor or circuit. Capacitive reactance is measured in ohms, designated by the Letter X_c and is equal to the reciprocal of the product of 2 pi times the frequency in cycles per second and the capacitance in farads. (Figure 5-3C).

$$X_c = \frac{1}{2\pi fC}$$

The mechanical equivalent of a capacitance in an AC circuit is equivalent to the elasticity of a spring that is under tension, in other words, the capacitive reactance tends to pull the current ahead of the voltage. (Figure 5-3C.)

Capacitors or condensers are made in several types such as electrolytic, a capacitor consisting of a combination of two conductors at least one of which is a valve metal, separated by an electrolyte. A di-electric film, usually a thin layer of gas, is formed between the conductors, adjacent to the surface of one or both. A mica capacitor is a fixed capacitor employing mica sheets as the di-electric material between adjacent plates. The complete unit is encased in molded bakelite. A variable capacitor is an air di-electric capacitor whose capacitance can be varied by adjusting the amount of meshing between a fixed set of plates (the stator) and a rotating set of plates (the rotor), or sometimes by varying the spacing between fixed plates as in a trimmer capacitor. Other types of variable air di-electric capacitors are straight-line capacity condensers in which the rate of change in capacity is linear as the rotor is turned through 180 degrees. A straight-line frequency air di-electric variable capacitor whose rate of frequency change in a specific circuit is linear through 180 degrees of rotation of the rotor.

13. OHM'S LAW FOR AC

Ohm's law for AC states that the current in an AC circuit is directly proportional to the total electro-motive force in the circuit and inversely proportional to the total impedance,

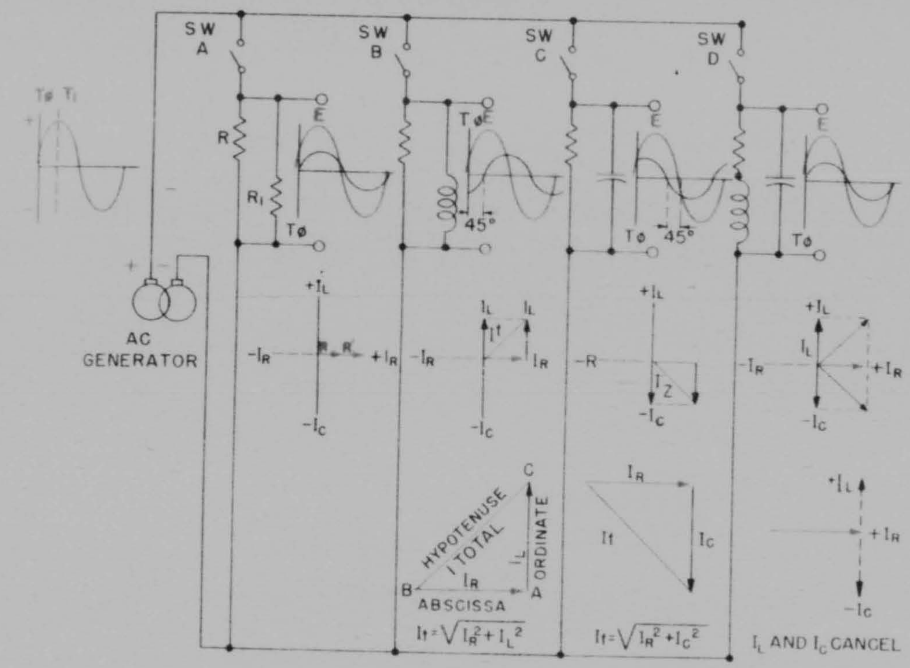

Figure 5—4. Parallel AC Circuits Containing Resistance, Inductance and Capacity.

which is the vector sum of the resistance and the reactance in the circuit. (Figure 5-3.)

14. WATTS' LAW FOR AC

Watts' law for AC states that the true power in watts is equal to the effective volts multiplied by the effective amperes and then multiplied by the circuit power factor. The apparent power in watts is equal to the effective volts times the effective amperes in an alternating current circuit. The apparent power includes the true power and the wattless or reactive components. The wattless component of the apparent power in an alternating circuit current is delivered to the circuit during part of a cycle, but is returned to the source during another part of the cycle. The true power in an AC circuit is usually called a "kilowatt," abbreviated KW (1,000 watts). The apparent power in an alternating circuit current is usually called "kilovolt amperes" abbreviated KVA (1,000 volt amperes).

15. SERIES AC CIRCUITS

Series AC circuits contain resistances in series. (Figure 5-3.) If switch A were closed, connecting resistances "R" and "R'" in series to the AC generator, the voltage would cause a current to flow. The voltage and current would be in phase and would pass through the zero and maximum magnitudes at the same times. If switch "B" were closed connecting resistance "R" and inductance "L" in series, the inductance would cause the current to lag the voltage. If the resistance in ohms and the inductive reactance in ohms were equal the lag would be approximately 45 degrees. The impedance "Z" in ohms would be the vector sum of the resistance and the inductive reactance.

Figure 5–5. Series Resonance.

If switch "C" were closed connecting resistance "R" and capacitance "C" in series in this AC circuit the condenser would cause the current to lead the voltage. If the resistance in ohms were equal to the capacity reactance in ohms the current would lead the voltage by approximately 45 degrees. The impedance Z in ohms would be the vector sum of the resistance and capacitive reactance.

If switch "D" were closed connecting the resistance "R", the inductance "L" and the capacitor "C" in series with the generator, and if the inductive reactance in ohms were equal to the capacitive reactance in ohms, the two reactances would be canceled out and the total impedance offered to the flow of an AC current through this series circuit would be the resistance "R". The voltage and the current would be in time phase with each other and would pass through their zero points and maximum magnitudes instantaneously.

16. PARALLEL AC CIRCUITS (Figure 5-4)

If switch "A" were closed connecting resistance "R" and "R" in parallel in the AC circuit the voltage produced by the generator would cause a current to flow. The voltage and the current would be in phase and would pass through their zero points and maximum magnitudes at the same time. If switch "B" were closed connecting resistance "R" and inductance "L" in parallel in this AC circuit, the voltage would cause a current to flow, but the inductive reactance of "L" would cause the current to lag the voltage. The total current flowing in this parallel circuit would be equal to the vector sum of the current through the resistance and the current through the inductance. If switch "C" were closed, the voltage would cause a current to flow but the capacitive reactance would cause the current to lead the voltage. The total current flow would be the vector sum of the current through the resistance and the current through the capacitor. If switch "D" were closed connecting the resistance "R" and inductance "L" and parallel with the capacitor "C" the voltage would cause a current to flow; if the inductive reactance in ohms of "L" is equal to the capacitive reactance in ohms of capacitor "C" the two would cancel

each other and the total current flow in this parallel circuit would be small and the impedance would be large due to the condition of resonance. The voltage and current would be in time phase with each other.

17. SERIES RESONANCE (Figure 5-5)

A series resonant circuit is a circuit with an inductance and capacitor in series, having electrical values such that the inductive reactance of the inductor is equal to the capacitive reactance of the capacitor at the frequency being impressed upon the circuit. At this condition, corresponding to resonance, the current is maximum and the voltage across either the inductor or the capacitor may be several times the voltage applied to the combination, depending on the "Q" of the circuit. The only impedance offered to the flow of current across this series resonant circuit is the resistor as the inductive reactance and the capacitive reactance cancel each other out. At low frequencies the capacitive reactance of the circuit is large and the inductive reactance is small so that much of the voltage drop is across the condenser, while the current is small and leads the applied voltage by nearly 90 degrees. At high frequencies the inductive reactance is large and the capacitive reactance is low, resulting in a small current which lags nearly 90 degrees behind the applied voltage, and most of the voltage drop is across the inductance. In between these two extremes, there is a frequency called the resonant frequency at which the capacitive and inductance reactances are exactly equal and consequently neutralize each other, leaving only the resistance of the circuit to oppose the flow of current. The current at the resonant frequency is accordingly equal to the applied voltage divided by the circuit resistance, and is very large if the resistance is low. The characteristics of the resonant circuit depend primarily upon the ratio of inductive reactance to the circuit resistance, that is, upon inductive reactance divided by resistance. This ratio is frequently denoted by the symbol "Q" and is called the circuit "Q". In the usual resonant circuit the radio frequency re-

THIS PAGE IS DECLASSIFIED IAW EO 13526

sistance circuit is made up almost solely of coil resistance because the losses in a properly constructed condenser are negligible in comparison with those of the coil. The phase angle of the impedance at resonance is zero.

$$\text{Resonant Freq.} = F_0 = \frac{1}{2\pi\sqrt{LC}}$$

$$\text{At Resonance } \omega L = \frac{1}{\omega C}$$

18. PARALLEL RESONANCE (Figure 5-6)

Parallel resonance is a steady state condition that exists in a circuit comprising an inductance and capacitance connected in parallel, when the inductive and capacitance reactance values are equal the current entering the circuit from the supply line is then in phase with the voltage across the circuit. A parallel resonant circuit at resonance (when the inductive reactance equals the capacitance reactance) the circuit has a high impedance and a high signal voltage value is developed across it at frequency to which the circuit is resonant. At high frequency the inductance has a high reactance compared with the capacity, resulting in a large leading line current and a correspondingly low circuit impedance that is leading in phase. At very low frequencies the inductive branch draws a lagging current while the leading current of the capacitive branch is small, resulting in a large lagging line current and a low lagging circuit impedance. In between these two extremes there is a frequency at which the lagging current taken by the inductive branch and the leading current entering the capacitance branch are equal and being 180 degrees out of phase are neutralized, leaving only a small resultant current flowing in the line. The impedance of the parallel circuit will then be, in effect, a very high resistance to this particular frequency.

19. TRANSMISSION LINES

A transmission line is the conductor used to transfer signal or power energy from one location to another. Most alternating current power transmission systems consist of the following elements: generating stations, step-up transformer stations, transmission lines suitably insulated to transmit this high voltage, step-down transformers and secondary line and load networks. Radio frequency transmission lines are usually spaced, paired lines, coaxial lines, or wave guides. A coaxial line is a metal tube having at its center a wire supported by insulators, it is also called a "concentric" line. A wave guide is a hollow tube or di-electric cylinder capable of propagating electro-magnetic waves through their interiors or radiating them into space, at frequencies of about 1,000 megacycles and higher. Widths or diameters range from ½ inch to 12 inches or more. There are two classes of guides, di-electric guides consisting of solid di-electric cylinders surrounded by air and having little practical use due to the high losses occurring in solid di-electrics, conducting guides which are air filled, gas filled, or evacuated hollow metal tubes which are circular, rectangular, or other cross section. The metal wall is called the sheath of the guide. It may be any conducting material and may be as thin as is practicable. Electro-magnetic waves travel through guides in much the same manner as sound waves travel through a speaking tube.

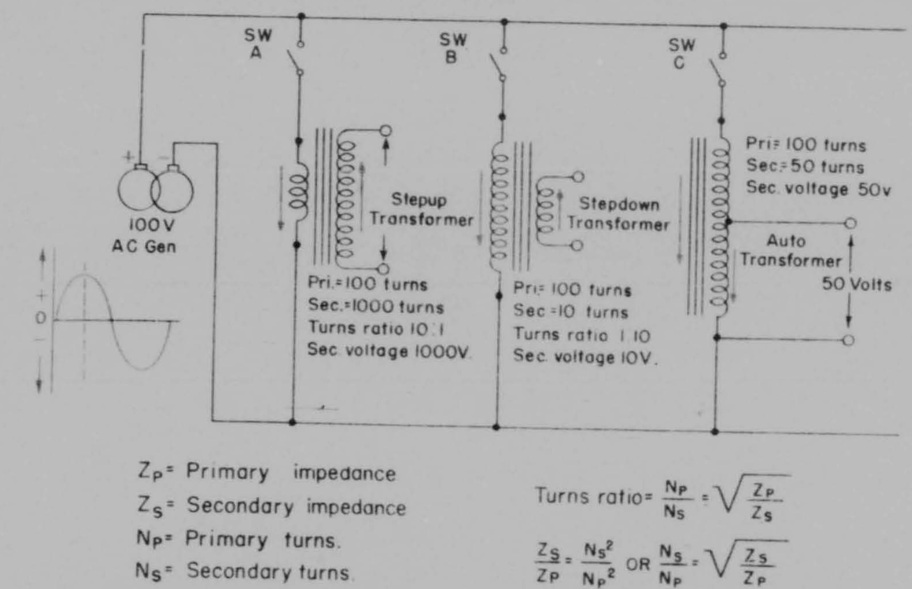

Figure 5–8. Transformers.

20. ANTENNAS

Antennas are a conductor or system of conductors for radiating or receiving radio waves.

A di-pole antenna is a simple antenna, ½ wavelength long. A wavelength in meters being equal to 300,000 frequency kilocycles.

A parabolic reflector brings parallel radio waves to a focus at a point for receiving, or produces a narrow parallel beam when a radio wave source is placed at its focus for transmitting. When a simple di-pole radiator is placed at the focus of a parabolic reflector the antenna gain over a single dipole may be 10 to 20 DB greater, or 100 to 1000 times as great.

21. INVERTERS

An inverter is a device for converting direct current into alternating current. It may be electro-mechanical, a vibrator, or electronic, as in a thyratron inverter circuit.

Inverters are commonly used in aircraft to supply 400 cycle, 110-volt power for radar equipment. See Figure 5-7.

22. DYNAMOTORS

A dynamotor is a combination electric motor and generator having two or more separate armature windings and a common set of field poles. One armature winding receives direct current as a motor and produces rotation, and the other generates current as a dynamo or generator. It is used to change a direct voltage to an alternating voltage or to a higher direct voltage, chiefly in connection with airborne radio and radar equipment.

23. TRANSFORMERS

A transformer is an electric device, without continuously moving parts, which transforms electric energy from one or more circuits to one or more circuits by means of electro-magnetic-induction without change in frequency, but usually with a change in the value

THIS PAGE IS DECLASSIFIED IAW EO 13526

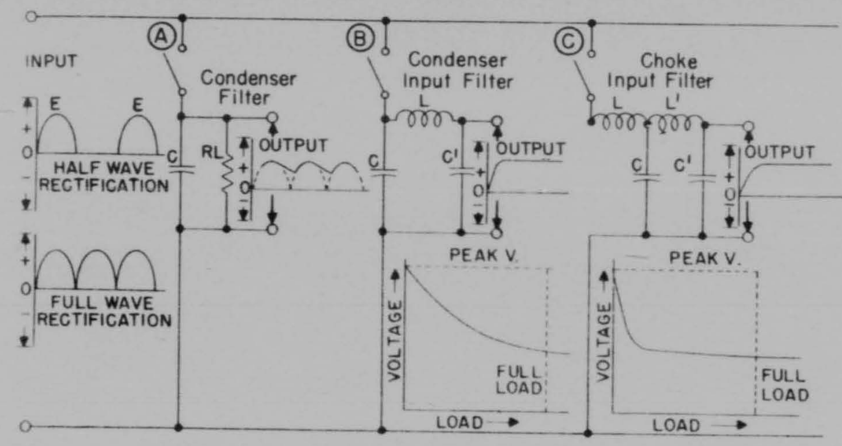

Figure 5–10. Power Filters.

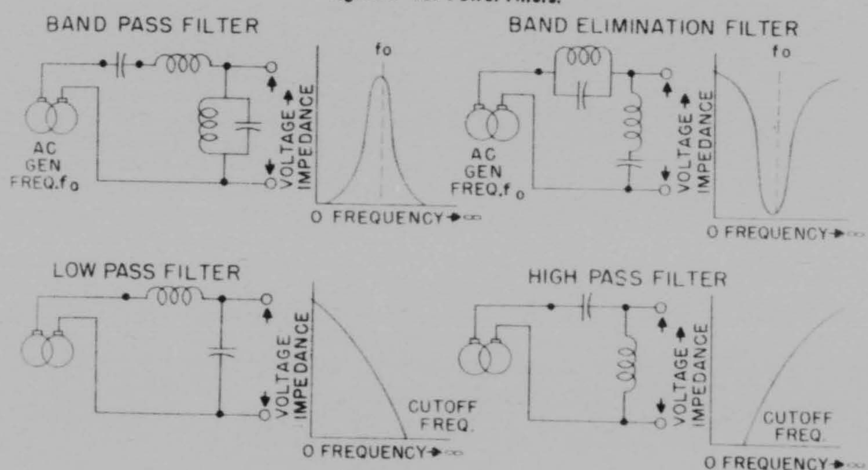

Figure 5–11. RF Filters.

of voltages.

Transformers may be single phase, two-phase, three-phase, or auto-transformers. (Figures 5-8 and 5-9.)

24. FILTERS

An electric filter is a selective circuit network designed to pass direct current or alternating current within a continuous band of frequencies, while substantially reducing the amplitudes of currents at undesired frequencies.

Filters may be of the band pass, band elimination, low pass filter, and high pass filters for radio frequencies.

Power filters are used to remove the ripple frequency after rectification. (Figures 5-10 and 5-11.)

SECTION II—VACUUM TUBES

1. INTRODUCTION

Since radio, television, radar and all other electronic circuits are built around vacuum tubes, this section will be devoted to the description and the simple operation of the principal tubes used in radar circuits.

2. THE ELECTRON AND ITS EMISSION

The whole foundation of electricity is based upon the "electron," a minute, negatively charged, particle. Atoms, of which all matter is composed, consist of a positively charged nucleus around which are grouped a number of electrons. The physical properties of any material depend upon the number of electrons and the size of the nucleus. In all matter there are a certain number of free electrons. The movement of these free electrons is known as a "current" of electricity. If the movement of electrons is in one direction only, the current is "direct." If, however, the source of voltage is alternated between positive and negative, the flow of electrons will likewise alternate; this is known as "alternating" current.

If certain metals, or metallic substances such as metallic oxides, are heated to a high temperature either by means of a flame or by passing current through them, they have the property of throwing off, or emitting, electrons. The element in a vacuum tube which is heated to emit electrons is called the "cathode."

If the cathode is heated to a high temperature in open air, it will burn up because of the presence of oxygen. For this reason the cathode is placed in a glass or metal bulb from which all air has been removed. Such a space is known as a "vacuum." Since it is difficult to heat an element in a vacuum tube by means of fire or flame, the cathode, which is in the form of a filament, is directly heated by passing a current through it.

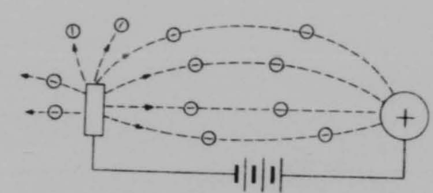

Figure 5—12. Emitted Electrons Attracted by a Positively Charged Body.

Any isolated, positively charged, body in the vicinity of the electron emitter will attract the negatively charged electrons. The positive charge on the body will soon be canceled by the electrons attracted to it unless some means is employed to remove the electrons as fast as they arrive. This can be done by connecting a source of constant voltage between the positively charged body and the electron emitter (Figure 5-12). This is the general arrangement in a two-element tube, or "diode." It is also the basis of operation of all types of vacuum tubes.

The emitter, or cathode, of a vacuum tube may resemble the familiar incandescent lamp filament which is heated by passing a current through it. The positively charged body usually surrounds the emitter and is called the "plate," or "anode." It should be noted that electrons travel from negative to positive.

Two types of cathodes, or emitters, are used in radio tubes. In one, known as the "filament" or "directly heated" type, the heating current is passed through the cathode itself. In the other, known as the "indirectly heated" type, the current is passed through a heating element, which in turn heats the cathode to a temperature sufficiently high for electron emission. In the indirectly heated type, the cathode is an oxide-coated metal sleeve which is placed over the heater element.

The higher the temperature of the cathode, the more electrons it will emit. However, if too much voltage is applied to a cathode, the

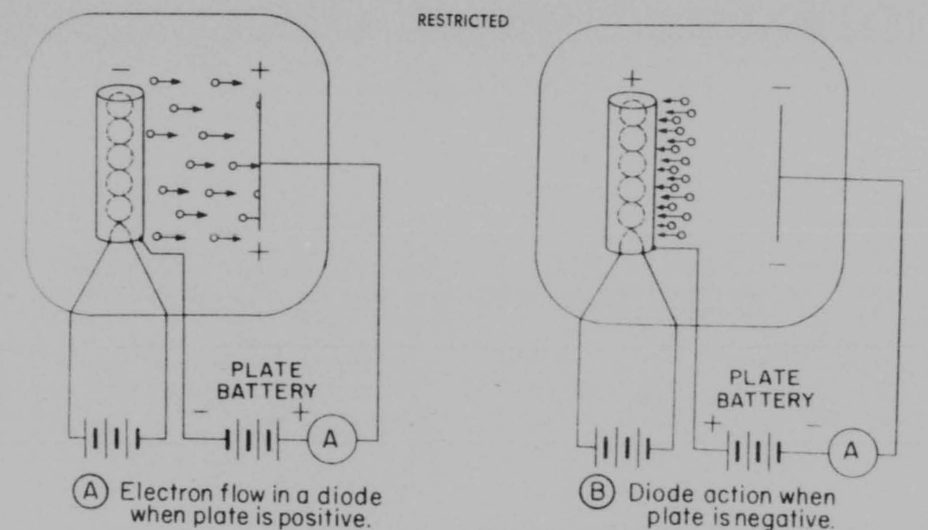

Figure 5—13. Diode Operation.

heavy current flow will cause the filament or heater to burn out. The safe filament or heater voltage is determined by the manufacturer, and this voltage rating must be observed for satisfactory operation. The cathode of a tube will not continue to emit electrons indefinitely. After several thousand hours of operation, the number of electrons emitted will gradually decrease, until finally an insufficient number is emitted for proper operation. The decrease in emission capacity is due to the chemical change which takes place in the cathode. This is one of the reasons why tubes wear out.

3. SECONDARY EMISSION

When an electron stream strikes an electrode surface, or, indeed, any surface, an emission of "secondary electrons" is produced. There is no known substance in which this effect does not occur. In fact, there is no known substance which acts as a perfect absorber of electrons that strike it.

As will be explained later, secondary radiation, in electronic tubes, is sometimes useful, and at other times, undesirable.

4. THE DIODE AND ITS OPERATION

The diode is the simplest type of vacuum tube, and consists of only two elements—a cathode and a plate.

If the positive terminal of a battery is connected to the plate of a diode and the negative terminal is connected to the cathode, the plate will be positive with respect to the cathode. Since the electrons emitted by the cathode are negative particles of electricity, and there is a positive charge on the plate, the electrons emitted by the cathode will be drawn to the plate (Figure 5-13A). In other words, there is an electron flow through the tube, which results in a current flow in the circuit. If the flow of current in the circuit is measured by meter A (Figure 5-13A), while the voltage applied to the plate (known as "battery voltage" or "plate voltage") is increased, it will be seen that the current flow through the tube, known as the "plate current," increases. This is illustrated by the plate-voltage plate-current curve of Figure 5-14.

When the negative terminal of a battery is connected to the plate of the diode and the positive terminal is connected to the cathode (Figure 5-13B), the plate will be negative with respect to the cathode; therefore, no electrons will be attracted to the plate. Since no electrons are traveling across to the plate, no current will flow through the tube.

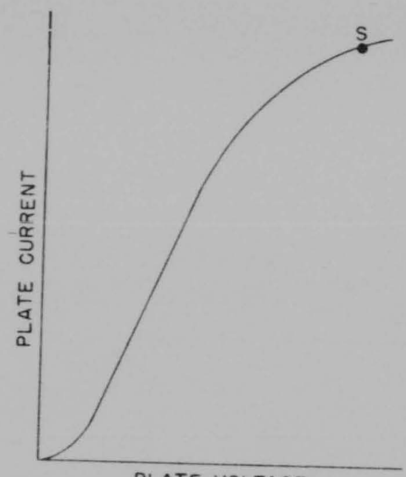

Figure 5—14. Plate Current Flow in a Diode.

The diode is a conductor when the plate voltage is positive. This property of the diode permits the use of this tube for two very useful functions—rectification and detection. Circuits to perform these two functions will be discussed in section III of this volume.

5. DIODE CHARACTERISTIC CURVES

The plate-current, plate-voltage curve shown in Figure 5-14 is an important characteristic of the diode vacuum tube, because it shows the amount of current that a diode will pass for any given plate voltage. Different types of diodes may have slightly different characteristic curves. All of these curves, however, indicate one important fact; the load, or plate current is not proportional to the applied, or plate voltage. For this reason, Ohm's law is strictly applicable only to small increments, or changes, of currents and voltages. In general, current-voltage relations in vacuum-tube circuits are studied by means of experimentally obtained characteristic curves.

The curved portions, or bends, in the graph of Figure 5-14 are the result of certain variations in the action of the diode. When the plate voltage is low, the electrons nearest the cathode are repelled back to the cathode by the accumulated emitted electrons which are a little farther from the cathode, and only those electrons which are nearest the plate are attracted to the plate. This repelling effect around the cathode is known as the "space charge." For intermediate values of the plate potential, the space charge in the vicinity of the cathode is reduced by the attraction of more electrons to the positively charged plate, and any increase in plate potential produces an appreciable increase in current, as shown by the curve of Figure 5-14. For large values of plate potential, when the space charge is completely removed, the number of electrons reaching the plate per second is limited by the number emitted per second by the cathode, and is independent of plate potential. This latter condition is referred to as "saturation," and a place along the curve (point S in Figure 5-14) is called the "saturation point."

6. DRY RECTIFIERS

The characteristic of undirectional electron flow between the two elements of a diode can be attained through the use of the so-called "barrier layer effect" as well as through the use of the two-element vacuum tube. Two common electronic components which utilize this effect are the "dry-disk rectifier" and the "rectifying crystal." Two common types of dry-disk rectifiers are the copper-oxide rectifier and the selenium rectifier. Copper-oxide rectifiers are frequently employed in power supplies where power line frequency alternating current must be converted into DC at moderate voltage (6 to 30 volts), and at currents from a few hundred milliamperes to 10 or 20 amperes. Selenium rectifiers are now also used in this field, and in some power supplies where moderate currents at from 1,000 to 5,000 volts are required.

Rectifying-crystal diodes are frequently employed in the rectification of r-f energy. The predecessor of these modern units is the galena or silicon crystal used in the "wireless" days of radio. Crystal diodes are available in two general types. The first type was developed for use as a mixer in s-h-f radar receivers and utilizes a small piece of silicon crystal sealed in a ceramic holder with a "cat whisker" factory-adjusted to the proper spot on the crystal. It is suitable for rectifying only a very small amount of energy, although types are available for use up to 30,000 megacycles. The second type, which uses a germanium crystal element, has more recently been developed for use at higher energy levels and at frequencies up to about 100,000 megacycles. It is widely used as a detector or demodulator in high-frequency FM and AM receivers. This type is also especially well suited for use as the rectifying element in field-strength meters and modulation monitors.

7. THE TRIODE AND ITS OPERATION

The triode differs in construction from the diode only in the addition of another element, called the "grid." The grid is a cylindrical structure made of a fine wire spiral or mesh, which is placed between the cathode and the plate of the tube so that all the electrons leaving the cathode must pass through it in order to reach the plate. Figure 5-15 shows the arrangement of the grid, cathode, and plate in a typical triode. The grid is placed considerably closer to the cathode than is the plate, and consequently will have a very great effect on the electrons which pass through it.

If a triode is connected in a simple circuit, as shown in Figure 5-16A, the action of the grid can be studied. When a small negative voltage (with respect to the cathode) is put on the grid, there is a resultant change in the flow of electrons within the vacuum tube. Since the electrons are negative particles of electricity, and like charges repel one another, the negative voltage on the grid will tend to repel the electrons emitted by the cathode, and thus tend to prevent them from passing through the grid on their way to the plate. However, since the plate is considerably positive with respect to the cathode, its attraction for the electrons is sufficiently strong to enable some of them to pass through the grid and reach the plate in spite of the opposition offered them by the negative voltage on the

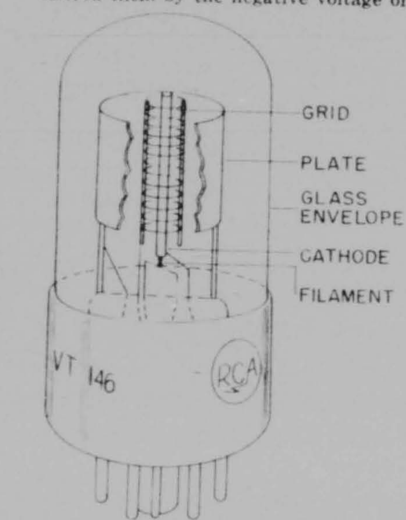

Figure 5—15. Typical Triode Construction.

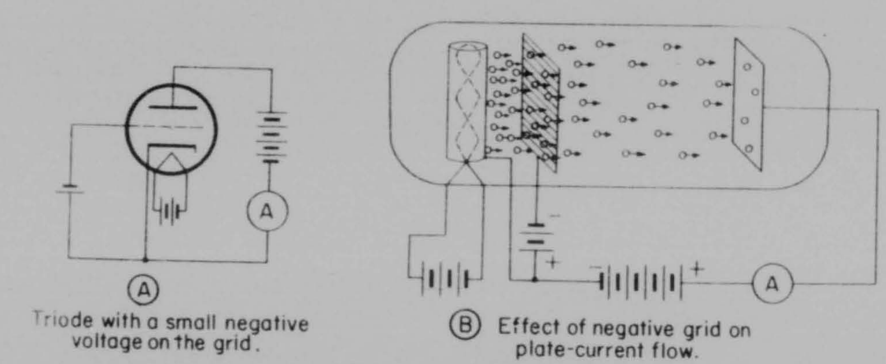

Figure 5—16. Triode Biased Negatively.

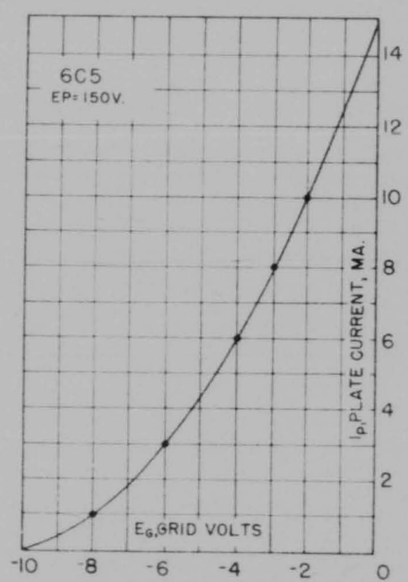

Figure 5—17. Grid-Voltage Plate-Current Curve.

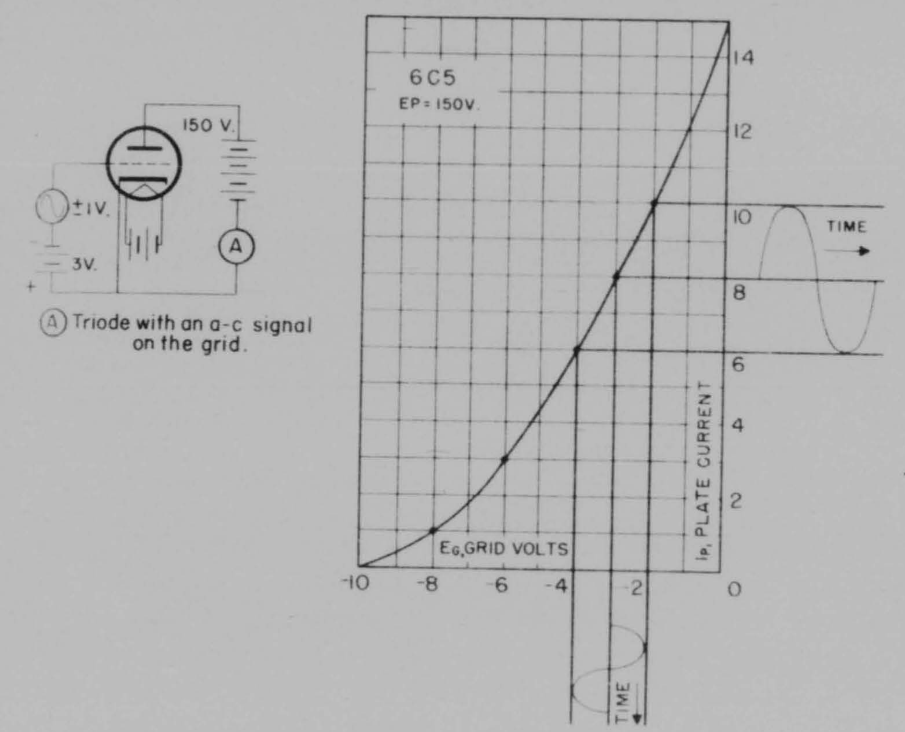
grid. Thus, a small negative voltage on the grid of the tube will reduce the electron flow from the cathode to the plate (Figure 5-16B) and consequently will reduce the value of plate-current flow between the cathode and the plate of the tube.

If the plate current in the circuit of Figure 5-16A is measured by means of meter A, while holding the plate voltage constant and making the grid of the tube gradually more negative with respect to the cathode, the plate current will vary as shown in the grid-voltage plate-current curve of Figure 5-17. Such a curve is also known as an E_G—Ip characteristic curve. From this curve, it can be seen that as the grid of the tube is made more negative, less plate current will flow, since the more negative the grid the fewer electrons it permits to pass on to the plate. In the case of this particular tube (type 6C5), it will be noted from the characteristic curve that if the grid is made sufficiently negative (—10 volts), the plate current drops to zero. Thus, this value of negative grid voltage has cut off the flow of electrons within the tube. A negative voltage which is applied to the grid of a tube to hold its plate current flow at a given value is known as the "grid-bias" voltage, or more simply, the "bias"; that value of grid bias which will cut off the flow of plate current is called the "cutoff bias" for that tube. Since the plate current in a tube increases as the plate voltage is increased, the bias required to cut off plate current flow will increase as the plate voltage applied to the tube is increased.

If the triode is connected in a circuit where an AC (signal) voltage of one volt is applied to the grid in series with 3 volts of negative bias (Figure 5-18A) on the positive half-cycle of the AC signal there will be —2 volts applied to the grid with respect to the cathode (+1—3 = —2); and on the negative half-cycle there will be —4 volts on the grid of the tube (—1—3 = —4). From the grid-voltage plate current curve shown in Figure 5-18B, it can be seen that when there is no AC signal applied to the tube, the plate current will be fixed at 8 milliamperes by the 3 volts of bias supplied by the bias battery. When the AC signal is applied to the tube, on the positive half-cycles there will be —2 volts on the grid of the tube and the plate current will increase to 10 milliamperes; but on the negative half-cycles there will be —4 volts on the grid and the plate current will decrease to 6 milliamperes. Thus, a 1-volt AC signal will cause a plate current change of 4 milliamperes in this tube. This can be demonstrated graphically by showing the AC voltage wave form on the grid-voltage scale of the E_G-I_P characteristic curve, and plotting the plate-current wave form on the plate-current scale of the graph (Figure 5-18B).

An examination of Figure 5-18B will show that the wave form of the plate current variation is an exact reproduction of the wave form of the AC voltage applied to the tube. By carrying this process further, it can be shown that if the negative bias is increased to 5 volts, so that the grid voltage varies from —4 to —6 volts over the AC cycle, the plate current change will vary from 3 to 6 milliamperes, showing a total change of only 3 milliamperes. If the negative bias voltage is



B Plate current waveform resulting from an a-c grid voltage.

Figure 5—18. Operation of a Simple Triode Circuit.

increased to 9 volts, so that the grid voltage varies from —8 to —10 volts over the AC cycle, then the plate current change will be only 1 milliampere. From this it can be seen that if the negative bias is increased, there is a resultant decrease in the plate current change for a given signal input. This method of controlling the output of a tube by varying the bias voltage is often used as a means of volume control. It should be noted, however, that if the grid voltage is increased to too high a negative value (Figure 5-19A), there is noticeable distortion of the output plate current wave. Distortion also results if the cathode temperature is lowered to such a degree that the emission is insufficient (Figure 5-19B). A distorted output is generally, but not always, objectionable.

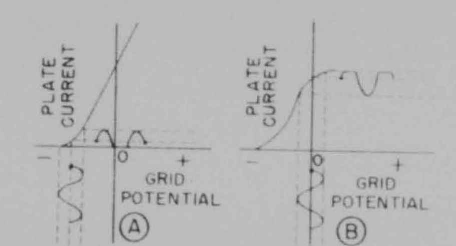


Figure 5—19. Distortion Due to a High Grid Bias and Low Cathode Temperature.

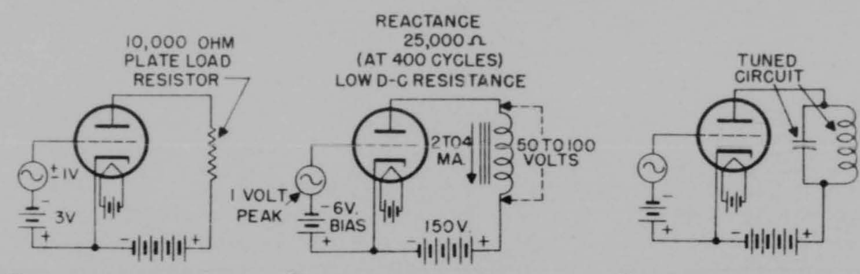


(A) Triode using a resistor as a plate load.
(B) Triode using an inductor as a plate load.
(C) Triode using a tuned circuit as a plate load.

Figure 5—20. Vacuum Tube Load Circuits.

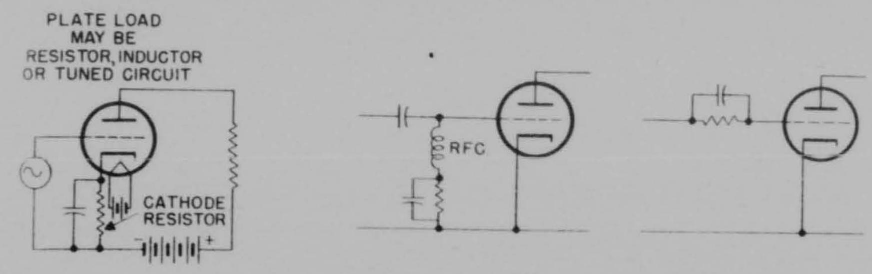
8. VACUUM TUBE PLATE LOADS

In order to make use of the variations in the plate current of a vacuum tube due to variations in grid voltage, some sort of a device must be present in the plate circuit of the tube to act as a load. This plate load can be a resistor, an inductor, or a tuned circuit.

A typical triode circuit with a resistor used as a plate load is shown in Figure 5-20A. If the tube in this circuit is biased at —3 volts and the applied AC signal voltage to the grid is 1 volt, the plate current variation of 4 milliamperes will produce a voltage variation of 40 volts across the 10,000-ohm resistor. On the positive half-cycles, the negative voltage of 2 volts applied to the grid causes a current flow of 10 milliamperes through the plate load resistor, thus producing a voltage drop of 100 volts (by Ohm's law). On the negative half-cycles, the negative voltage of 4 volts applied to the grid causes a current flow of 6 milliamperes through the plate-load resistor, and a corresponding voltage drop of 60 volts. The difference between these two voltage drops, or 40 volts, is the voltage variation in the plate circuit produced by the AC voltage applied to the grid. Thus it can be seen that a signal voltage change from —1 to +1 (or a total change of 2 volts) can produce a voltage change of 40 volts in the plate circuit; in other words, the original (grid) signal voltage has been amplified 20 times. This process is the basis for all vacuum-tube amplification.

The use of a resistor as the plate load of a vacuum tube has one disadvantage; its resistance will reduce the actual DC voltage applied to the plate of the tube, and so reduce the amplification of the tube. To overcome this loss in plate voltage, inductors are often used as plate loads of vacuum-tube circuits (Figure 5-20B). By choosing an inductor which has a high value of reactance at the frequency of the alternating current, a large voltage will be built up across the reactance, because of the plate-current changes in the tube. However, the DC plate voltage applied to the plate of the tube will be quite high, since the DC resistance of an inductor may be very small, and consequently the amplification of the tube will be increased.

If it is desired to amplify a signal of a given frequency, a tuned circuit which resonates at this frequency may be used for a plate load (Figure 5-20C). Since the impedance of such a circuit will be very high at the resonant frequency, the signal voltage appearing across the tuned circuit will also be high. By using a tuned circuit as the plate load for a vacuum tube, it is possible to obtain the amplification only at the resonant frequency of the tuned circuit. The circuit of Figure 5-20C is typical of the r-f amplifier circuits used in radio transmitters.



(A) Cathode resistor bias
(1) Shunt arrangement
(2) Series arrangement.
(B) Grid-leak bias circuits

Figure 5—21. Vacuum Tube Self Bias Circuits.

9. VACUUM TUBE BIASING METHODS

There are several different methods of obtaining a negative grid-bias voltage for a vacuum tube. The simplest of these is the fixed bias, where suitable negative voltage is obtained from a fixed source, such as batteries or a rectifier power supply. Examples of this type of bias are shown in Figure 5-20.

A vacuum-tube circuit can be arranged to produce its own bias, and such a method is known as "self-bias." One type of self-biasing, called the "cathode-return-resistor bias," is shown on a triode-amplifier circuit in Figure 5-21A. In this circuit, the plate current from the battery flows through the cathode resistor on its way through the tube and back to the battery through the plate-load resistor. Since the current flows through the cathode resistor toward the cathode, there is a voltage drop across this resistor which makes the grid negative with respect to the cathode. This is the proper condition for biasing. The convenience of this type of bias is obvious, since it eliminates the need for a separate source of bias voltage. For this reason, cathode-resistor bias is widely used. Omission of the shunt capacitor, or too small a value of this capacitor, produces less amplification or degeneration as a result of the variations of grid bias which then accompany the AC pulsations of the plate current. This capacitor should have a low reactance at the signal frequency, thus keeping the cathode resistor from dropping the AC signal voltage as well as the DC plate voltage.

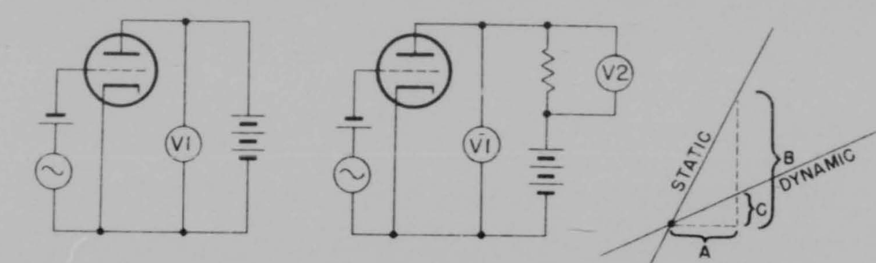
Another form of self-bias is called "grid-leak bias," and is used under conditions where grid current flows. Two examples of this type of bias are shown in Figure 5-21B. The bias results from the drop in potential across the resistor when grid current flows on positive AC signal swings. This resistor is called a "grid-leak." The capacitor across the leak offers a low impedance to alternating current, so that the bias is essentially steady in character and is a function of only the magnitude or size of the grid current. A disadvantage of grid-leak bias is that if for any reason the excitation is removed, the bias is removed also, and the plate current may assume dangerous proportions, causing damage to the vacuum tube.

To combine the advantage of grid-leak and battery (or fixed) bias, transmitter amplifiers often use a combination of both types in series. Some types of amplifier tubes are conveniently designed, as regards bias supply, to operate with the grid at cathode potential; these are known as "zero-bias" tubes.

10. TRIODE CHARACTERISTIC CURVES

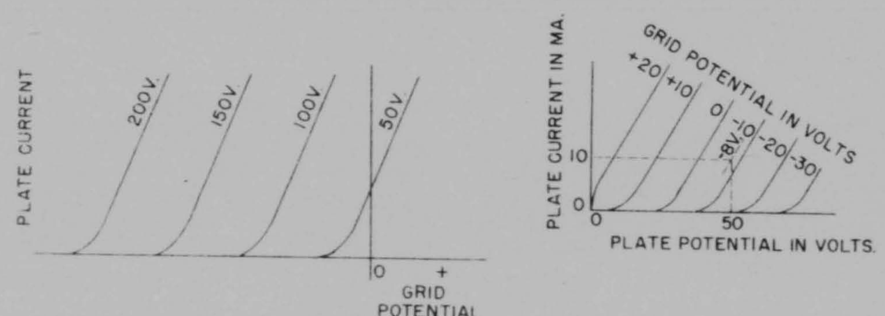
There are two general types of characteristic curves for triodes. One is for the case of no load in the plate circuit, and is called the "static characteristic curve"; the other is for

THIS PAGE IS DECLASSIFIED IAW EO 13526



(A) Without external load. (B) With external load. (C) Corresponding characteristics

Figure 5–22. Triode Characteristic Curves.



(A) Plate current vs grid potential curves for triode.

(B) Plate current vs plate-voltage curves for a triode.

Figure 5–23. Triode Characteristics.

the case of a load in the plate circuit, and is known as the "dynamic characteristic curve." Use has already been made of the static curve in Figure 5-18B, where the tube was operating without a plate load. In practice, however, the output of a tube feeds into some sort of load which can be represented by a resistance value (assumed to be the equivalent of the load). This results in dynamic characteristic curves that reflect more accurately the operating conditions of the tube. A comparison of the static and dynamic curves, with the two circuits that are used to obtain each, is shown in Figure 5-22. The difference in the slope of the two curves is due to the fact that the plate-to-cathode potential for no load is constant regardless of the plate current, whereas with a load in the plate circuit, the potential across the load (and consequently the plate-to-cathode potential) varies with the current. Assume that the normal operating point is the same for the tube with or without external load; that is, regard the operating point as the point of intersection of the two curves of Figure 5-22C. Without an external load (Figure 5-22A) on a positive swing of signal potential A (Figure 5-22C), the plate current rises by an amount B. With an external load (Figure 5-22B), the increase in current which follows a positive grid swing is in turn accompanied by a potential drop ($I \times R$) across the load resistor (as read by voltmeter V_2). Thus the potential available across plate to cathode within the tube (as read by voltmeter V_1) is reduced; and the consequent increase in current C is less than it was under the no-load

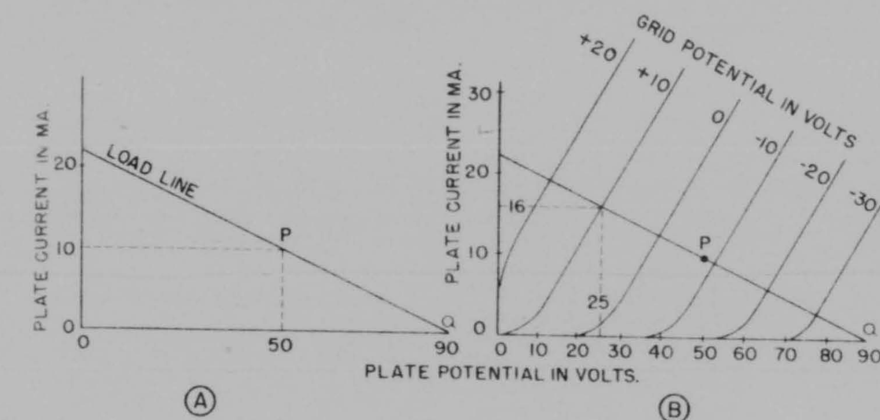


Figure 5–24. Load Line for a Triode.

condition. On the negative half-cycle of the signal voltage, the plate current is reduced, and the potential drop across the load is less than it is when no signal is applied. Thus the voltage across the tube rises, so that the available plate-to-cathode potential exceeds the corresponding value under the no-load condition. A typical set of static plate-current grid-voltage curves for various plate potentials is shown in Figure 5-23A. Many handbooks on vacuum tubes confine the characteristics illustrated to families of curves of the static type.

Observe from the set of static characteristic curves of Figure 5-23B, that of the three quantities, grid potential, plate potential, and plate current, any two will determine the third. Thus, corresponding to a plate current of 10 milliamperes and a plate potential of 50 volts, the required grid potential is —8 volts. Assuming that it is desired to obtain these same relations—plate current, 10 milliamperes; plate potential, 50 volts; and grid potential —8 volts—with a load resistance of 4,000 ohms. This requires a total plate-supply potential of $50 + (4{,}000 \times 10/1{,}000)$ volts = 90 volts, 50 across the tube and 40 across the load resistance. The current in the load resistance follows Ohm's law; that is, the current through the resistance is proportional to the potential across it. This proportionality is represented by a straight line on the current-voltage graph of Figure 5-24. The line is determined by any two points on it, two convenient points being P and Q, as in Figure 5-24A. P is for a current of 10 milliamperes and a voltage drop across the resistance of 40 volts (50 volts across the tube); Q is for zero current and zero drop across the resistance (90 volts across the tube). If P is taken as the normal operating point, the grid swing due to an impressed signal voltage will cause variations along this load line in both directions from P. Corresponding to an instantaneous grid potential of 10 volts, the plate current, plate voltage, and voltage across the load can be found by following the 10-volt characteristic to where it intersects the load line. From the curves of Figure 5-24B, this yields 16 milliamperes plate current, 25 volts plate potential, and 90—25 = 65 volts drop across the load. The family of plate-current plate-potential curves is thus useful in determining the limitations of a particular tube under various operating conditions. A particular tube can be selected to fit certain circuit constants, or vice versa, with the aid of the information contained in the vacuum-tube characteristics.

11. SPECIAL CHARACTERISTICS OF VACUUM TUBES

Since many different types of vacuum tubes are used in modern radio circuits, it is important to have different means of classifying these tubes according to the performance which may be expected of them. Among these characteristics, are the amplification factor, the mutual conductance, and the plate resistance of the tube.

The amplification factor μ, or mu, of a tube is the ratio of the plate-voltage change to the grid-voltage change required to produce the same plate-current change in the tube. For example, if the plate voltage of a tube must be increased by 20 volts in order to increase the plate current as much as would a 1-volt change of grid voltage, then the tube has an amplification factor of 20. The amplification factor of a tube is stated for a given set of operating conditions, such as grid-bias voltage, plate voltage, etc., since the amplification factor will change if these conditions are changed. The amplification factor of a tube gives a theoretical approximation of the maximum voltage amplification which can be expected from the tube under given operating conditions.

The mutual conductance, or transconductance of a tube is a characteristic from which the power sensitivity can be estimated, since it determines what plate-current change may be expected from a given grid-voltage change under a given set of operating conditions. Mutual conductance, or transconductance, is the ratio of a small change in plate current to the change in grid voltage producing it. It is measured in mhos, which is simply the word ohm spelled backwards and with an "s" added. For example, if a grid-voltage change of 1 volt produces a plate-current change of 1 ampere in a given tube under certain operating conditions, the tube will have a mutual conductance of 1 mho. But since very few tubes will stand a plate current flow of 1 ampere (receiving tubes draw only a few milliamperes of plate current), it is more convenient to rate mutual conductance in micromhos (or millionths of a mho). Thus, if a tube has a mutual conductance of 5,000 micromhos, a 1-volt change in grid voltage will produce a 5-milliampere change in plate current.

The plate resistance of a tube is simply the resistance between the cathode and plate of the tube to the flow of alternating current. It is the ratio between a small change in plate voltage and the corresponding change in plate current. For example, if a 10-volt change in plate voltage produces a 1-milliampere change in plate current, the plate resistance of the tube is 10,000 ohms.

12. INTERELECTRODE CAPACITANCE

The inherent capacitance between grid and plate elements of a triode is of sufficient importance at high frequencies to require special consideration in radio circuits. Where this capacitance is undesirable, it can be counteracted by introducing a neutralizing circuit which presents r-f potentials equal in magnitude but opposite in phase to those occurring across the interelectrode capacitance, with the result that the effects of the interelectrode capacitance are nullified. The extra circuit complications can generally be avoided by the use of tetrodes or pentodes, 4- and 5-element tubes, respectively, which are particularly designed to have low interelectrode capacitance. The grid-plate capacitance of an ordinary receiving triode runs about 3 micromicrofarads. This represents a capacitance reactance of 53,000 ohms at 1 megacycle and only 530 ohms at 100 megacycles. Tetrodes and pentodes offer corresponding reactances of about 16,000,000 ohms at 1 megacycle and 160,000 ohms at 100 megacycles.

13. THE TETRODE

In an effort to reduce the grid-plate capacitance within the tube, a fourth element was added to the conventional triode. This fourth element is called a screen grid, and is placed between the grid and the plate of the tube. A typical screen grid, or tetrode (4-element) tube connected in a circuit is shown in Figure 5-25. In observing the changes in this circuit due to the addition of the screen grid, it is noted that the screen grid is operated at a positive voltage somewhat lower than that which is applied to the plate. Since it is operated at a positive voltage, the screen assists the plate in attracting electrons from the cathode. Some of these electrons are attracted to this grid by the positive voltage on it, thus causing screen current to flow in the circuit. However, since the construction of the screen grid is similar to that of the control grid, most of the electrons pass through the spaces between its wires to the plate, because of the attraction of the higher positive voltage on the plate. Since the screen grid is bypassed to the negative side of the circuit (bypassed to ground) by a screen-bypass capacitor having a small reactance at the signal frequency, it acts as a shield, or screen, between the grid and the plate, and thus effectively reduces the capacitance between these two electrodes.

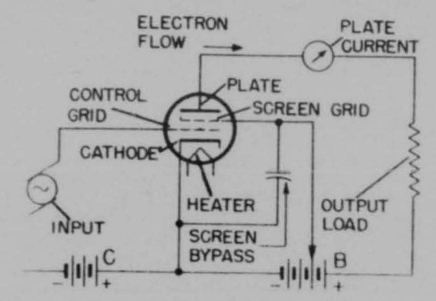

Figure 5–25. Tetrode Amplifier Circuit.

If the screen grid in this circuit is not operated at a positive voltage, but is connected to the cathode, it will have a controlling effect on the electron flow, similar to that of the control grid of the tube, thus reducing the plate-current flow to a value too small for satisfactory operation. The value of a positive voltage on the screen grid of a tetrode will determine, to a large extent, the maximum value of current which will flow in the plate circuit. Thus, improper screen voltages can cause faulty operation in tetrode-amplifier circuits.

The tetrode has several advantages over the triode, in addition to its greatly reduced grid-plate capacitance. Among these are a higher amplification factor, and greater power sensitivity. In general, tetrodes can be used for the same purpose as triodes. Since they were developed to overcome the need for neutralization in r-f amplifier circuits, tetrodes have been widely used in the amplifier stages of radio receivers and transmitters.

14. THE PENTODE

Although the tetrode would seem to be an ideal tube, since it overcomes the disadvantage of the higher grid-plate capacitance of the triode, and, at the same time, is capable of providing higher amplification in a circuit than is the triode, the effect known as "secondary emission" limits its application to a great extent. The pentode, or 5-element tube, was developed to overcome the effect of secondary emission. If a tetrode is operated at fairly high plate and screen voltages, and large values of signal voltage are applied to its control grid, the electrons strike the plate with sufficient force to knock loose other electrons already on the surface of the plate. These other electrons, known as "secondary electrons," are attracted by the positive voltage on the screen grid. When secondary emission occurs, the screen gets more than its share of the available electrons, while the number reaching the plate is greatly reduced. Thus, the screen current will increase while the plate current will decrease, causing a reduction in the amplification of the tube and distortion in its output.

If a third grid is placed between the screen grid and the plate of the tetrode, and is connected to the cathode, so that it has the same charge as the electrons, it will force any secondary electrons back to the plate, since like charges repel one another. This third grid is called the "suppressor grid," since it suppresses the effects of secondary emission by preventing the flow of secondary electrons to the screen. The suppressor grid will not reduce the electron flow to the plate, even though it is operated at a negative potential. This is because it is placed so close to the plate that the attraction of the positive voltage on the plate is much greater than any tendency on the part of the suppressor grid to repel the electrons.

Although the effect of secondary emission is usually a nuisance, it has been found useful in the operation of certain oscillators such as the dynatron.

15. VARIABLE-MU TUBE

The amplification of a tube is controlled by varying the bias voltage applied to the grid, but normally the range of this control is limited by the value of cutoff bias for the tube. It is most desirable in the r-f amplifiers of receivers, the gain of which is controlled by automatic volume control, to be able to vary the amplification over a much wider range so that large values of signal voltage (strong signals) may be handled. To permit this increased range of gain control, the variable-mu tube has been developed. This type of tube is also known by several other names, two of which are supercontrol and remote cut-off. The only difference in construction between variable-mu tubes and normal, or sharp cut-off types, is the spacing of the grid turns. In sharp cutoff tubes, the turns of the grid wire are equally spaced, while in remote cutoff types, the grid turns are closely spaced on both ends and widely spaced in the center. When small negative voltages are applied to the grid of a variable-mu tube, the electrons will flow through all the spaces in the grid. As the negative voltage is increased, however, the electrons will no longer be able to pass through the narrow spaces on the ends of the grid structure, although they will still be able to pass through the relatively greater spaces at the center of the grid. A much greater value of negative voltage will thus be required to cut off the plate-current flow in this type of tube. This remote cutoff tube is so named because the cutoff bias value is greater than (remote from) the value required to cut off plate-current flow in a tube of evenly spaced grid turns.

Figure 5-26 shows the E_G—I_P curves for a typical sharp cutoff pentode and a typical remote-cutoff pentode on the same graph. Note that the cutoff bias for the tube with the uniformly spaced grid is —6 volts. Thus the range of gain control which can be effected by grid-bias variation, and the maximum value of signal voltage which can be applied to the grid, are both limited. But the curve for the super control pentode shows that plate current still flows even at a grid bias of —24 volts. Thus, by the use of a variable-mu tube, both the range of gain control by grid bias

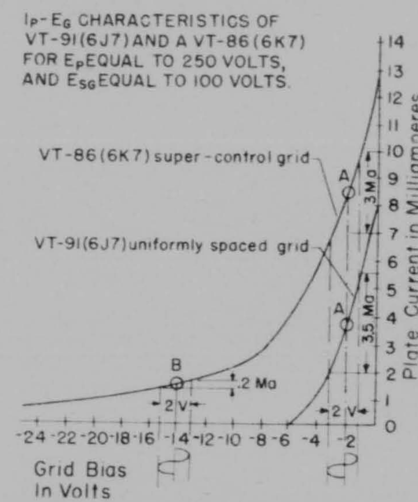

Figure 5–26. Comparison Between a Sharp Cut-Off Pentode and a Remote Cut-Off Pentode.

variation and the value of signal voltage which can be handled by the grid have been extended several times.

16. BEAM-POWER TUBE

In recent years, a new type of power-amplifier tube has been developed. Compared with other tetrode and pentode power-amplifier tubes, this tube has the advantages of higher power output, higher power sensitivity, and higher efficiency. This type of tube is called the "beam-power" tube, because by its construction the electrons are caused to flow in a concentrated beam from the cathode, through the grids, to the plate. The only difference in construction between the beam-power tube and normal tetrodes and pentodes is that the spaces between the turns of the several grids are lined up and two beam-forming plates are added. Figure 5-27 shows the internal construction of a beam-power tetrode. Since the spaces between the turns of the grids are lined up, fewer electrons will strike the screen grid. The screen current will therefore be decreased, while the plate current will be increased. Since the power output of a circuit is proportional to the value of plate current flowing through the load, the power output will thus be increased. The two beam-forming plates are usually connected to the cathode, and, having the same charge as the electrons, cause them to flow in a beam from the cathode, through the grids, to the plates. The placement of the beam-forming plates is such that it forces the electrons to flow through the desired portion of the grids, and prevents them from striking the wires which support the grids. Thus, by causing the electrons to flow in a beam, the number of electrons reaching the plate can be increased, thereby greatly increasing the operating efficiency of the tube.

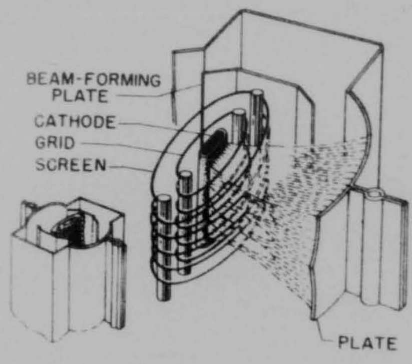

Figure 5–27. Internal Structure of a Beam-Power Tube.

A beam-power tube operated at the same voltages as a normal tetrode or pentode type will provide more power output for a given value of signal (input) voltage than the latter, and have a much higher plate-circuit efficiency. In beam tetrodes, the effect of secondary emission is reduced to a minimum by the action of the beam. Both beam tetrodes and beam pentodes are used in receivers and transmitters.

17. MULTI-ELEMENT TUBES

In addition to the diodes, triodes, tetrodes, and pentodes, there are many special types of vacuum tubes used in radio circuits; a large number of types are used which combine the electrodes of two or more tubes in one envelope. These complex tubes are usually named according to the equivalent single-tube types of which they are composed. Thus a twin triode contains the electrodes for two triodes in one envelope. Other complex tubes are diode-triodes, diode pentodes and triode pentodes. **All of these tubes, however complex, follow the basic rules for tube operation. To understand the operation of any one of them in a circuit, it is only necessary to consider the effect of the various electrodes on the flow of electrons within the tube.**

The pentagrid-converter tube is a special type which has five grids, and is used for frequency conversion in the superheterodyne receiver.

18. MERCURY-VAPOR TUBES

The space charge of electrons in the vicinity of the cathode in a diode causes the plate-to-cathode voltage drop to be a function of the current flowing between the cathode and the plate. This voltage drop can be rather high when large currents are being passed, causing a considerable amount of energy loss which shows up as plate dissipation. However, this negative space charge can be neutralized by the presence of the proper density of positive ions in the space between the cathode and plate. These positive ions can be obtained by the introduction of mercury into the tube. When a filament is heated, the mercury vapor pressure within the tube increases to such a value that the electron flow between cathode and plate will ionize enough mercury vapor to neutralize the space charge. Since the ionization potential of mercury vapor under these conditions of temperature and pressure is between 10 and 15 volts, the voltage drop across a mercury-vapor rectifier is substantially constant at this voltage regardless of the current carried up to the maximum rating of the tube.

Mercury-vapor tubes have the disadvantage, however, that they must be operated within a specified temperature range (25° to 70° C), in order that the mercury vapor pressure within the tube be within the proper range. If the temperature is too low, the drop across the tube becomes too high, causing im-

THIS PAGE IS DECLASSIFIED IAW EO 13526

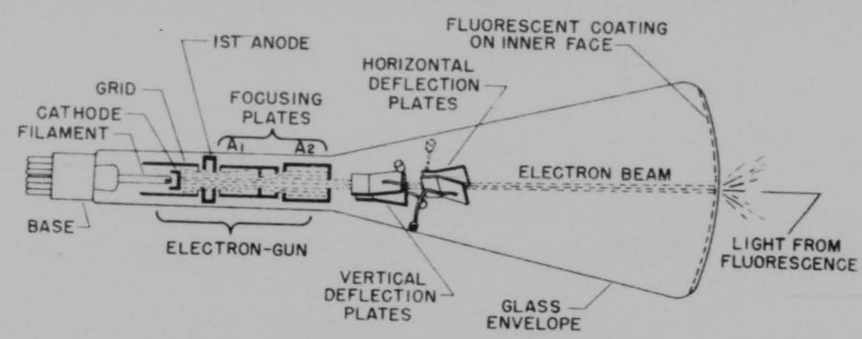

Figure 5–28. Simplified Construction of Typical Cathode-Ray Tube.

mediate overheating and possible damage to the elements. If the temperature is too high, the vapor pressure is too high, and the voltage at which the tube will "flash back" is lowered to the point where destruction of the tube may take place. Since the ambient temperature range specified above is within the normal room temperature range, no trouble will be encountered under normal operating conditions. However, by the substitution of xenon gas for mercury, it is possible to produce a rectifier with characteristics comparable to those of the mercury-vapor tube, except that the tube is capable of operating over the range from approximately —70° to 90° C. Since these tubes are more expensive than mercury-vapor rectifiers, their use is recommended only when extremely low or unusually high temperatures are likely to be encountered in the vicinity of the tubes.

19. THYRATRON TUBES

If a grid is inserted between the cathode and plate of a mercury-vapor gaseous-conduction rectifier, a negative potential placed upon the added element will increase the plate-to-cathode voltage drop required before the tube will ionize or "fire." The potential upon the control grid will have no effect on the plate-to-cathode drop after the tube has ionized. However, the grid voltage may be adjusted to such a value that conduction will take place only over the desired portion of the cycle of the AC voltage being impressed upon the plate of the rectifier.

20. COLD-CATHODE TUBES

Cold-cathode tubes are devices in which, as the name would imply, external heating of the cathode is not necessary to initiate current flow between cathode and plate. Such tubes are available both in the form of diodes and triodes, and always have a certain amount of controlled gas content. Initial breakdown of the gas within the tube is caused, after anode voltage is applied, by the high potential gradient between a point, which serves as the cathode, and an element of much larger area which serves as the anode or plate. It always takes a certain amount more voltage between cathode and anode to initiate the discharge than to sustain it continuously.

The most commonly used cold-cathode tubes are the VR-tube series of voltage regulators. The application of these tubes to the problem of voltage regulation is discussed in the following section. In addition to the cold-cathode diodes, or VR tubes, several cold-cathode triodes are available. In these tubes, the ionic discharge within the gas is initiated by the application of an r-f or AC voltage of 50 to 100 volts peak to a starter anode. These tubes are normally used in remote control devices where it is desired that no energy be taken by the controlled device until it is desired that the controlled device be completely operative.

21. THE CATHODE-RAY TUBE

The construction of a typical cathode-ray tube is illustrated in the pictorial diagram of

Figure 5-28. The indirectly heated cathode releases free electrons when heated by the enclosed filament. The cathode is surrounded by a cylinder which has a small hole in front for the passage of the electron stream. Although this element is not a wire mesh as is the usual grid, it is known by the same name because its action is similar; it controls the electron stream when its negative potential is varied.

Next in order is found the first accelerating anode, which resembles another disk, or cylinder, with a small hole in its center. This electrode is run at a high or moderately high positive voltage, to accelerate the electrons toward the far end of the tube. The focusing electrode, A_1, is a sleeve which usually contains two small disks, each with a small hole.

After leaving the focusing electrode, the electrons pass through another accelerating anode, A_2, which is operated at a high positive potential. In some tubes, this electrode is operated at a higher potential than the first accelerating electrode; while in other tubes, both accelerating electrodes are operated at the same potential.

The electrodes which have been described up to this point constitute the "electron gun," which produces the free electrons and focuses them into a slender, concentrated, rapidly-traveling stream for projection onto the viewing screen.

To make the tube useful, means must be provided for deflecting the electron beam along two axes at right angles to each other. The more common tubes employ electrostatic deflection plates, one pair to exert a force on the beam in the horizontal plane and one pair to exert a force in the vertical plane.

Certain of the cathode-ray tubes employ magnetic deflection, utilizing an electromagnet in the form of a yoke to deflect the electron beam. However, this discussion will be confined to those tubes which use electrostatic deflection.

The fact that the beam is deflected by a magnetic field is important even in an oscilloscope which employs a tube using electrostatic deflection, because it means that precautions must be taken to protect the tube from the transformer fields and sometimes even the earth's magnetic field. This normally is done by incorporating a magnetic shield around the tube and by placing any transformers as far from the tube as possible, orientated to the position which produces minimum effect upon the electron stream.

With most tubes, the spot will be very accurately centered if all four deflecting plates are at ground potential. However, a means of varying the DC voltage slightly on one of each pair of electrodes often is provided so as to permit accurate centering of the "spot" under all conditions.

After the spot is once centered, it is necessary only to apply a positive or negative voltage (with respect to ground) to one of the ungrounded or "free" deflector plates in order to move the spot. If the voltage is positive with respect to ground, the beam will be attracted toward that deflector plate, while if negative, the beam and spot will be repulsed. The amount of deflection is directly proportional to the voltage (with respect to ground) that is applied to the free electrode.

With the larger-screen higher-voltage tubes, it becomes necessary to place deflecting voltage on both horizontal and both vertical plates. This is done for two reasons: First, the amount of deflection voltage required by the high-voltage tubes is so great that a transmitting tube operating from a plate supply of 1500 to 2000 volts would be required to attain this voltage without distortion. By using push-pull deflection with two tubes feeding the deflection plates, the necessary plate supply voltage for the deflection amplifier is halved. Second, a certain amount of defocusing of the electron stream is always present on the extreme excursions in deflection voltage when this voltage is applied only to one deflecting plate. When the deflecting voltage is fed in push-pull to both deflecting plates in each plane, there is no defocusing because the average voltage acting on the electron stream is zero, even though the net voltage (which causes the deflection acting on the stream) is twice that on either plate.

Cathode-ray tubes are obtainable with any one of several types of screen material, each having its characteristic "persistence" and

THIS PAGE IS DECLASSIFIED IAW EO 13526

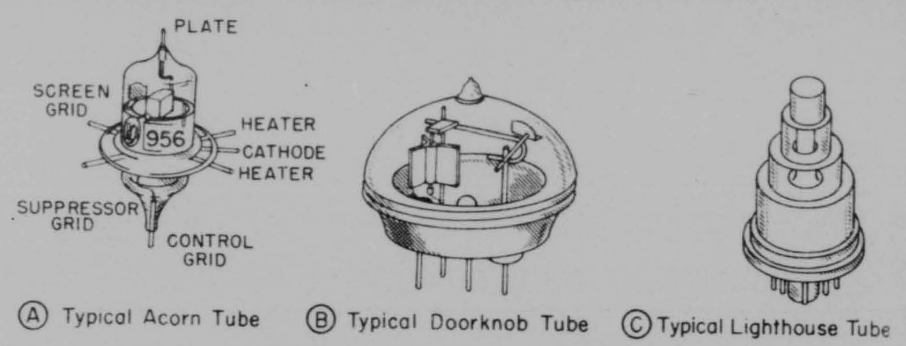

Figure 5—29. VHF Vacuum Tubes.

fluorescent color. The persistence is the degree to which the screen material will glow after being bombarded with electrons. The fluorescent material will give off light for an instant after the bombardment is terminated, and the longer the time, the longer the persistence.

22. SPECIAL VACUUM TUBES FOR U-H-F USE

The most suitable vacuum tubes for u-h-f use are those having low interelectrode capacitance, close spacing of the electrodes to reduce transit time, a high amplification factor, and a low or medium optimum value of load impedance. While some of these requirements are necessarily conflicting, tubes have been produced which are well adapted for u-h-f operation. The "lighthouse," "acorn," and "doorknob" tubes are examples of this type (Figure 5-29). The "doorknob" tube is simply a larger version of the "acorn."

23. SPECIAL VACUUM TUBES FOR U-H-F AND S-H-F USE

Two special type tubes necessary for u-h-f and s-h-f radar are the magnetron and klystron; the magnetron being used in radar transmitters and the klystron in the receivers.

The magnetron is an s-h-f oscillator tube normally employed where very high values of peak power or moderate amounts of average power are required in the range of from perhaps 700 Mc. to 100,000 Mc. In its simplest form, the magnetron tube is a filament-type diode with two half-cylindrical plates or anodes situated coaxially with respect to the filament. The construction is illustrated in Figure 5-30A. Under the influence of the strong magnetic field, electrons leaving the filament are deflected from their normal paths and move in circular orbits within the anode cylinder (Figure 5-30B). This effect results in a negative resistance which sustains oscillations.

Complex magnetron tubes employ no external tuned circuit, but utilize instead one or more resonant cavities which are integral with the anode structure. Figure 5-31 shows a magnetron of this type having a multicellular anode of eight cavities. It will be noted also that alternate cavities (which would operate at the same polarity when the tube is oscillating) are strapped together. Strapping was found to improve the efficiency and stability of high-power radar magnetrons. In most radar applications of magnetron oscillators, a powerful permanent magnet rather than an electromagnet is employed to supply the magnetic field.

The **klystron** is a specialized microwave tube which depends upon velocity modulation of an electron stream for its operation. In various sizes, this tube is employed as a voltage amplifier, power amplifier, superheterodyne oscillator or mixer, detector, and frequency multiplier. The klystron removes the

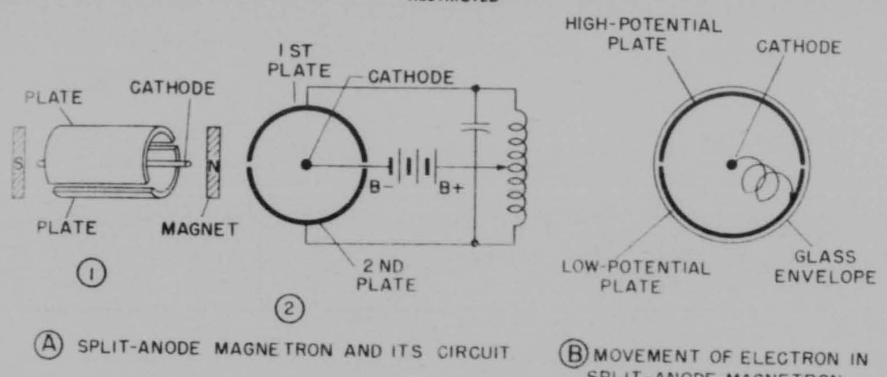

Figure 5—30. Simple Magnetron Tube.

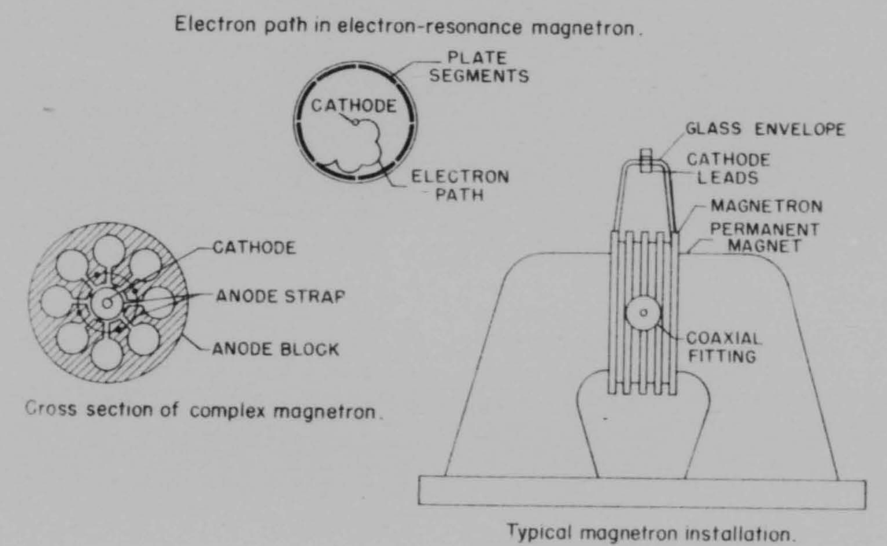

Figure 5—31. Complex Magnetron Tube.

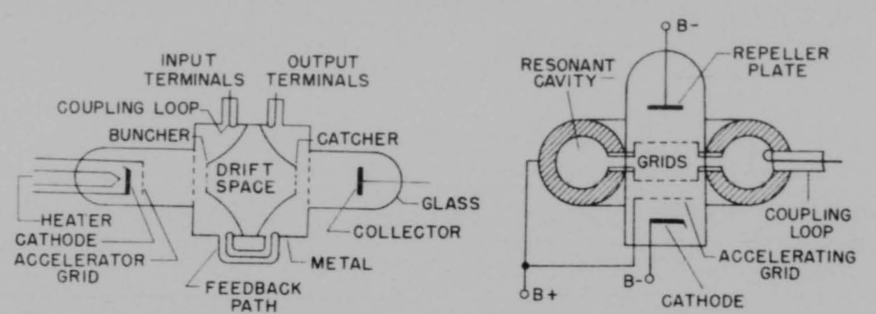
necessity (so important in conventional grid-controlled tubes) of limiting electron transit time to a fraction of the time required for one microwave cycle.

The klystron is an electron-coupled device. When used as an oscillator, its output voltage is rich in harmonics. Klystron oscillators of various types afford power outputs ranging from less than one watt to several hundred watts. Tuning is done mechanically in some klystrons by altering (by means of knob settings) the shape of the resonant cavity.

In addition to heater, cathode, and control grid (which, together form an electron gun),

THIS PAGE IS DECLASSIFIED IAW EO 13526



(A) Klystron tube with cavity resonator.

(B) Schematic diagram of a reflex klystron

Figure 5—32. Klystron Tubes.

and a collector plate, two cavity resonators of reentrant shape are included in the klystron tube. One of these, known as the "buncher," immediately follows the control grid. The electron beam from the gun section enters the buncher through a grid in the aperture in one of its reentrant walls, and leaves through a similar grid aperture in the other parallel reentrant wall. The second cavity, known as the "catcher," follows the buncher and has a similar pair of grids in its own parallel reentrant walls. Buncher and catcher are mounted back to back to provide a drift space for the electron beam passing from one cavity to the other.

The electron beam from the gun comes under the influence of the electrostatic field between the two buncher grids as the beam passes through the buncher apertures. The grid field is oscillating if the buncher cavity is being excited by oscillating energy, and this field is parallel to the electron beam which it acts alternately to accelerate and retard. The beam thus becomes velocity-modulated.

When the electron beam reaches the drift space, where there is no field, those electrons which have been sped up on one-half cycle overtake those immediately ahead which were slowed down on the other half-cycle. In this way, the beam electrons become bunched together. As the bunched groups pass through the two grids of the catcher cavity, they impart some of their energy to these grids. The catcher grid-space is charged to different voltage levels by the passing electron bunches, and a corresponding oscillating field is set up in the catcher cavity. The catcher is designed to resonate at the frequency of the velocity-modulated beam.

The two-cavity klystron (Figure 5-32A) as described in the preceding paragraphs is primarily used as a transmitting device since quite reasonable amounts of power are made available in its output circuit. However, for applications where a much smaller amount of power is required—power levels from milliwatts to a watt or two—for low-power transmitters, receiver local oscillators, etc., another type of klystron having only a single cavity is more frequently used.

The theory of operating of the single-cavity or reflex klystron is essentially the same as the multi-cavity type with the exception that the velocity-modulated electron beam, after having left the "buncher" cavity is reflected back into the area of the buncher again by a repeller electrode as illustrated in Figure 5-32B. The potentials on the various electrodes are adjusted to a value such that proper bunching of the electron beam will take place just as a particular portion of the velocity-modulated beam re-enters the area of the resonant cavity. Since this type of klystron has only one circuit it can be used only as an oscillator and not as an amplifier. Effective modulations of the frequency of a single-cavity klystron for FM work can be obtained by modulating the repeller electrode voltage.

SECTION III—ELECTRONIC CIRCUITS

1. POWER SUPPLIES

General

Any device which incorporates vacuum tubes requires a power supply for the filament and plate circuits of the tubes. The filaments must be heated in order to produce a source of electrons; direct-current voltages are needed for the other electrodes in order to obtain amplification, oscillation, and some methods of detection.

Either AC or DC voltage may be used for filament power supply in most applications. The plate potential is secured from a DC source, such as from batteries or from a rectified and filtered AC power supply.

First the AC must be converted into a unidirectional current; this is accomplished by means of a rectifier of either the full- or half-wave type.

Half-wave Rectifier. A half-wave rectifier (Figure 5-33A) passes one half of the wave of each cycle of the alternating current and blocks the other half. The output current is of a pulsating nature, which can be smoothed into pure, direct current by means of filter circuits. Since half-wave rectifiers produce a pulsating current which has zero output during one half of each AC cycle, it is difficult to filter the output properly into pure DC and to secure good voltage regulation for varying loads.

Full-wave Rectifier. A full-wave rectifier consists of a pair of half-wave rectifiers working on opposite halves of the cycle, connected in such a manner that each half of the rectifier AC wave is combined in the output as shown in Figure 5-33B. This pulsating unidirectional current can be filtered to any desired degree, depending upon the particular application for which the power supply is designed.

Bridge Rectifier. The bridge rectifier (Figure 5-33C) is a type of full-wave circuit in which four rectifier tubes are operated from a single high-voltage winding of the power transformer. While twice as much output voltage can be obtained from a bridge rectifier as from a center-tapped circuit, the permissible output current is only one-half as great for a given power transformer.

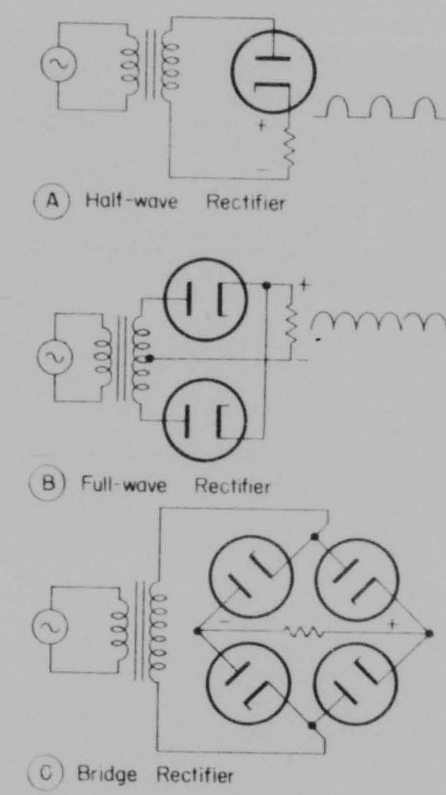


Figure 5—33. Typical Rectifier Circuits.

Filters. The filter circuit for a conventional power supply (Figure 5-34) consists of a low-pass section whose cutoff frequency is lower than the minimum ripple or pulsating fre-

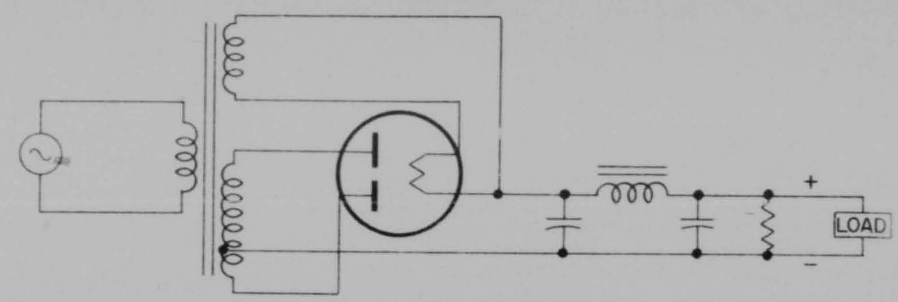

Figure 5–34. Full-Wave Rectifier and Filter.

quency to be expected from the power supply. An electric current always follows the path of least resistance of impedance. The direct-current component of the rectifier output will travel through the choke coil and back to the return path through the external load which normally consists of the plate circuits or vacuum tubes. The AC component of the rectifier output, however, tends to be impeded by the choke and short-circuited by the parallel capacitors so that the amount of alternating current at the output of the filter is very much less than that at the input.

Filter inductors consist of a coil of wire wound on a laminated iron core. The size of the wire is determined by the amount of direct current which is to flow through the choke coil.

Filter capacitors are of two types. Either the paper dielectric or the electrolytic type may be used. Paper capacitors possess the advantage of withstanding high breakdown potentials and reduced leakage currents, but are physically much larger and bulkier than the electrolytic type of capacitor.

A heavy duty resistor (bleeder) should be connected across the output of a filter in order to draw some load current at all times. This resistor avoids soaring of the voltage at no load, and also provides a means for discharging the filter capacitors when no external load is connected to the circuit.

Voltage Regulators (Figure 5-35)

Where it is desired in a circuit to stabilize the voltage supply to a circuit requiring no more than 25 milliamperes, a glow-discharge type of voltage-regulator tube may be used.

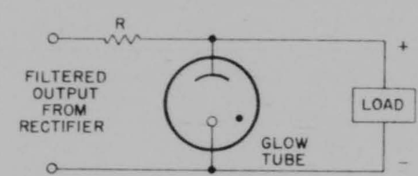

Figure 5–35. Glow-Tube Voltage Regulator.

The OC3 VR-105 and OD3 VR-150 are of this type. When it is desired to stabilize the potential across a circuit drawing more than a few milliamperes, a more complex electronically-regulated power supply must be used.

Voltage Doubler (Figure 5-36)

Another type of rectifier circuit, called a "voltage doubler," is sometimes used in special applications. This circuit, in effect, charges two filter capacitors separately across a source of voltage and then discharges them in series through the load. The output voltage is therefore approximately twice the input voltage.

2. AMPLIFIERS

General

The ability of the control grid of a vacuum tube to control large amounts of plate power with a small amount of grid energy allows the vacuum tube to be used as an amplifier. It is this ability to amplify an extremely small amount of energy up to almost any level without change in anything except amplitude which makes the vacuum tube such an ex-

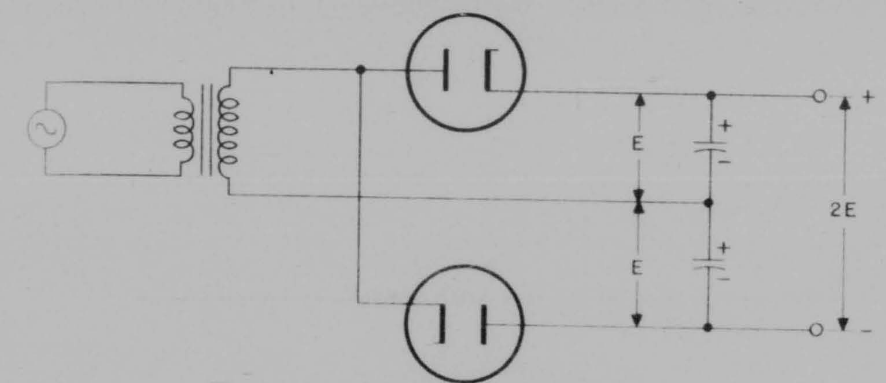

Figure 5–36. Voltage-Doubler Power Supply.

tremely valuable adjunct to modern electronics and communications.

Voltage and Power Amplifiers

Every amplifier circuit may be classified as either a voltage or a power amplifier. Voltage amplifiers are designed to provide a maximum amount of voltage amplification, but usually cannot deliver an appreciable amount of current or power to a load. Since many electrical loads (radio loudspeaker, cathode-ray tube deflection coils, or a radar antenna system) represent a low impedance and therefore absorb power from the driving source, a power amplifier is generally used. A complete amplifier system usually consists of several voltage amplifiers and a power amplifier. The number of voltage amplifier stages employed depends upon the amount of amplification required in order to raise the signal level to a voltage which will properly drive the grid of the power amplifier.

Amplifier systems are also classified according to the range of frequencies which they are intended to handle. That is, audio amplifiers operate within a frequency range of 15 to 15,000 cycles per second; video amplifiers from 15 cycles to approximately 4 megacycles per second; and a radio frequency amplifier will amplify any group of frequencies above 15,000 cycles per second. Any one of these amplifiers may be of the voltage or power-amplifier type.

Classes of Amplifiers

Vacuum-tube amplifiers are grouped into classes according to the type of work they are to perform. The difference between the various classes is determined primarily by the value of average grid bias employed and the maximum value of the exciting signal to be impressed upon the grid.

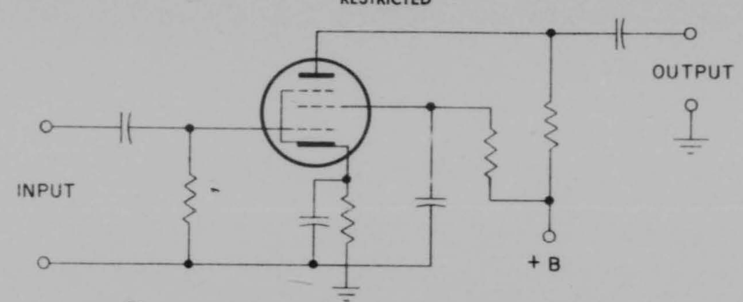
A class A amplifier is an amplifier biased and supplied with excitation of such amplitude that plate current flows continuously and grid current does not flow at any time. Such an amplifier is normally operated in the center of the grid-voltage, plate-voltage, plate-current transfer characteristic and gives an output waveshape which is a substantial replica of the input waveshape.

A class AB amplifier is operated under such conditions of grid bias and exciting voltage that plate current flows for more than one-half the input voltage cycle but for less than the complete cycle. The suffix 1 may be added in order to indicate that grid current does not flow over any portion of the input cycle.

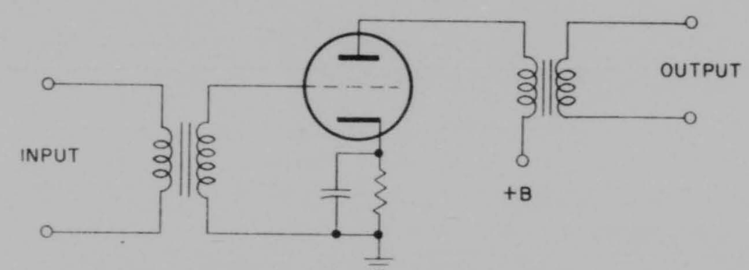
A class AB_2 amplifier is operated under essentially the same conditions of grid bias as the class AB_1 amplifier, but the exciting voltage is of such amplitude that grid current flows over an appreciable portion of the input wave cycle.

A class B amplifier is biased substantially to cutoff of plate current (without exciting

THIS PAGE IS DECLASSIFIED IAW EO 13526



(A) Resistance Coupled Amplifier



(B) Transformer Coupled Amplifier

Figure 5—37. Resistance and Inductance Coupled Amplifiers.

voltage) so that plate current flows essentially over one-half the input voltage cycle. It is almost always excited to such an extent that grid current flows.

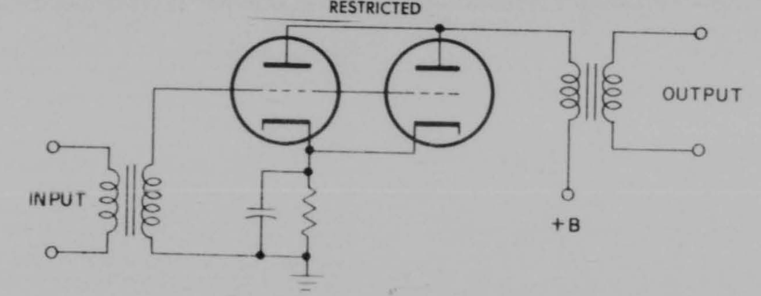
A class C amplifier is biased to a value greater than the value required for plate current cutoff and is excited with a signal of such amplitude that grid current flows over an appreciable period of the input voltage waveshape. The plate current flows appreciably less than one-half the time.

Voltage amplifiers are almost invariably operated class A, while power amplifiers may be of any class. Although class A power amplifiers introduce the least amount of distortion to the incoming waveshape, their use is limited since the plate efficiency is low. This is due to the continuous flow of plate current, even in the absence of a signal on the grid.

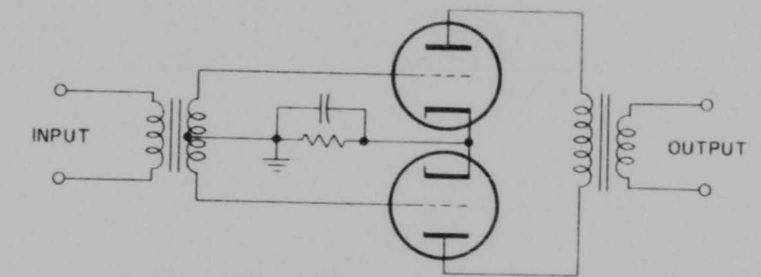
Class AB, B and C amplifiers are used largely in high-powered high-efficiency circuits. However, since plate current flows for only a brief portion of the input cycle to a class C amplifier, it can be used only in equipments where fidelity of the output waveshape is not important.

Resistance Coupled Amplifiers. Any type of amplifier may also be designated by the type of load included in its plate circuit (Figure 5-37A). That is, a resistance coupled amplifier employs a load resistor in the plate circuit of the vacuum tube. The output is usually coupled to the following stage by means of a DC blocking capacitor. Voltage amplifiers are often the resistance coupled type.

Transformer coupled amplifiers (Figure 5-37B) substitute the primary of a transformer for the load resistor that was used in the resistance coupled amplifier circuit. This type of circuit is widely used in power-amplifier equipment since it is possible to match the dynamic impedance of the vacuum tube to the load impedance by employing a transformer with the proper turns ratio. An



(A) Parallel Amplifiers.



(B) Push-Pull Amplifiers.

Figure 5—38. Parallel and Push-Pull Amplifiers.

impedance match is necessary in order to secure maximum power transfer.

Either push-pull or parallel operation of power tubes may be employed to obtain increased output (Figure 5-38). The parallel connection (Figure 5-38A) provides twice the output of a single tube with the same value of grid-signal voltage. The push-pull or paraphase connection (Figure 5-38B) requires twice the input-signal voltage, but has, in addition to an increase in power, a number of important advantages over single tube operation. Distortion due to even order harmonics and hum due to plate-supply-voltage fluctuations are either eliminated or decidedly reduced through cancellation. Since distortion is less than for single tube operation, appreciably more than twice single-tube output can be obtained by decreasing the load resistance.

Audio amplifiers may be transformer-coupled, impedance coupled, or resistance-coupled. Video-frequency amplifiers are usually resistance-coupled amplifiers as their gain characteristics must be flat over a very wide frequency range. Intermediate and radio-frequency amplifiers are designed ordinarily for tuned-circuit coupling, although in actual operation they may resemble either the transformer coupled or the impedance-coupled circuit.

Distortion

Three types of distortion that may occur in amplifiers are frequency distortion, phase distortion, and amplitude or nonlinear distortion.

Distortion which occurs when some frequency components of a signal are amplified more than others is known as "frequency distortion." Most coupling circuits shift the phase of a sine wave, but this has no effect on the shape of the output. However, when more complex waveshapes are amplified, each component frequency of the waveshape may be shifted by different amounts so that the output is not a faithful representation of the input waveshape. This is known as "phase distortion."

THIS PAGE IS DECLASSIFIED IAW EO 13526

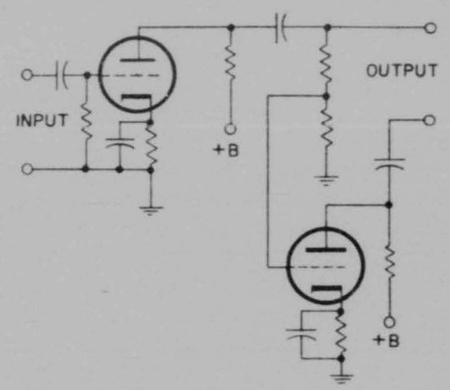


Figure 5–39. Phase Inverter.

If a signal is passed through a vacuum tube that is operating on any nonlinear part of its characteristic, amplitude distortion will occur.

Radio-frequency Amplifiers

In a tuned amplifier, part of the coupling circuit is a parallel resonant circuit. Because of the selective properties of the resonant circuit tuned amplifiers are used as radio-frequency and intermediate-frequency amplifiers where a narrow band of frequencies is to be amplified and all other frequencies eliminated.

Inverse Feedback

An inverse-feedback circuit, sometimes called a degenerative circuit, is one in which a portion of the output voltage of a tube is applied to the input of the same or a preceding tube in opposite phase to the signal applied to the tube. Two important advantages of feedback are: reduced distortion from each stage included in the feedback circuit; reduction in the variations of gain due to changes in line voltage, possible differences between tubes of the same type, or variations in the values of circuit constants included in the feedback circuit.

Phase Inversion

A phase inverter is a circuit (Figure 5-39) used to provide resistance coupling between the output of a single-tube stage and the input of a push-pull stage. The necessity for a phase inverter arises because the signal-voltage inputs to the grids of a push-pull stage must be 180 degrees out of phase and approximately equal in amplitude with respect to each other. Thus, when the signal voltage input to a push-pull stage swings the control grid of one tube in a positive direction, it should swing the other grid in a negative direction by a similar amount. With transformer coupling between stages, the out-of-phase input voltage to the push-pull stage is supplied by means of the center-tapped secondary. With resistance coupling, the out-of-phase input voltage is obtained by means of the inverter action of a tube.

Gain Measurement

When voltage amplifier stages are operated in such a manner that the output voltage of the first is fed to the grid of the second, and so forth, such stages are said to be "cascaded." The total voltage gain of cascaded amplifier stages is obtained by taking the product of the voltage gains of each of the successive stages.

Inasmuch as the ear and eye respond logarithmically to variations in sound and light intensity, any unit used to compare such levels must, in order to be practical, vary logarithmically. Such a unit is the decibel. The abbreviation for decibel is db. The total db gain of cascaded amplifier stages is obtained by taking the sum of the db gains of each of the successive stages. The average person would not notice a change in a radio-program level of less than 3 db.

3. GENERATION OF RADIO-FREQUENCY ENERGY

General

An oscillator is a nonrotating type of AC generator. A vacuum tube and its associated components replace the mechanical type of alternator. A negative-grid type of oscillator is essentially a vacuum tube amplifier with a sufficient portion of the output energy coupled back into the input circuit to sustain oscillation. The control grid is biased a considerable amount negative with respect to the cathode.

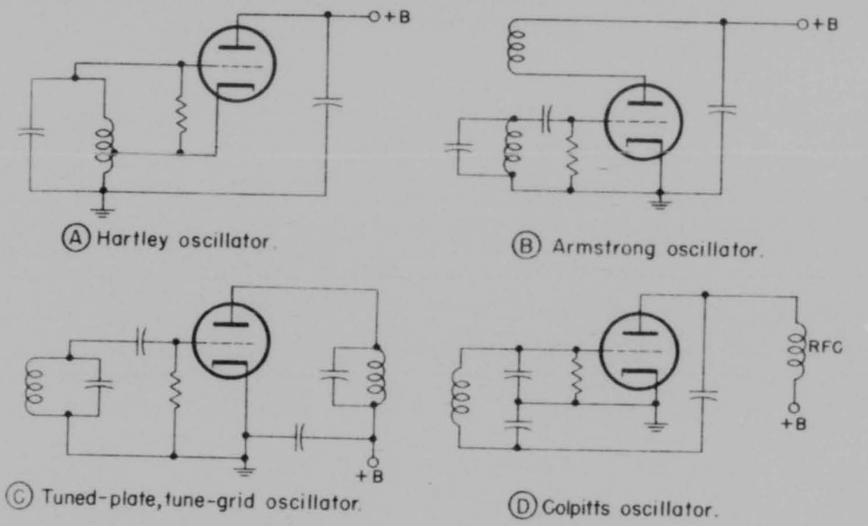

Figure 5–40. Negative Grid Oscillators.

This oscillator finds most common application in low- and medium-frequency transmitter circuits. Common types of negative-grid oscillators are diagrammed in Figure 5-40.

The operation of each of these oscillators (Hartley, Colpitts, T.P.T.G.) is fundamentally the same. The essential differences involve the methods employed to obtain regenerative feedback.

Theory of Operation

When plate voltage is applied to the Hartley oscillator shown in Figure 5-40A, the sudden flow of plate current accompanying the application of plate voltage will cause an electro-magnetic field to be set up in the vicinity of the coil. The building-up of this field will cause a potential drop to appear from turn-to-turn along the coil. Due to the inducive coupling between the portion of the coil in which the plate current is flowing and the grid portion, a potential will be induced in the grid portion.

Since the cathode tap is between the grid and plate ends of the coil, the induced grid voltage acts in such manner as to increase further the plate current of the tube. This action will continue for a short period of time determined by the inductance and capacitance of the tuned circuit, until the flywheel effect of the tuned circuit causes this action to come to a maximum and then to reverse itself. The plate current then decreases, the magnetic field around the coil also decreasing, until a minimum is reached, when the action starts again in the original direction and at a greater amplitude than before. The amplitude of these oscillations, the frequency of which is determined by the coil-capacitor circuit, will increase in a very short time to a limit determined by the plate voltage or the cathode emission of the oscillator tube.

In any of the oscillator circuits just illustrated (Figures 5-40B, C, D) it is possible to take energy from the oscillator circuit by coupling an external load to the tank circuit. Since the tank circuit determines the frequency of oscillation of the tube, any variations in the condition of the external circuit will be coupled back into the frequency determining portion of the oscillator. These variations result in frequency instability.

THIS PAGE IS DECLASSIFIED IAW EO 13526

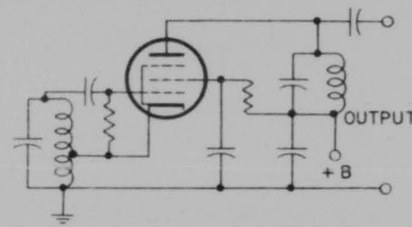

Figure 5—41. Electron Coupled Oscillator.

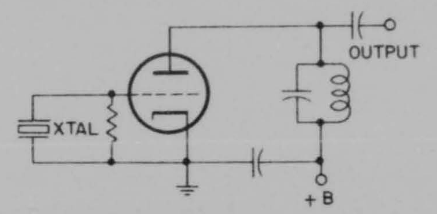

Figure 5—42. Crystal Oscillator.

Electron-coupled Oscillators

The electron-coupled oscillator (Figure 5-41) has great stability with respect to load and voltage variation. Load variations have very little effect on the frequency, since the only coupling between the oscillating circuit and the load is through the electron stream flowing through the other elements to the plate. The plate is electrostatically shielded from the oscillating portion by the bypassed screen.

The stability of the e.c.o. with respect to variations in supply voltages is explained as follows: The frequency will shift in one direction with an increase in screen voltage, while an increase in plate voltage will cause it to shift in the other direction. By a proper proportioning of the resistors that comprise the voltage divider supplying the screen voltage, it is possible to make the frequency of the oscillator substantially independent of supply voltage variations.

Quartz Crystal Oscillators

Quartz and tourmaline are naturally occurring crystals having a structure which, when plates are cut in certain definite relationships to the crystallographic axes, will show the piezo-electric effect—the plates will be deformed in the influence of an electric field, and, conversely, when such a plate is compressed or deformed in any way a potential difference will appear upon its opposite sides.

The crystal has mechanical resonance, and will vibrate at a very high frequency because of its stiffness, the natural period of vibration depending upon its dimensions and crystallographic orientation. Because of the piezo-

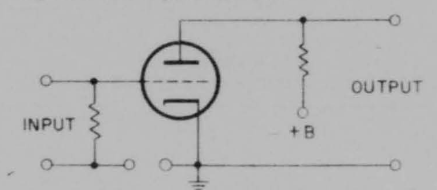

Figure 5—43. Direct-Current Amplifier.

electric properties, it is possible to cut a quartz plate which, when provided with suitable electrodes, will have the characteristics of a parallel resonant circuit with a very high Q. The Q is several times as high as can be obtained with an inductor-capacitor combination in conventional physical sizes. This parallel resonant characteristic permits the crystal to be used in place of an L C tank in an oscillator (Figure 5-42) with greatly increased stability as a result of the much higher Q.

4. SPECIAL CIRCUITS

DC Amplifiers

Direct-current amplifiers (Figure 5-43) are special types used where amplification of very slow variations in voltage or of DC voltages is desired. A simple DC amplifier consists of a single tube with a grid resistor across the input terminals, and with the load in the plate circuit. The load may be some sort of mechanical device such as a relay, a meter, or a counter, or the output voltage may be used to control the gain of an amplifier.

The DC voltage to be amplified must be applied directly to the grid of the amplifier tube.

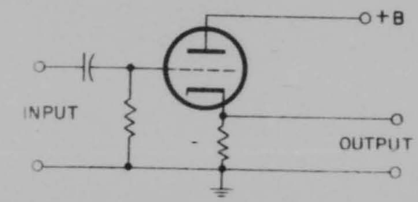

Figure 5—44. Cathode Follower.

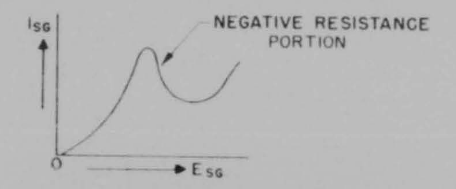

Figure 5—45. Screen-Current vs Screen Voltage Characteristic of a Pentode with Screen-Suppressor Coupling.

Therefore, direct coupling is required in the input circuit.

Cathode Followers

The cathode follower (Figure 5-44) is a degenerative vacuum-tube circuit in which the inverse feedback is obtained by way of an unbypassed cathode resistor, across which the output is taken. This circuit is essentially an impedance-matching or impedance-lowering device having less than unity voltage gain but capable of producing power gain. Its high input impedance and very low output impedance render it particularly suitable for coupling between pulse-generating or pulse-transmitting stages and transmission lines of circuits with shunt capacitance which otherwise might cause objectionable effects. The cathode-follower output "follows" the grid-input voltage and hence is of the same polarity. The output voltage of a cathode follower has good regulation because of its low impedance while the input voltage to the cathode follower may have a high impedance and very poor regulation.

The output of one unit of equipment often must be fed through a coaxial cable which may be, in some cases, as long as fifty feet. Such a cable, because of its distributed capacity, inductance and resistance, represents at the output an impedance which is much lower than the output impedance of a conventional amplifier. A cathode follower designed with a low impedance output can deliver much more of its output through such a line than can a conventional amplifier.

Transitron Oscillator (negative GM)

Figure 5-45 shows that the characteristic curve of screen current vs screen voltage of a pentode in which the screen is coupled to the suppressor has a portion with negative slope. Between the screen and screen supply, therefore, such a circuit may act like a negative resistance, and sustained sinusoidal oscillations may occur in an LC tank inserted in the screen circuit. Such an oscillator is called a "transitron" or "negative transconductance oscillator" (Figure 5-46).

Resistance-capacitance Oscillators

In an R-C oscillator, the frequency is deter-

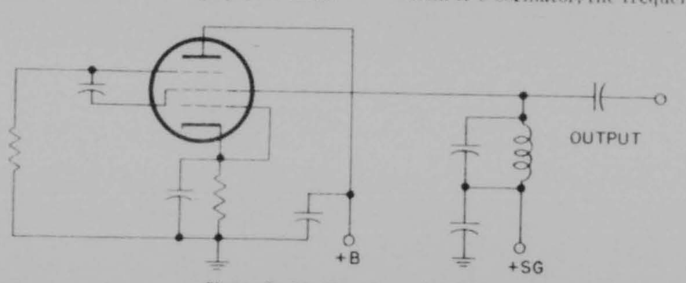

Figure 5—46. Transitron Oscillator.

THIS PAGE IS DECLASSIFIED IAW EO 13526

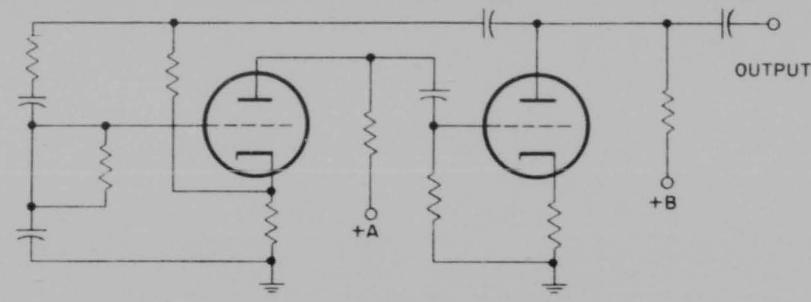

Figure 5—47. Wein-Bridge Oscillator.

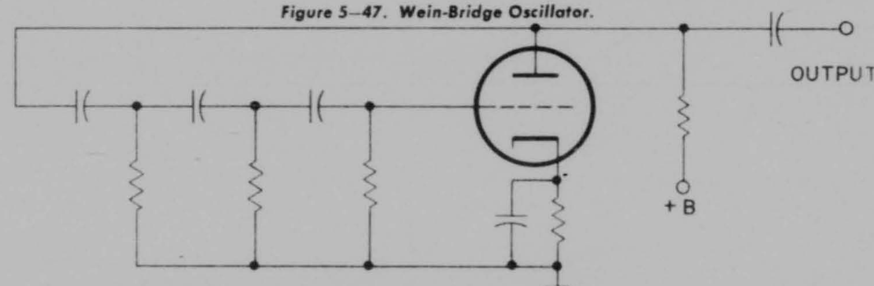

Figure 5—48. Phase-Shift Oscillator.

mined by a resistance-capacitance network which provides regenerative coupling between the output and input of a feedback amplifier. No use is made of a tank circuit consisting of inductance and capacitance to control the frequency.

Wien Bridge

An oscillator in which a frequency-selective Wien-bridgé circuit is used as the resistance-capacitance feedback network is called a "Wien-bridge oscillator." One widely used circuit for this type of oscillator is shown in Figure 5-47.

The bridge allows a voltage of only one frequency to be effective in the circuit because of the degeneration and phase shift provided by this circuit. The Wien-bridge oscillator has many advantages over other types of audio-frequency oscillators. For instance, it may conveniently be made to produce a wide range of frequencies. The waveshape is very nearly a true sine wave. Frequency stability is excellent. Finally, the output amplitude is nearly constant over a very wide frequency range.

Phase-shift Oscillator

The phase-shift oscillator is a special type of resistance-capacitance-tuned oscillator that operates with a single tube. The circuit consists of only one amplifier tube plus a phase-shifting feedback circuit which creates a phase shift in proportion to the frequency passed through it (Figure 5-48). The standard feedback-oscillator circuit requires that the signal from the plate be shifted 180 degrees in order that reinforcing action can take place on the grid to make up for circuit losses. In the phase-shift oscillator this is accomplished by three resistance-capacitance sections.

Limiting Circuits

The term "limiting" refers to the removal by electronic means of one extremity or the other of an inout wave. Circuits which perform this function are referred to as "limiters" or "clippers."

Limiters are useful in waveshaping circuits where it is desirable to square off the extrem-

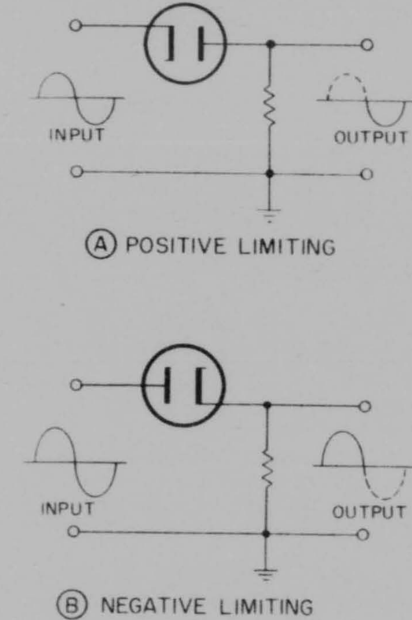

Figure 5—49. Typical Series Limiting Circuits.

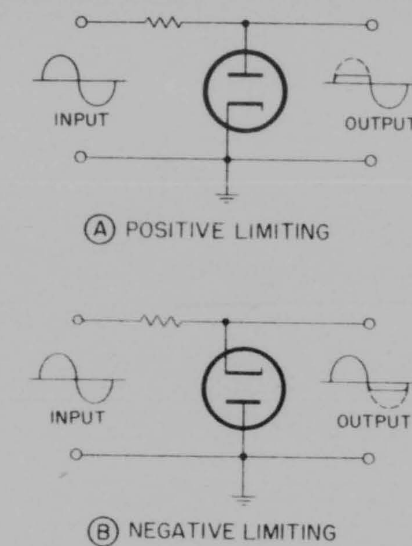

Figure 5—50. Typical Parallel Limiting Circuits.

ities of the applied signal. A sine wave may be applied to a limiter circuit to obtain a rectangular wave. A peaked wave may be applied to a limiter to eliminate either the positive or the negative peaks from the output. In frequency modulation receivers, where it is necessary to limit the amplitude of the signal applied to the detection system to a constant value, limiter circuits are employed. Limiters find application as protective devices in circuits in which the input voltage to a stage must be prevented from swinging too far in the positive or the negative direction.

Series-diode Limiting

The characteristics of a diode are such that the tube conducts only when the plate is at a positive potential with respect to the cathode; in other words, when the cathode is negative with respect to the plate.

The series-diode limiter shown in Figure 5-49A is commonly used to limit the positive half of a sine wave. The rectifying characteristics of the diode are utilized so that it may be considered as a switch. Thus, the output voltage remains at zero throughout the positive half cycle of the input since the diode switch is open and no current flows through R. During the negative half cycle, on the other hand, the cathode is negative with respect to the plate and the tube conducts.

In a similar manner, the same circuit, with the diode connections reversed, may be used to limit the negative swing of the input voltage. This application is illustrated in Figure 5-49B.

Parallel-diode Limiting

An alternate method of employing diodes in limiter circuits is shown in Figure 5-50. The tubes in the two circuits are connected in parallel with the load, which is assumed to be a very high impedance so that the output current is negligible.

In Figure 5-50A, the diode is connected so as to limit the positive signals at approximately ground potential. Since the cathode is held at ground potential, the diode conducts

THIS PAGE IS DECLASSIFIED IAW EO 13526

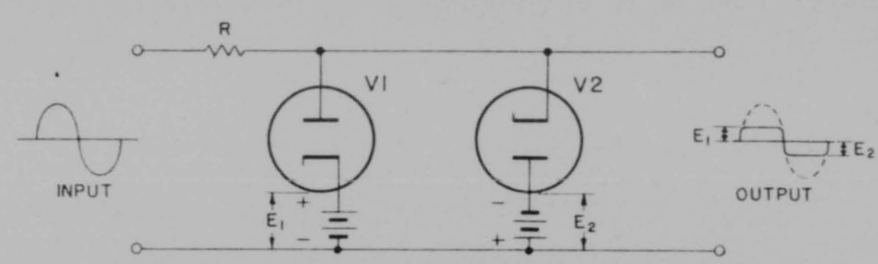

Figure 5—51. Double-Diode Limiter.

throughout the entire positive half cycle. Current flows through the tube and through the series resistor R. As R is large as compared to the plate-to-cathode resistance of the diode, essentially the entire input voltage is developed across R and the output voltage is only the very low voltage drop across the diode. On the negative swing of the input, the diode does not conduct; thus no current flows through R and the output voltage equals the input.

In Figure 5-50B, the plate of the diode is held at ground potential so that the tube does not conduct during the positive half cycle. Thus the output voltage equals the input. During the negative half cycle of the input voltage, the cathode is negative with respect to the plate and the diode conducts. The diode current flows through the series resistance R across which essentially the entire input voltage is developed. The output voltage is limited to the very low voltage drop across the tube. This low negative voltage as a rule may be neglected, and, in this and the previous examples, the outputs may be considered as being limited at essentially ground potential as a result of the switching action of the diode.

An input voltage can be limited to any desirable positive or negative value by holding the proper diode electrode at that voltage by means of a battery or a biasing resistor.

Double-diode Limiting

It is possible to limit both amplitude extremities of an input waveform at any desirable levels by placing two diodes in parallel in the limiter circuit. The circuit (Figure 5-51) represents a simple method of producing a satisfactory square-wave output with a sine-wave input voltage.

Grid Limiting

The grid-cathode of a triode, tetrode or pentode may be employed as a limiter circuit in exactly the same way as the plate-cathode circuit of the diode limiter illustrated in Figure 5-51.

The grid limiter circuit shown in Figure 5-52 is held normally at zero bias. During the positive portion of the input signal the grid attempts to swing positive. Grid current flows through the resistor R, developing drop of such polarity as to oppose the positive input voltage. The drop may be considered as an automatic bias developed during the part of the input which causes grid current to flow.

Cutoff Limiting

Electron current through a vacuum tube can flow only from cathode to plate and not from plate to cathode. Therefore, a plate current cannot become a negative value. When the grid is driven to cutoff, the plate current is decreased to zero and remains at zero during the time the grid is below cutoff. Since no current flows through the plate circuit when the tube is cut off, no voltage is developed across the load resistance and the plate is maintained at the full value of the plate-supply voltage. Thus a type of limiting is achieved in which the positive extreme of the plate waveform is flattened as a result of driving the grid beyond cutoff.

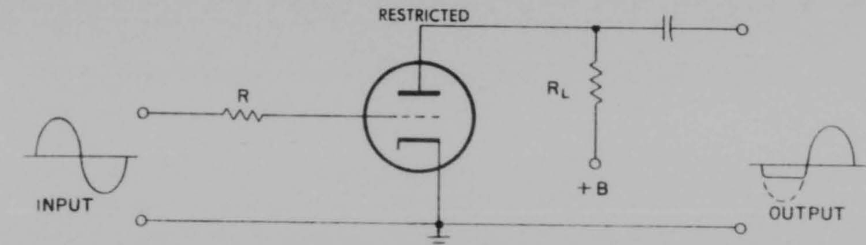

Figure 5—52. Unbiased Grid-Limiter.

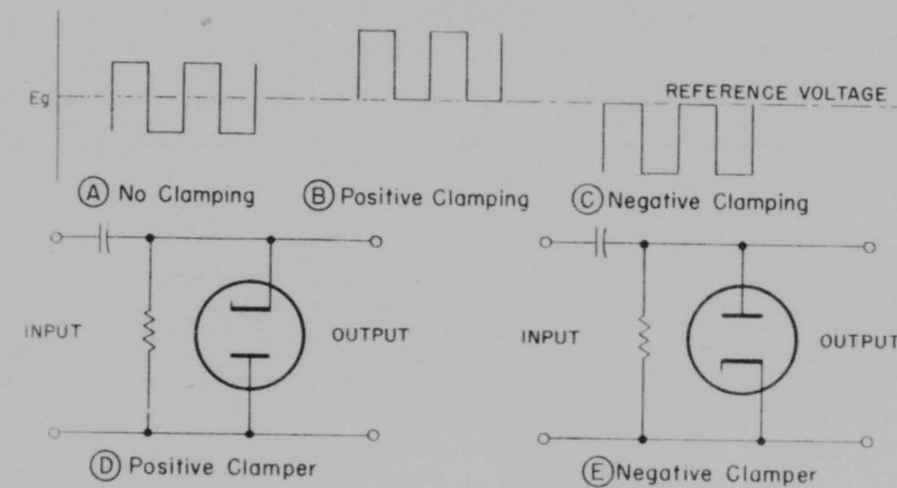

Figure 5—53. Clamping Circuits and Waveforms.

Saturation Limiting

The grid-limiting resistor may be omitted, if the input signal comes from a low-impedance high-power source, and limiting in the plate circuit may still be realized. This is due to plate-current saturation and is usually referred to as "saturation limiting." Plate-current saturation should not be confused with emission saturation since in tubes using oxide-coated cathodes there is no definite saturation value of emission currents.

Overdriven Amplifier

An amplifier circuit in which saturation-limiting is employed in conjunction with cut-off limiting to produce a rectangular wave from a sine wave is generally known as an "over-driven amplifier." The driving circuit for such an amplifier should have a relatively low-output impedance and be capable of delivering power, as considerable current is drawn during the positive swing of the grid.

Limiter Applications

In radar work, very narrow pulses often are required to start oscillators into action, to force grids above cutoff so that the tube may conduct for a short period, or to modulate radio frequencies into brief pulses. Alternately positive and negative pulses, obtained in various ways, may be passed through a limiting circuit to obtain pulses which are either positive or negative with respect to a reference value. This reference level may be at zero voltage or any positive or negative potential. By alternate stages of amplification and limit-

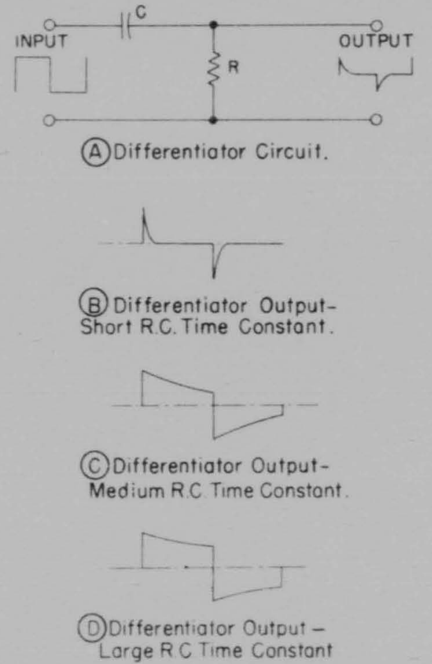

Figure 5—54. Differentiation Circuit and Waveforms.

ing, the pulse may be narrowed to any width desired.

Clamping Circuits

A circuit (Figure 5-53) which holds either amplitude extreme of a waveform to a given reference level of potential is called a "clamping circuit"; the terms "DC restorer" and "baseline stabilizer" also are commonly used.

To demonstrate the utility of clamping circuits, a brief review of the action of coupling networks is useful. In coupling between stages in radio and radar circuits, a coupling capacitor almost always must be used to keep the high positive DC plate potential of the first tube isolated from the grid of the second tube. It is desirable that only the varying component of the plate potential be transmitted to the grid as a signal varying above and below fixed reference level. If the lower end of

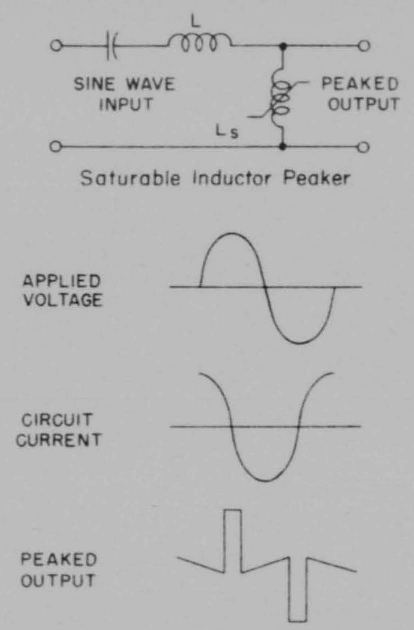

Figure 5—55. Inductive Peaking Circuit and Waveforms.

the grid-leak resistor is grounded, the signal varies about ground. If a biasing potential is employed, the signal applied to the grid varies above and below this DC bias voltage.

In other circuits, however, the waveform swing must be entirely below the reference voltage, instead of alternating on both sides of it. For these applications a clamping circuit is used to hold either the positive extreme or the negative extreme of the waveform to the desired level.

Peaking Circuits

In the development of trigger pulses for use in controlling the operation of various types of circuits, peaking circuits are often employed. As a rule, it is necessary to have a trigger pulse of very short duration and with an extremely sharp leading edge. In order to produce such pulses it is necessary to use a circuit capable of distorting an input signal in

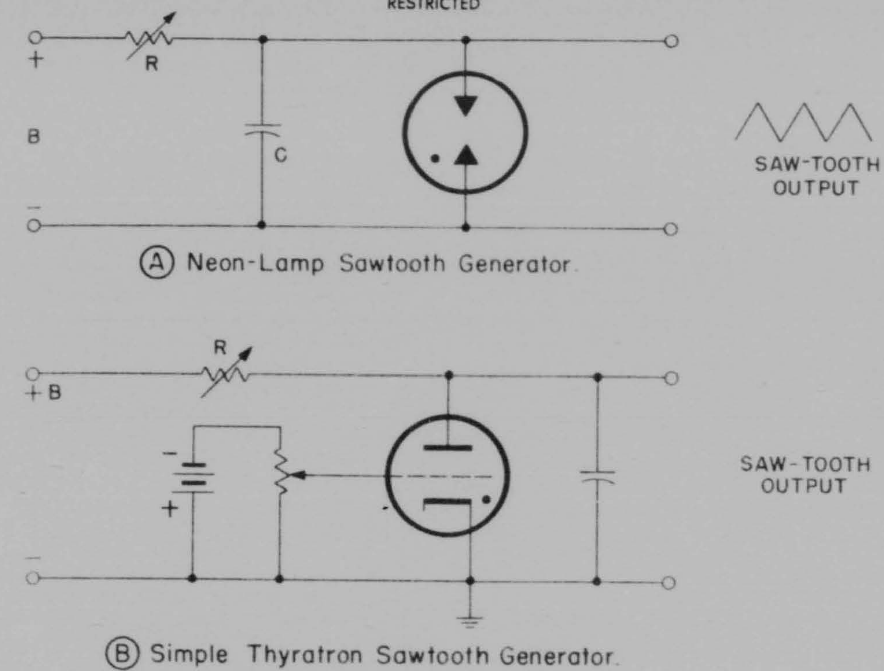

Figure 5—56. Sawtooth Generator Circuits.

such a way as to produce an output waveform in which the time duration is shortened and the leading edge is as nearly vertical as possible.

The choice of peaking circuit used depends primarily upon the kind of input signal available. If the input signal is a rectangular wave and R-C differentiator circuit is employed to produce the peaked output. An alternate method employs a transformer to produce the peaked output. If the available signal is a sine wave a saturable inductor can be used to produce the trigger pulses.

R-C Differentiator

A differentiator circuit (Figure 5-54) produces an output voltage the amplitude of which is proportional to the rate of change of the input voltage. In an R-C differentiator circuit, the time constant is made short relative to the duration of the applied pulse in order that the capacitor will become fully charged in a small fraction of the pulse duration. The charge on a capacitor cannot change in value instantaneously, but changes only at the rate established by the R-C product. This is equivalent to the statement that sudden change in the voltage of one terminal of a capacitor must occur simultaneously with an equal change in the voltage of the other terminal. Since the two circuit components act as a voltage-divider network, the portion of the applied voltage which does not appear across the capacitor, because of the time required for a change of charge, must appear across the resistor as an output voltage.

Saturable Inductor

A special coil in which a low value of current produces magnetic saturation of the core is termed a "saturable inductor." This type of inductor which is sometimes called a "nonlinear coil," can be used to produce sharp pulses directly from a pure sine wave.

An inductor (Figure 5-55) offers an impedance to the flow of alternating current because the current produces a changing flux which induces in the coil a voltage of such polarity that it resists the flow of current by opposing the applied voltage. The larger the inductance, the larger is the impedance to the flow of alternating current. In an iron-core inductor the impedance at any frequency is proportional to the inductance as long as the core is not magnetically saturated. However, when the core is saturated, the flux linking the coil can no longer be increased by an increase of the current through the coil so that the induced back voltage drops to a low value.

Sawtooth Generators

Voltages having sawtooth waveforms have wide application in radar. The simplest method of obtaining this type of waveshape is by means of a gas-tube relaxation oscillator. This oscillator is one in which no tuned circuits are employed, and the output shows abrupt changes in voltage usually brought about by charging or discharging a capacitor through a resistance.

Neon Tube Sawtooth Generator

The tube illustrated in Figure 5-56A is a neon glow tube. Until the potential across this type of tube reaches a value high enough to ionize the gas, the tube presents an almost infinite impedance. However, once ionized, a very small voltage is sufficient to keep the current flowing, and until the voltage across the tube falls below the value required to maintain the ionization, the tube has a low impedance. When the voltage falls below this value, the gas de-ionizes and current flow ceases. The potential at which the gas ionizes and conduction begins is called the "firing potential" of the tube, and that at which deionization takes place is known as "deionizing potential." The tube can be considered as a switch which is open when the tube is not ionized and closed when it is ionized.

The simplest form of sawtooth generator consists of a capacitor, a variable resistor, a source of power, and a gas-tube switch. Since the voltage across this capacitor may be controlled by the neon switch, the circuit is called a neon sawtooth generator (Figure 5-56A). When constant voltage is applied to the input of this circuit, the capacitor is charged through the resistor. The voltage across the capacitor rises from zero, approaching the full supply voltage along a normal R-C charging curve. The voltage across the neon tube is the same as the voltage across the capacitor, because these elements are in parallel. The neon tube acts as an open switch until the voltage across it reaches the firing point. At the firing potential, the neon tube ionizes and forms a discharge path for the capacitor. The capacitor thus discharges very rapidly until the voltage falls to the deionizing potential of the neon tube, when conduction stops and the tube again becomes an open switch. The capacitor then begins to charge again toward the supply voltage. The voltage rises along the R-C curve to the firing potential of the neon tube, and then falls. This process continues as long as a DC supply is maintained.

The frequency of a sawtooth wave is the number of times the voltage rises and falls per second. This frequency can be varied by changing the firing and deionizing potentials, but this means of variation requires a change in neon-tube characteristics. A simpler method of frequency control is to vary the value of the resistor, the value of the capacitor, or the magnitude of the supply voltage.

Thyratron Sawtooth Generator

This relaxation oscillation is similar in operation to the neon sawtooth generator. A thyratron tube (Figure 5-56B), or gas triode, is used as an electronic switch. The thyratron acts in the same manner as the neon tube, except that a grid has been added to control the firing potential.

Multivibrators

The multivibrator is a form of relaxation oscillator which is frequently used in radar circuits. There are several different types in use, depending on the function they are required to perform. Multivibrators may be designed as continuous or free-running or as driven oscillators whose operation and frequency is controlled by a synchronizing or triggering voltage applied from an outside source. The output of a multivibrator is usually nearly rectangular in form and the frequency may range from about 1 cycle per minute to 100 kilocycles per second.

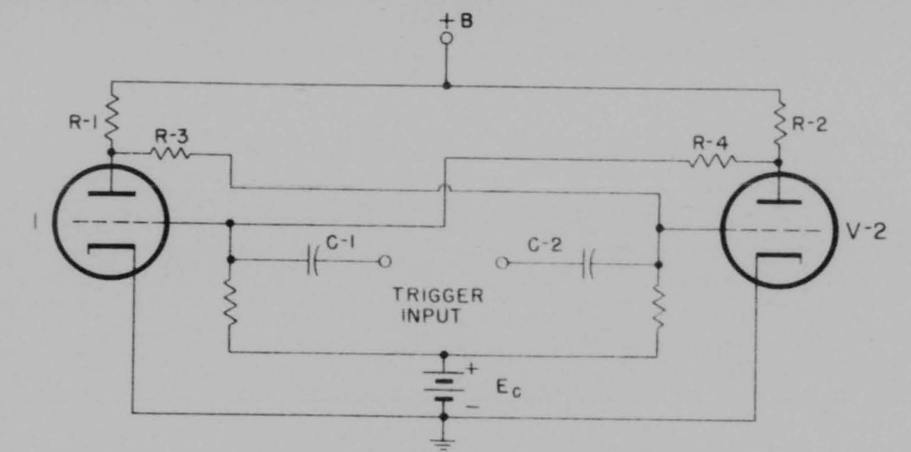

Figure 5—57. Eccles-Jordan Trigger Circuit.

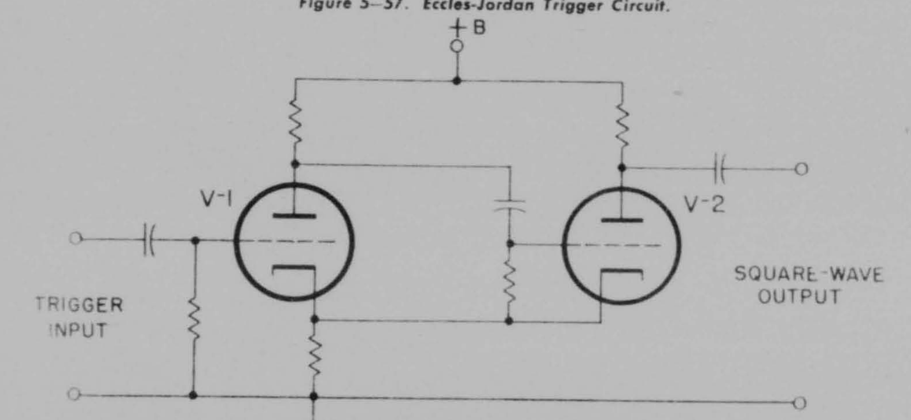

Figure 5—58. One-Slot Multivibrator.

Trigger Circuits

The multivibrator will be more easily understood if the action of the Eccles-Jordan trigger circuit is first studied. This circuit is shown in Figure 5-57. This form of multivibrator employs direct coupling between the plates and grids of the two tubes. It is not an oscillator in the true sense; rather it is a circuit possessing two conditions of stable equilibrium. One condition is when V_1 is conducting the V_2 is cut off; the other when V_2 is conducting and V_1 is cut off. The circuit remains in one or the other of these two conditions with no change in plate, grid, cathode potentials, or plate current, until some action occurs which causes the nonconducting tube to conduct. The tubes then reverse their functions and remain in the new condition as long as no plate current flows in the cutoff tube. Because of this sudden reversal of "flopping" from one state of equilibrium to the other, this type of circuit is often referred to as a "flip-flop circuit."

One-shot Multivibrators

The circuit shown in Figure 5-58 is a modi-

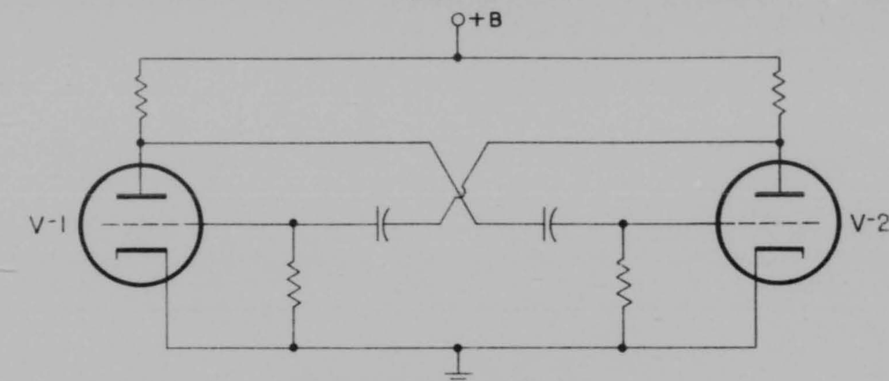

Figure 5–59. Basic Multivibrator.

fication of the Eccles-Jordan which accomplishes a complete cycle when triggered with a positive pulse. It is essentially a two-stage resistance-capacitance-coupled amplifier with one tube cut off and the other normally conducting. The balanced condition of the circuit is established by the arrangement for biasing the tubes.

Conventional or Plate-coupled Multivibrator

This basic free-running multivibrator circuit is a simple two-stage resistance-capacitance-coupled amplifier with the output of the second stage coupled through a capacitor to the grid of the first tube (Figure 5-59). Since the signal applied to the grid of a resistance-capacitance-coupled amplifier is reversed in phase in the output, the output of the second stage is in phase with the input to the first, as each stage reverses the polarity of its input. Because the output of the second stage is of the proper polarity to reinforce the signal applied to the first tube, oscillations can take place.

Synchronization of Multivibrators by Pulses

Although multivibrators can be synchronized with a sine-wave voltage, more satisfactory synchronization may be obtained by the use of short trigger pulses. These pulses may be either positive or negative.

A positive trigger pulse applied to a conducting tube of a multivibrator has no effect on the action of the multivibrator. A positive trigger pulse applied to a nonconducting tube in a multivibrator can cause switching action to take place only if the pulse is large enough to raise the grid above the cutoff voltage.

Applications of Multivibrators

The output of a multivibrator may be used as a source of square waves, as an electronic switch, and as a means of obtaining frequency division. It often is used to introduce a time delay between the operation of two circuits by using the leading edge of the square-wave output to trigger one circuit and the trailing edge to trigger the second. Thus, time can be controlled by varying the R-C constants of the multivibrator circuit. In radar, the action of the multivibrator itself is usually accurately timed by triggering it with the output of a master oscillator circuit. As an electronic switch, the output of one tube allows one circuit to operate while the second is cut off by the output of the second multivibrator tube. When the multivibrator switches, the two external circuits are also switched. In radar, the chief use of multivibrators as electronic switches is to produce gate voltages which permit some component part of the circuit to operate only during an accurately controlled interval.

Shock-excited Oscillator

A vacuum tube may be used as a switch to

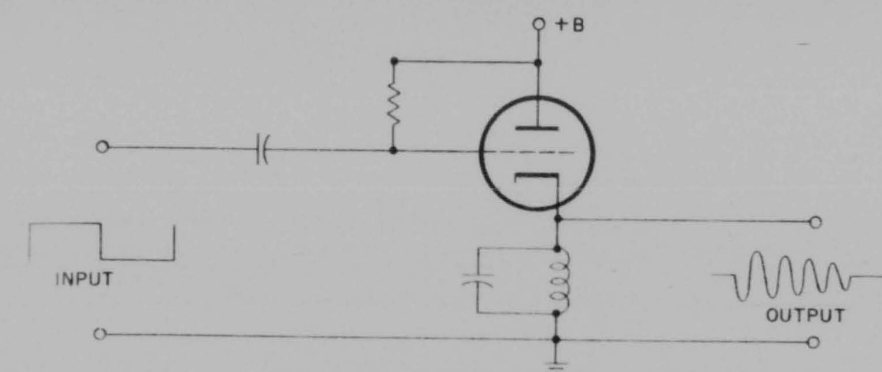

Figure 5–60. Shock-Excited Oscillator.

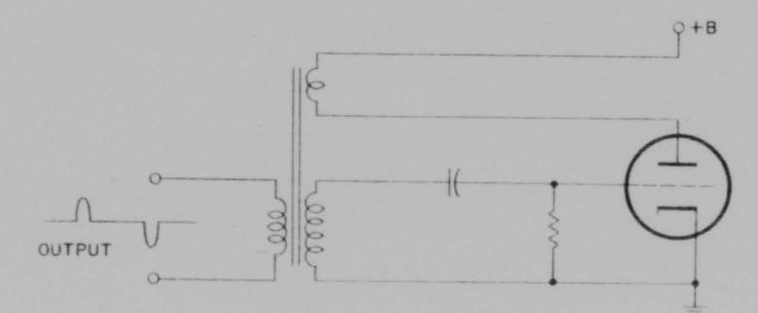

Figure 5–61. Self-Pulsing Blocking Oscillator.

interrupt the steady flow of plate current through a resonant L-C tank circuit as a means of exciting oscillations in the tank. Such a circuit is known as a "shock-excited oscillator" (Figure 5-60) and finds practical applications in instances where oscillations of a certain frequency occurring over short intervals of time are required periodically. It is sometimes referred to as a "ringing oscillator."

Blocking Oscillator

A blocking oscillator (Figure 5-61) is any oscillator which cuts itself off after one or more cycles on account of the accumulation of a negative charge on the grid capacitor. Thus, in an oscillator in which the grid swings positive with respect to the cathode, electrons are attracted to the grid and accumulate on the plate of the grid capacitor nearest the grid. Since these electrons cannot return to the cathode through the tube, they must return through the grid-to-cathode resistor. If the resistor is sufficiently large, electrons may accumulate on the capacitor faster than the resistor permits them to return to the cathode. In this case, a negative charge is built up at the grid which may bias the tube beyond cutoff. After the tube is cut off, it provides no additional electrons to the grid capacitor. However, the capacitor continues to discharge through the resistor, and a point is reached eventually where the tube again conducts. Thus the process repeats and the tube becomes an intermittent oscillator. **The rate of the recurrence of operating conditions is determined by the R-C time constant of the grid circuit.**

THIS PAGE IS DECLASSIFIED IAW EO 13526

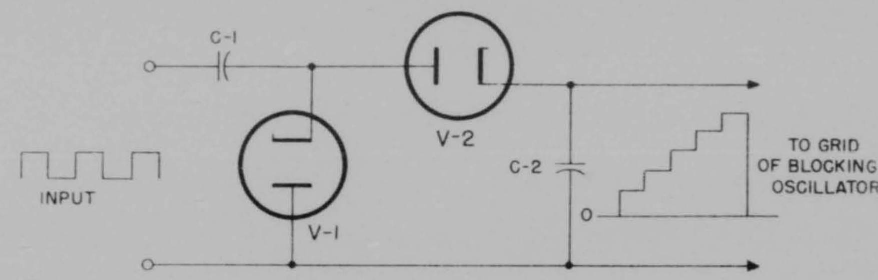

Figure 5-62. Step-by-Step Counter.

Counting Circuits

A counting circuit, also known as a "frequency divider," is one which receives uniform pulses, representing units to be counted, and produces a voltage proportional to their frequency. By slight modifications, the counting circuit is used in conjunction with a blocking oscillator to produce a trigger pulse which is a submultiple of the frequency of the pulses applied.

The pulses applied to the counting circuit must be of the same amplitude and time duration if accurate frequency division is to be made. Thus, counting circuits are ordinarily preceded by shaping and limiting circuits to insure this uniformity by amplitude and width. Under these circumstances, the pulse-repetition frequency constitutes the only variable, and frequency variations may be measured.

Step-by-step Counting

The charge on this capacitor, C_2 of Figure 5-62, is increased slightly during the time of each positive pulse, producing a step voltage across the output. These steps decrease in size exponentially as the voltage across C_2 approaches the final value, the rate being dependent upon the output impedance of the driving circuit. As long as there is no path through which C_2 can discharge, the voltage across it continues to increase with each successive pulse until it is equal to the amplitude of the applied signals. At this point, the cathode of V_2 is held at a positive voltage equal to that on the plate during the pulse time and the tube fails to conduct.

In order to use the step-by-step counter as a frequency divider, a sensitive circuit, such as a single-swing blocking oscillator, is connected to the output terminals (Figure 28). The blocking oscillator V_3 is triggered into operation when the voltage across C_2 reaches a point sufficiently positive to raise the grid of V_3 to cutoff. The regenerative action of the blocking oscillator is such that, once conduction starts, the grid swings positive with respect to the cathode and grid current quickly discharges capacitor C_2 back to ground potential. Any attempt for C_2 to charge to a negative voltage is prevented by the clamping action of V_2 and V_1.

5. FUNDAMENTALS OF A RADAR SYSTEM

Detection by Radio Echoes

Basically, a radar set includes a radio transmitter, a receiver at the same location, and an indicator to show the presence of echoes and thus of objects, as shown in Figure 5-63. The transmitter has a directional radiating system from which electromagnetic waves are propagated with the velocity of light until they strike a distant object or objects and are scattered or reflected thereby. Some of the scattered or reflected energy is returned to the radar station, where it is received. The received signals are then employed in the equipment to determine the position of the object that reflected some of the transmitted energy.

A very great amount of power must be radiated, because an almost infinitesimally

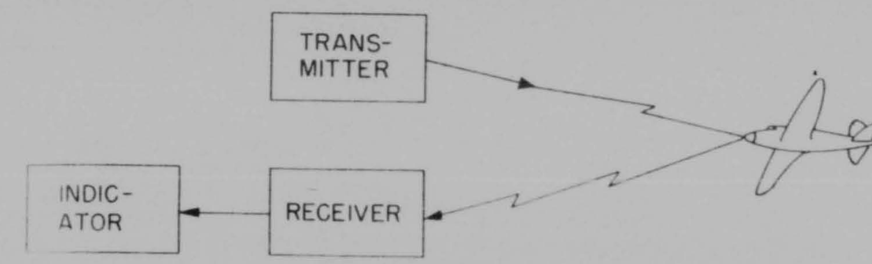

Figure 5-63. Elementary System for Radio Echo Detection.

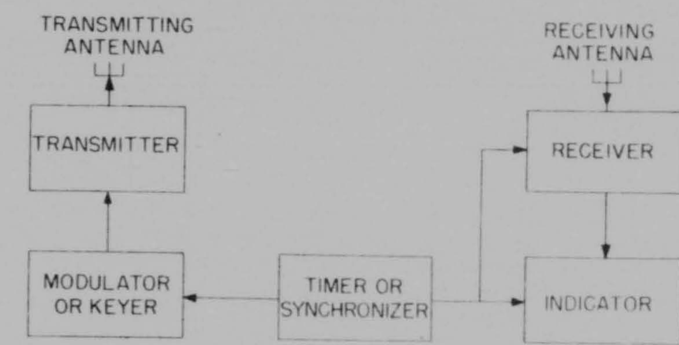

Figure 5-64. Pulse Radar System Using Two Antennas.

small portion of it returns to the receiver on account of the distance traversed and the small reflecting power of a target. Moreover, since the powerful transmitter is operated adjacent to the highly sensitive receiver, which must be able to detect this minute quantity of reflected power, some means must be provided whereby the power radiated by the transmitter may be excluded from the receiver.

Pulse Systems

Most radar equipment is based upon the transmission and reception of pulses of electromagnetic energy of very short duration. The pulse-echo process is repeated periodically at a rate so rapid that a steady image is obtained in a cathode-ray tube. The time interval between the transmission of the pulse and the reception of the echo is proportional to the range of the object. In order to determine the direction of the object as well as its range, the radiation of energy is made highly directive so that any desired region of space may be explored by controlling the direction of the beam.

The basic elements of a typical pulse system are represented in block-diagram form in Figure 5-64. A train of radio-frequency pulses is generated by the transmitter under the immediate control of the modulator, or keyer, and is radiated by the transmitting antenna. The echo pulse is picked up by the receiving antenna, is amplified and detected by the receiver, and is passed on to the indicator, which is usually a cathode-ray tube, where the range and direction of the reflecting object are displayed. The timer serves to synchronize various functions of the transmitter, receiver, and indicator.

Antennas

The transmitting antenna is at least moderately directive in most applications and is often highly directive. It is usually con-

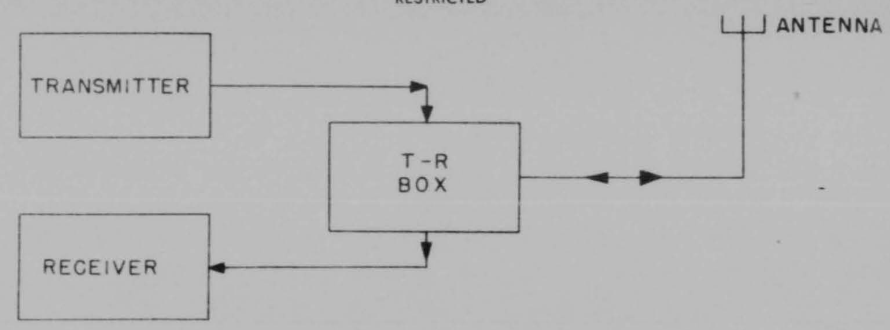

Figure 5—65. Single-Antenna Radar System.

structed to permit orientation in any desired direction. In order to obtain the required directivity and at the same time to limit the size of the antenna to meet space and weight requirements, the radio frequency employed must be very high, being seldom below 100 megacycles or higher frequencies (shorter wavelengths) and greater directivities. Waves shorter than 50 cm. are usually called microwaves. Microwave systems now in use employ frequencies of about 3,000 Mc/s (10 cm.), or 10,000 Mc/s (3 cm.). At lower frequencies—of the order of hundred of megacycles per second—the antenna system comprises a multiple array of linear elements, but at the higher frequencies, parabolic reflectors and other special devices are used almost exclusively.

The receiving antenna is similar to the transmitting antenna, and, in many sets, the same antenna is used for both transmitting and receiving. The use of one antenna instead of two saves space and weight and obviates the mechanical difficulty of making two highly directive antennas point in exactly the same direction. When only one antenna system is used, some kind of switching means is required to connect the transmitter to the antenna when a pulse is to be radiated, and then to connect the receiver with the antenna during the interval between pulses. This device, indicated in Figure 5-65, is generally called a "T-R (transmit-receive) box." It usually comprises a spark-gap tube and associated resonant system in which a spark is produced when a pulse is transmitted. The spark reduces the portion of the transmitter power reaching the receiver.

Transmitters

Successful power amplifiers for very high frequencies are almost nonexistent; consequently, radar transmitters invariably use a simple oscillator that is directly coupled to the transmitting antenna system. In microwave transmitters, the oscillator is usually a magnetron; for longer waves, it is usually a group of vacuum tube triodes.

Modulators

The modulator is a controlled source of anode power for the oscillator. The modulator can be thought of as a "keyer," and it is frequently referred to by this name since it supplies power to the transmitter only during the pulse period. In order to control the modulator so that it supplies plate power to the transmitter in pulses of the desired duration and repetition rate, a combination of circuits called the "timer" or "synchronizer" is employed which supplies signals for actuating the keyer at precisely regular intervals.

Radar Receivers

Radar receivers are usually of the superheterodyne type and must be capable of accepting signals lying in a frequency band considerably broader than the bands encountered in conventional communication practice. Bandwidths of from one to ten megacycles per second may be encountered in radar receivers.

Indicators

The output signals from the receiver, to-

gether with data representing the orientation of the antenna, provide the available information as to the position of the reflecting object. An indication of this information, suited to the particular operational characteristics of the equipment, must be made. Apparatus for performing this function is called the "indicator;" generally it comprises a combination of circuits and cathode-ray tubes. Such tubes can present vastly more information than can a simple pointer-type meter; nevertheless, certain special applications employ meters or other electromechanical devices.

Types of Presentation

There are many types of indication and many different ways in which the direction of the antenna beam may be varied with time. Each combination has its particular field of application in radar work. Three especially important types of presentation are denoted as Type A, Type B, and Type P. Type P presentation is also called **"plan position indication"** (abbreviated PPI).

Type A Indication

Type A presentation employs a cathode-ray tube for presenting data primarily on the range of a reflecting object. The scanning spot is maintained at constant intensity, and is set in uniform motion horizontally across the face of the cathode-ray tube at the instant at which a pulse of energy is radiated by the transmitter. The spot starts at a point near the left-hand side of the fluorescent screen and moves to the right across the tube at constant speed.

Received signals cause vertical deflections of the scanning spot roughly proportional to the signal strength. Upon reaching the right end of the screen, the spot is extinguished by grid control in the tube and is returned to the left end, where it is illuminated again to retrace the same path on the next succeeding transmitted pulse. The persistence of the screen of the tube reduces flickering of the image on the screen. The appearance of the fluorescent screen, when, for example, echoes from two separate targets at different ranges are received is that shown in Figure 5-66A. A vertical deflection corresponding to the

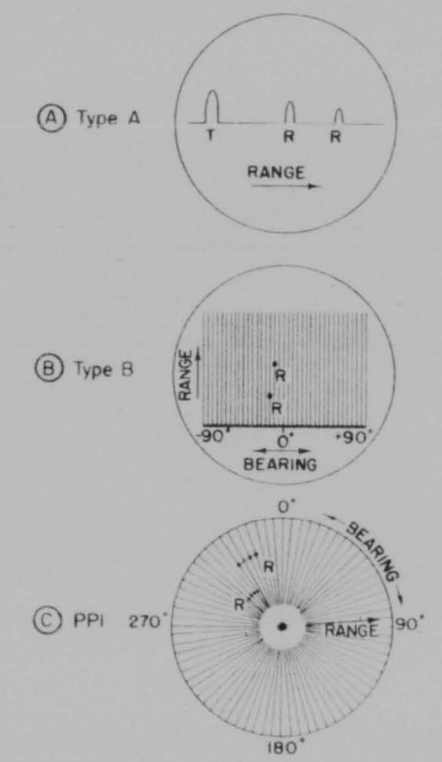

Figure 5—66. Types of Indication.

transmitted pulse appears at the beginning of the scanning line, and others—in the form of smaller replicas of the original pulse—appear at positions on the trace that depend on the range to each reflecting object. The vertically presented pulse outline is dubbed a "pip," in radar parlance.

The horizontal distances across the screen from the end of the transmitted pulse to the ends of the several received pulses constitute indications of the distances to the respective reflecting objects. A rough indication of the direction of an object may be obtained by rotating the antenna beam to that position which gives maximum pip height. A large number of targets may be shown at the same

THIS PAGE IS DECLASSIFIED IAW EO 13526

time on a Type A indicator, and a series of objects lying in a straight line from the radar station may be resolved on the screen and have their respective ranges indicated.

Type B Indication

In Type B presentation, the azimuth (bearing) and the range of reflecting objects are presented on the screen of the tube as absciasa and ordinate, respectively. In radar sets having this presentation, a highly directive antenna system is rotated about a vertical axis so that the radiated beam covers a horizontal plane. The potential spot which would appear if the grid control were to turn it on, is given a horizontal motion synchronously with the rotation of the antenna, corresponding to at least a portion of the angle of rotation of the antenna system. Thus, in the absence of other deflection, the scanning spot would describe a horizontal line across the lower portion of the indicator screen.

A uniform vertical motion from bottom to top of the screen is also imparted to the scanning spot, each vertical line being synchronized with a transmitted pulse for the indication of range. The repetitive vertical sweep is very much more rapid than the horizontal sweep. In Type B presentation, the spot is maintained at very low intensity, and the received signal is impressed upon the grid of the cathode-ray tube to intensify the spot and to cause a bright area to appear on the screen at a point representing the azimuth and range of the target. The transmitted pulses are represented by a bright horizontal line at the bottom, called the "base line" of the pattern. The appearance of the indicator screen is shown in Figure 5-66B.

The frequency with which pulses are transmitted is important in relation to the width of the radiated beam and the speed of rotation of the antenna in determining the angular coverage and resolution of the system. The pulse repetition rate should be so chosen that pulses are transmitted at sufficiently small angular intervals to insure that targets within range are not missed simply because no power is radiated toward them. In some equipment, the pulse repetition rate is relatively high, and the vertical range-sweep lines are correspondingly closely spaced on the screen.

PPI Indication

Type P presentation is employed where the tactical conditions require that range and bearing information—but not elevation information—be obtained concerning objects in or near a horizontal plane centered at the site of the radar station. The PPI screen, which is illustrated in Figure 5-66C, provides information on range and bearing, plotted in polar co-ordinates. In a set employing plan position indication, the antenna is rotated uniformly about a vertical axis so that the principal axis of the radiated beam periodically searches all angles in a horizontal plane. The beam is usually narrow in azimuth and broad in elevation. A very large number of pulses are transmitted for each revolution of the antenna.

As each pulse starts, the unintensified spot starts to move outward with uniform speed along a radial line from the center of the screen to provide a radial range indication. After reaching the edge of the tube, it returns quickly to the center to begin another radial trace when the next pulse is transmitted. Normally, the cathode-ray tube is biased so that the scanning spot is at the threshold of visibility, but when an echo is received, the spot is intensified to make it visible.

The polar angle of the radial line on which the spot appears indicates the azimuth of the antenna beam and hence of the reflecting object. The radial distance of the spot from the center of the tube indicates the range of the object. In this way, what is essentially a map of the territory surrounding the observing station is produced on the indicator tube.

Radar Receivers

A distant target reflects back to the receiving antenna in a radar system a very small fraction of the transmitted energy—less, perhaps, than one-billionth of a billionth part. The echoes return as pulses of high-frequency energy of the same nature as those sent out by the transmitter, except that the power during a pulse may be measured in

RESTRICTED

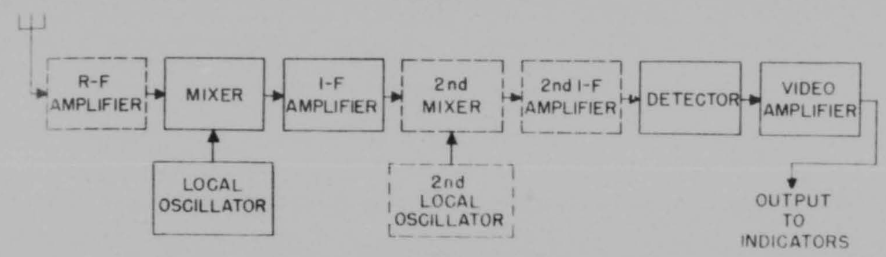

Figure 5—67. Block Diagram of a Radar Receiver.

fractions of micromicrowatts instead of in kilowatts, and the voltage at the antenna is in the range of microvolts instead of kilovolts.

Information about the position of the target is presented to the eye when the reception of an echo causes the movement or appearance of a spot of light on a cathode-ray tube, which requires for its operation a voltage of the order of 20 volts at least, and which will not respond to the high frequencies within a pulse. An amplifier and detector must therefore be used which are capable of producing a visible indication on the cathode-ray tube when connected to an antenna giving pulses of extremely high-frequency voltage whose amplitude is measured in microvolts and which last, at the most, a few microseconds. This very special amplifier and detector is the radar receiver.

The most suitable arrangement of the receiver components to meet the requirement outlined has been found to be that shown in the block diagram in Figure 5-67. This is a superheterodyne receiver, which utilizes amplification at a frequency intermediate to the frequencies of the input and output circuits.

An r-f amplifier of one or two stages is usually found in receivers operating in systems at or below 1,000 Mc/s. Above this frequency, the incoming signal is converted directly to the intermediate frequency without amplification at the input frequency. The principal factor in determining what the first few stages shall be is the amount of noise which they produce in the receiver output. Noise introduced in the first stage or two, where the signal is weakest, will be amplified by the full gain of the receiver, and, therefore, will be the most important noise in determining the signal-to-noise ratio in the output.

After conversion to the intermediate frequency, the signal is amplified in several stages. Most of the gain of the receiver is obtained in the i-f amplifier, and the overall bandwidth of the receiver is often determined in large part by that of the i-f stages. To reduce feedback, a few receivers use a second mixer to convert the signals to a second intermediate frequency for further amplification, since feedback between stages operating at different frequencies is negligible.

Detection of the signal is followed by amplification in one or more stages at the video frequency. The output stage is usually a cathode follower, which provides a low-impedance source for supplying the video pulses through a cable to the indicator.

Various modifications in the type of coupling between stages, type of mixer, detector, and local oscillator, and number of stages of amplification at the different frequencies, are found in different receivers, depending in large part upon the carrier frequency of the radar system. However, the receiver is always designed with as little noise as possible and with sufficient gain so that noise, rather than lack of gain, limits the smallest visible signal.

In the superheterodyne, the incoming signal is applied to a mixer consisting of a nonlinear impedance such as an over-biased vacuum tube or a diode. The signal is mixed with a steady signal generated locally in an oscillator stage, with the result that a signal bearing all the modulation applied to the original signal **but of a frequency equal to the differ-**

THIS PAGE IS DECLASSIFIED IAW EO 13526

ence between the local oscillator and incoming signal frequencies appears in the mixer output circuit. The output from the mixer stage is fed into a fixed tuned intermediate-frequency amplifier, where it is amplified and detected in the usual manner and passed on to the video amplifier.

The advantages of superheterodyne reception are directly attributable to the use of the fixed-tuned intermediate-frequency (i-f) amplifier. Since all signals are converted to the intermediate frequency, this section of the receiver may be designed for optimum selectivity and amplification. High amplification is easily obtained in the intermediate-frequency amplifier, since it operates at a relatively low frequency, where conventional pentode-type tubes give a great deal of voltage gain.

SECTION IV—SYNCHROS AND SERVOMECHANISMS

1. INTRODUCTION

Often in fire control and radar equipment, an arbitrary motion imparted to one shaft must be reproduced accurately by the motion of a second shaft, sometimes with torque amplification. A direct mechanical connection between the input or control shaft and the output or load shaft may not be feasible because of their separation distance or because of the need for torque amplification. When torque amplification is not required, extensive use is made of electrical data-transmission or remote-indication systems. The device most commonly used for remote indication are synchros, which resemble small electric motors and operate on single-phase alternating current. When torque amplification is required, use is made of electrical or hydraulic devices called servomechanisms. Servomechanisms commonly include synchro units when control from a remote point is required.

2. GENERAL

Radar sets use remote-control systems to turn the antennas, to drive dials which indicate the antenna position, and to synchronize the PPI (plan position indicator) deflection coil with the antenna. The antenna and the PPI coil of shipborne and airborne radar sets may be controlled either in true bearing or in relative bearing. In fire-control work, one group of remote control mechanisms transmits data on range, bearing (azimuth or train), and elevation of the target to a computer. A computer is a machine which calculates the proper aiming of the gun to place a projectile on the future position of the target, with allowances for the relative motion of the target, and for gravity, wind, and other ballistic effects on the projectile. A second group of servomechanisms transmits to the gun the computed bearing and elevation of the gun, and sometimes the range of the target. The gun may be aimed either automatically by servomechanisms or manually by operators who match pointers with pointers driven by remote-indication mechanisms.

Synchros and servomechanisms find many other uses, especially on ships and on aircraft. For example, synchros are used as compass repeaters, and for indicating the positions of wing flaps, rudders, and landing gear. Servomechanisms are used for pointing searchlights, for remote control of landing gear, and for manual and automatic steering.

3. SYNCHROS

A synchro is a small alternating-current machine used for the transmission of angular-position data. Synchros are known also as "synchronous" units or "selsynchronous" units, and by various trade names such as Selsyns, Synchrotie, Autosyn.

A special example of the use of synchros is the system for turning a PPI deflection coil in accordance with the rotation of the radar antenna. The antenna is connected by gears to the shaft of the synchro generator. Voltages from the generator are transmitted to the PPI synchro motor and cause the motor

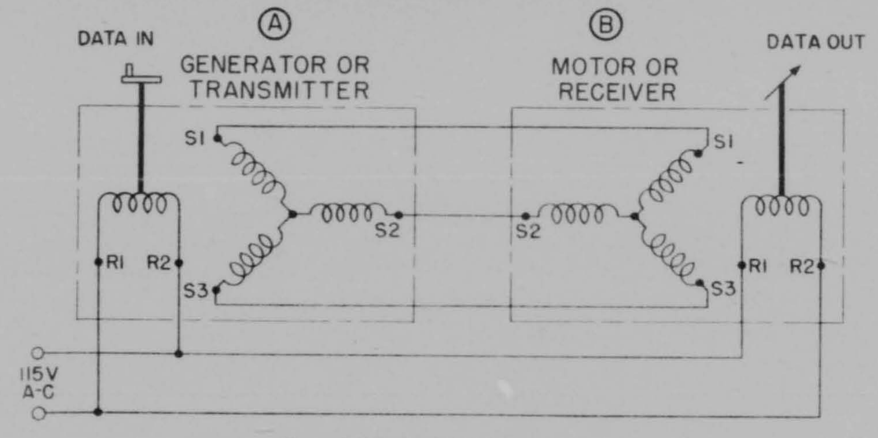

Figure 5–68. Typical Selsyn System.

to turn in correspondence with the generator motion; therefore, the deflection coil geared to the motor is made to follow the antenna motion, and the direction of the range trace on the indicator tube corresponds with the direction of radiation from the antenna. For greater accuracy, the synchros are usually geared to turn faster than the antenna and coils.

The synchro generator is often called a transmitter, and the motor, a receiver, or follow-up. The generator and motor are identical in construction except that the motor is equipped with a mechanical, oscillation damper and with low-friction ball bearings, whereas the generator does not have the damper and usually does not have ball bearings. Each machine has a stator (stationary part) and a rotor (rotating part), built of sheet steel laminations and wound with coils of wire.

The rotor has two salient (projecting) poles and one winding. Connection to the winding is made through brushes resting on two slip rings.

The electrical construction of both receiving and transmitting Selsyns is identical. The rotors are single-phased and fed from the common power source such as the 60 cycle line supply. The stators of both the transmitting and receiving Selsyns are three-phase with the corresponding legs of the transmitting and receiving Selsyns connected together. (Figure 5-68).

The transmitter Selsyn (A) is frequently called a "Selsyn generator," and the receiver Selsyn (B), a "Selsyn motor." Electrically, the Selsyn generator and the Selsyn motor are identical. The physical difference mentioned above is in the damper which consists of a lead ring within friction plates on a sleeve which is secured to the rotor shaft. The lead ring has a large amount of inertia and can be rotated on the sleeve only with considerable difficulty. Any violent oscillation of the rotor rotates the sleeve. The lead ring cannot follow this motion immediately because of its inertia, so that a large damping effect is produced on the oscillating motor, which quickly stops the movement. It should be noted that a Selsyn generator does not necessarily rotate continuously as do most electrical generators, but, may change its position by a few degrees. As the rotator of (A) is turned to a specific position with respect to the stator, voltages are induced in the stator's windings. These voltages cause current to flow in the identically connected stator windings of the receiver Selsyn. These currents set up a field in the receiving Selsyn which will cause the receiving rotor's Selsyn to assume a position where its field will generate a voltage in the receiver's stator's windings. This will exactly cancel those generated in the transmitter stator's winding. There is one and only one

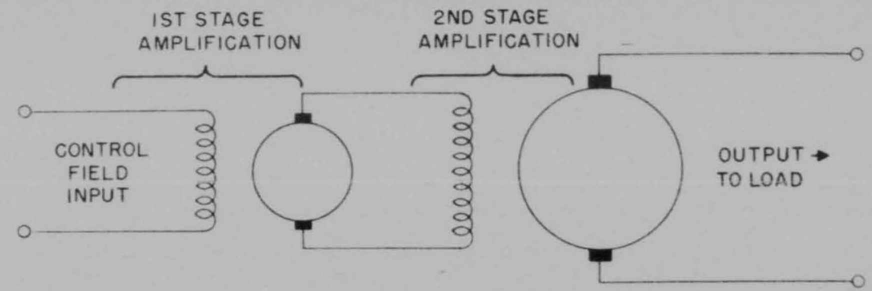

Figure 5—69. Electromechanical Amplifier.

position of the "data out" rotor, whereby this system is in electrical equilibrium as just described. Any angular displacement of the "data in" rotor will be exactly and instantly reflected by the "data out" rotor to keep this system in equilibrium. If the "data out" rotor should become restrained, heavy electrical stresses and currents would be set up in both the generator and receiver stator windings.

Another interesting and useful phenomena of the Selsyn system is that if the power connections, R_1 and R_2 of the "data out" Selsyn rotor, were removed and a common-voltage measuring device such as a voltmeter were placed across these two terminals, then any angular displacement would be shown as a voltage having its phase relations to the line voltage as a function of the angular displacement. This voltage is known as an "error-voltage" and is very useful in many positioning devices.

4. SERVOMECHANISMS

It can be seen that if the Selsyn system is connected normally, that is with both rotors connected to the 115-volt 60-cycle power source, that accurate data will be transferred from the transmitter to the receiver. However, if any load is placed upon the receiver, it will be necessary to generate a voltage and current in the receiving Selsyns to furnish the power for carrying this load. Therefore, a new device has to be considered if the receiving system is to have a load such as a radar antenna, control mechanism for anti-aircraft guns, etc.

Any system which will take this received data and enable it to carry a heavy mechanical load is known as a "servo system" or "servo-mechanism." A simple servo system can be constructed as follows: (Figure 5-69.) The "data out" Selsyn rotor is fixed and the power connections to its rotor windings disconnected. The error-voltage explained above is matched against the line-voltage supplied to the "data in" rotor windings. These voltages are matched by a vacuum tube circuit both for phase relation and magnitude. For example, if the error-voltage is leading the line-voltage, a positive DC voltage is turned out by this electronic device. If it is lagging, a negative voltage will be turned out by the electronic device. Thus it can be seen that any angular turning of the "data in" Selsyn would be reflected by a positive or negative voltage depending on the direction of the displacement of "data in" rotor from the "data out" rotor. This DC voltage may be turned into a high torque rotary motion by the use of two generators and a motor. (Figure 5-69.) The small DC voltage from the electronic device may be fed to the field of a small electrical generator. The output from this generator may be fed to the field of a larger generator, the output of this larger generator may then be fed to a turning motor. The polarity of the final output will be in direct relation to the polarity of the input to the first generator. Thus, the polarity of the output of the electronic device which has matched the error-voltage to the line-voltage determines the direction of rotation of the final motor. In this manner, a hand wheel connected to a small Selsyn motor in a building several hundred feet from a radar antenna may activate and control the rotating of this antenna through electrical linkage.

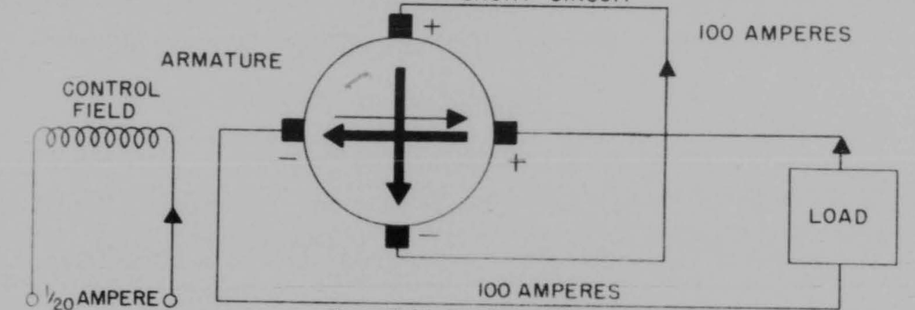

Figure 5—70. Simple Amplidyne.

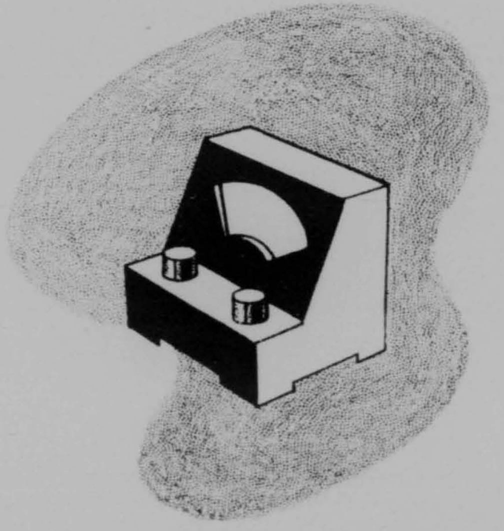
There is a device which eliminates the use of this complicated series of motors and generators to take care of this load. It is called an "amplidyne". The amplidyne consists of one drive motor and one generator. The small control field is fed to the generator in the usual manner. The output caused by this small control field is then short-circuited causing a very heavy current. (Figure 5-70.) The large magnetic field associated with this heavy current then supplies the field for other windings in the same generator. This heavy field, controlled by the light field, controls the output to a heavy load.

Often there is a requirement for a servo system that does not have to carry a heavy load such as the light, fast-moving servo systems in antiaircraft gun-laying computers and airborne gun-laying computers. These servo systems usually consist of the error-voltage from a Selsyn system being fed to a light two-phased motor. The phase comparison and the magnitude of the error-voltage determines which way the light motors turn.

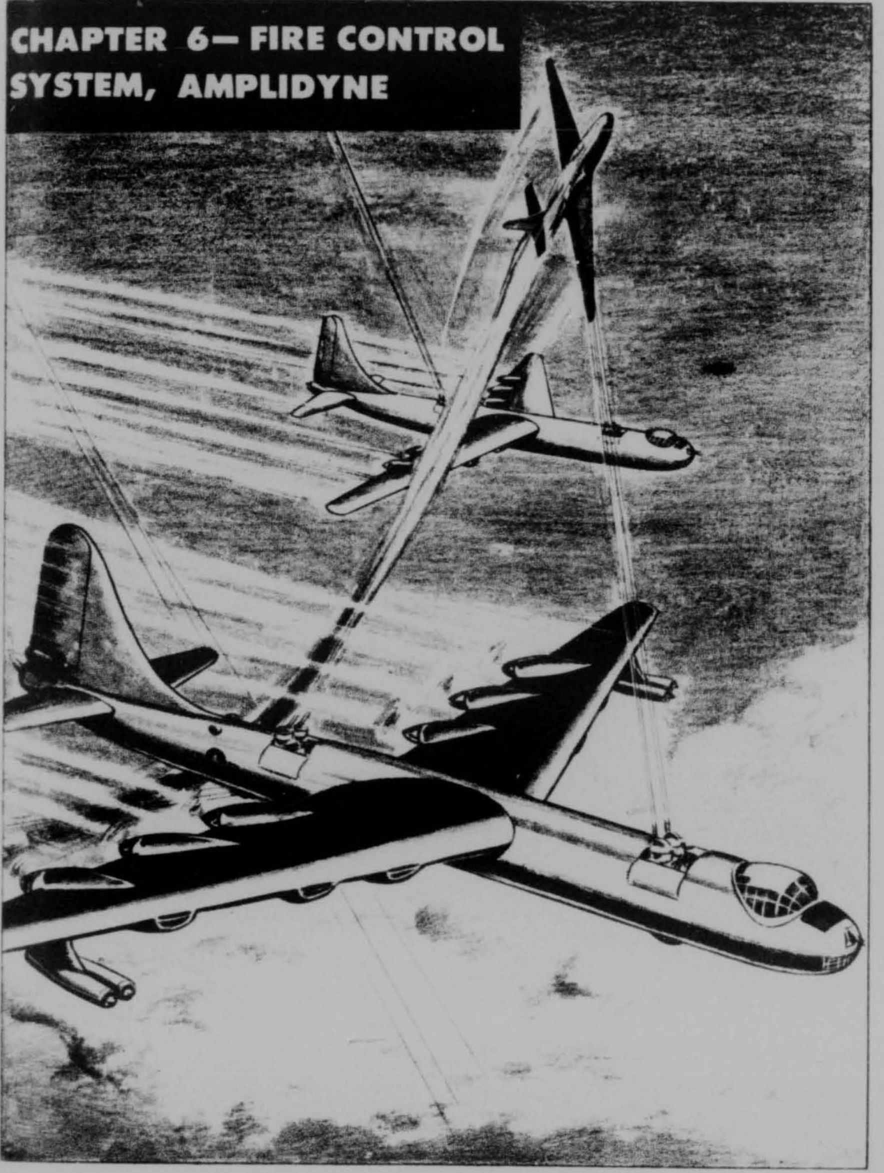
5. COMPUTERS

Computers are electromechanical devices in which voltages are made to represent distances and other data. For example, one voltage equals two hundred yards. Height of an aircraft, distance north, or distance east from a certain point, can be represented by these voltages. As the aircraft moves, the voltage representing these distances will be fed to a resistance capacity network, which will put out a voltage in proportion to the rate of change of the applied voltage. This is known as a "differentiating network." This differentiated voltage will represent speed giving a basis for calculating future points of aircrafts or other targets based on their rate of travel. Servo systems can then rotate specially wound potentiometers whose voltages vary in proportion to sine-cosine ballistic curves charts of the atmospheric effect on trajectory and parallax.

THIS PAGE IS DECLASSIFIED IAW EO 13526



CHAPTER 6— FIRE CONTROL SYSTEM, AMPLIDYNE



SECTION I—THE B-29 AND B-50 FIRE CONTROL SYSTEMS

1. INTRODUCTION

The application of armament to aircraft in combat had its origin in the first World War, when enemy flyers on observation missions were actually known to have thrown rocks at one another. Such meager and inaccurate armament gradually developed into the fixed and flexible cal. .30 machine guns which typify air movies of World War I.

This type of armament, with the pilot having two fixed forward guns and the observer having twin guns on a flexible scarf-and-ring mounting, was in use up until the last few years. Then as larger cal. .50 guns were adopted to give greater fire power and increased range, it became no longer practical for the gunner to try to maneuver the guns by hand, due to increased recoil and to the much greater wind loads developed by high speeds of modern aircraft.

2. ADVENT OF POWER-DRIVEN TURRETS

To overcome flinching of the gunners, to combat wind loads as high as 350 foot-pounds for two guns, to give increased accuracy, and to permit locating guns outside a pressure-sealed cabin, a new prime-mover was required for the guns now mounted in a turret. The earliest powering of turrets was done by the British, who developed well-engineered and accurate hydraulically-moved turrets, locally operated by gunners sitting and sighting in the turrets. These hydraulic turrets were successfully used in the Boulton-Paul "Defiant", two-place night fighter, and in such bombers as the Vickers-Armstrong "Wellington"

The first known German power turret made a belated debut, probably because of production difficulties rather than problems of design. The German policy military aviation has traditionally been one of standardization and concentration on easily produced planes, and, having early frozen their designs on non-power-driven turrets, they had been slower than expected in the utilization of this type of armament.

3. ELECTRICALLY-DRIVEN TURRETS—GENERAL

The armament applications with which this chapter is concerned are primarily defensive installations, on bombers and heavy aircraft. On these, flexible gun turrets counteract the fighter plane's advantage of speed and maneuverability. The fighter is usually a one-place plane, very fast and maneuverable, with a large array of machine guns and cameras, all fixed, pointed forward and fixed by the pilot. Several multiplace fighters, both for day and night work, have been produced. These "destroyers of the air" are heavily armed, sometimes having numerous fixed guns for the pilot as well as a remote turret which is used both offensively and defensively. An example is the Northrop P-61, a night fighter, which carries a single upper four-gun turret controlled primarily by a nose gunner for offensive use, but also controllable from an aft sighting station by a rear gunner.

4. FACTORS AFFECTING APPLICATION

The two most important factors influencing aircraft armament installations are (1) fire coverage and (2) fire power. The satisfactory solution of these two problems is imperative, as they determine more than anything else how long the aircraft will stay aloft in combat.

Fire Coverage

Every effort is made to eliminate "blind spots"—vulnerable directions from which an aircraft's guns can not shoot—because enemy pilots are surprisingly quick to discover these

areas and capitalize upon them in battle. Our early Flying Fortresses, the B-17-C's, for example, had no tail guns. The Germans and Japanese quickly found that the plane was defenseless against attack straight from the rear, and a large number were shot down because of that situation. The later model B-17's had tail gunners, and many had fine shooting until the enemy learned of the change of design. Some blind spots, such as those caused by the rudder and elevators of an aircraft, are very hard to cover. The use of a tail turret eliminates this blind area.

Fire Power

Fire power determines the amount of destruction of which the military aircraft will be capable to perform. The modern tendency, successfully advocated by the British, is to crowd as many guns as possible into the plane, and to throw as much weight of projectiles as possible into the enemy, relying on blasting him to pieces rather than hitting a few vital spots.

The guns on some British planes are now throwing over 200 pounds of projectiles a minute, and engineers are talking of rates as high as 1200 pounds per minute in the future. These high rates of fire are particularly desirable for night fighting which provides such a short time for sighting and firing.

There is, of course, a weight limit on the number of guns and the amount of ammunition a plane can carry without cutting down its bomb load, range and maneuverability. A plane must not be so heavily armed that its aerodynamic efficiency is seriously hampered and, at the same time, it must be able to defend itself successfully in the air. This balance of armament versus weight is usually the problem of the aeronautical engineer and the Air Force, but it also is a problem which affects armament products.

To achieve increased fire power without excessive increase in weight, the Air Force has utilized what is probably the best aircraft machine in the world—the cal. .50 Browning machine gun.

Still larger guns are used, such as the 37-mm (1.45" bore) cannon. The shells for this gun are so heavy that few can be carried, and the rate of fire is considerably less than the cal. .50 machine gun. Thus the "spray effect" of a machine gun is lost, and it becomes a single shot proposition, requiring accuracy and a computing sight. However, hits from this gun are highly effective against heavily armored planes, tanks, and ground fortifications.

5. PROBLEMS INVOLVED

Maneuverability

Increased number of guns per turret and larger weapons have been a prominent motivating factor in the development of the power-driven enclosed gun position. Among the early considerations for these turrets was the type of motive power which had to be accurate as well as sensitive, require little effort to operate, possesses reserve power, and be comparatively light in weight. Furthermore, it had to be capable of smooth and instantaneous variable speed from one direction of rotation to full speed in the other direction. In addition to rotation of the turret, controls had to be provided which would adjust the turret or gun mount in a vertical direction, simultaneously with an independent or horizontal motion.

Gunsights

Besides the problem of providing power to move a turret and gun mount in several directions, the designers have had to consider the problem of close installation. Since the only available and practical gunsights were mounted directly on the guns or in the line with them, the gunner required a seat which would move in coordination with the guns, enable him to keep his eye continually on the sight, allow him to maintain full control under all flying maneuvers.

Sizes

In the earliest powered turrets, installed on smaller airplanes, great difficulties were experienced because of the lack of space in the fuselage, causing serious restrictions to be placed on the turret dimensions. The gunner had his parachute packed in the seat, oxygen flasks, radio equipment, camera, interphone communication, life preserver, gun and clothing heaters, flares, all in addition to the gun mount, the guns and spare ammunition boxes. Modern turrets further require the guns be fed, not from magazines, but from continuous belts, these belts hanging from the guns, and even with the best of design they clutter up the turret. These requirements, and others, have already been met in several designs of British and American turrets.

Cutouts

One important consideration which has to be met by all turret designs for amidships positions is an efficient fire cutout or gun restrictor, which automatically stops the guns from firing when the field of fire is across the control surfaces, radio masts, or sections of the fuselage. This is done both mechanically and electrically. One cutout mechanism also incorporates a compensator for rotational speeds, which assures a minimum of cutout cover for slow operational speeds, the cutout cover being automatically increased as the speed of rotation increases.

6. PROBLEMS AFFECTING TURRET DESIGN

Tailoring Armament to Aircraft

As both fire-coverage and fire-power problems are usually decided by the USAF in cooperation with airplane designers, most of the armament manufacturer's work is concerned with tailoring armament into airplanes which are designed. The armament is built into the plane, rather than the plane being built around the armament.

Space Limitations

Aircraft, space limitations are critical, particularly on light and medium bombers, consequently the General Electric turret equipment, which is used extensively, is quite compact. The limiting feature of the horizontal diameter is the sweep of the gun butt, about which very little can be done.

Weight

Another important consideration is that of weight and its distribution. Added weight not only reduces range and maneuverability but also affects the initial position of the airplane's center of gravity which, in turn, affects the ship's handling characteristics. Aircraft companies are greatly concerned with any added weight because their planes must meet specified performance requirements, and the more weight, the more difficult is the job.

Structural Strength

Structural strength in the neighborhood of the gun emplacement must be sufficient to stand the recoil forces and the wind loads caused by addition of the guns. The average recoil force of the cal. .50 machine gun is about 1750 pounds per gun, 3500 pounds for a two-gun turret, and 7000 pounds loading for a four-gun turret, assuming synchronized firing. This is an intermittent impact load which may last for several seconds. For horizontal firing, it is sheer load in the longerons and frames. For up or down firing, it constitutes a compressive load. This great stress must be properly distributed to the bulkheads.

Torques

Wind loads cause torques tending to rotate the guns and produce torsional stresses on the supporting members. It is important, for accuracy of fire, that the structural stiffness be sufficient to hold the guns rigid against this torque, which may be higher than 350 foot pounds for two guns.

Muzzle Blast

The discharge of gases from the gun barrel, known as "muzzle blast", may be very violent and injurious to the thin metal "skin" of the plane near the muzzle. Every General Electric turret installation has required some protection against muzzle blast. This can be obtained by means of a sheet of sponge rubber cemented to the airplane's skin with a sheet of .015" stainless steel over it, a device which has proved to be effective in the prevention of denting and burning of the skin and the tearing up of rivets.

Rigidity

An important factor in the accuracy of a remote-control turret is the rigidity of the aircraft structure between the sight and guns. Twisting motion of the structure due to motion of the rudder, bending loads from the elevators, and roughness of the air, all cause structural weave and lack of correspondence between the sight and the gun. Sometimes a permanent set gets into the structure and spoils an installation alignment. It is best, of course, to have the sight and guns located as near to each other as possible. On some airplanes such as the B-29, however, they will be about forty feet apart.

Protection

Ease of protecting personnel and accessory equipment must be considered. Pilots and other personnel on the plane usually have some armor protection but, as yet most armament equipment has no protection. It would be highly desirable to armor the vital spots of such systems, such as junction boxes and servo-amplifiers, but always the problem of weight must be considered.

Maneuver Loadings

The location of turret equipment is influenced by maneuver loadings, or the tremendous forces of acceleration in places remote from the center of gravity, such as the tail.

7. PRESSURIZATION

Pressurization of planes for high-altitude flying brings in many more complications. It is quite difficult to maintain pressure in an ordinary plane, but when we mount flexible guns on a ship, making holes in its skin, we are faced with exceedingly complex problems of pressurization. The gun stations must be sealed, which is easier to do with a remotely controlled emplacement than with a locally handled turret.

8. EFFECTS OF USE FOR WHICH AIRPLANE IS INTENDED

The intended tactical use of the plane is another important consideration in engineering turret equipment. Air speed affects drag, wind loads, and the range of the computer. Altitude also affects wind loads; causes poor motor commutation; makes the brushes wear rapidly, as much as 1/4 inch an hour due to a dessicating effect; makes lubrication difficult because of the stiffening of any oil in low temperature; reduces the cooling of rotating equipment due to the decreases in weight of air flow; makes the opening of the turrets liable to freezing; and necessitates heating the turret. This heating is necessary to keep the ammunition at its maximum power and is a problem which is not yet known to be solved.

9. PERFORMANCE SPECIFICATIONS FOR TURRETS

The power supply for the turrets must be adequate to provide the necessary turret velocities and accelerations. From British data, the optimum motions are velocities of 45 degrees per second in azimuth and 30 degrees per second in elevation, and accelerations of 90 degrees per second^2 in azimuth and 60 degrees per second^2 in elevation. Turret systems now in use are still retaining approximately the same velocities and accelerations. In addition to these values, the instantaneous peak demands, which occur when the guns are accelerated at their maximum rates from position at right angles to the line of flight at maximum speed of the plane, also depends upon the degree of synchronization required (the rapidity with which the guns must follow the sight).

10. GUN INSTALLATION TYPES

There are several types of armament systems, or gun installations for military aircraft, each with advantages peculiar to itself. These advantages usually determine the selection of a certain type of armament for a particular airplane. The following are the types of armament systems which are used:

Fixed Mounts

The guns are mounted in fixed positions of the airplane. (Figure 6-1.) The pilot maneuvers the plane in order to aim the guns.

THIS PAGE IS DECLASSIFIED IAW EO 13526

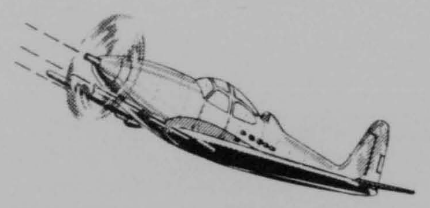


Figure 6—1. Flexible Mount.

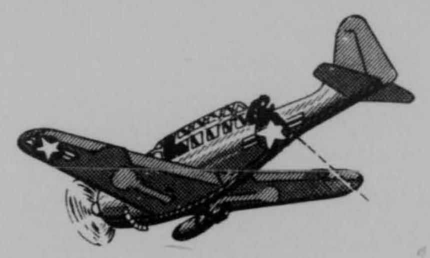

Figure 6—3. Flexible Mount—Power Drive.

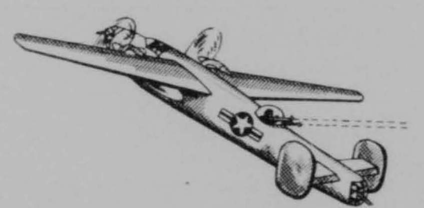

Figure 6—2. Flexible Mount—Manual Drive.

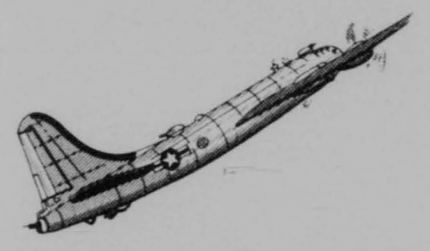

Figure 6—4. Turret Positions.

Flexible Mounts—Manual Drive

The airplane (see figure 6-2) has a flexible mount for the gun. The gunner can move the gun, making it possible for him to aim without maneuvering the airplane into position as in fixed mounts. In this installation, the force required to move the gun is supplied by the gunner himself.

Flexible Mounts—Power Drive

The airplane carries a power-driven gun turret. (Figure 6-3.) The gunner, located in the turret, aims the guns by controlling the electrical or mechanical power which drives the turret.

Central-station Fire-control System

The central-station fire-control system is one in which the gunner is located apart from the gun turret or turrets. In the illustration (Figure 6-4) which is simply to show the principle of a turret located at a point remote from its sight, the gunner's post and the sight are in the forward "blister" above the wings, while the turret which mounts the guns can be seen back toward the tail. The gunner manually aims the sight at the target, and through power control, the guns are also made to point at the same target.

11. ADVANTAGES OF REMOTELY CONTROLLED TURRETS

Position of Gunner

It is this system, central-station fire-control, that is to be discussed. With it, the gunner and his sights can be located at that part of the plane which suits his purpose best, that is, where he has a maximum area of vision, where he can be protected by armor, and where he can be relatively comfortable. This last point is of considerable importance, since a gunner loses efficiency if forced to sit or lie in a cramped position for long periods of time.

Position of Guns

Guns, on the other hand, can be located at the part of the plane where they can operate

most effectively i.e., where their field of fire coverage is greatest.

Remote Control

In some installations, one gunner can control two or more turrets thus increasing effective fire power. Because undesirable compromises need not be made in locating gunners and turrets, over-all design of the plane can often be improved. For example, the gunner can be located in the pressurized part of the ship, and the guns outside this area. The amount of pressurized space required can, therefore, be reduced and the turrets can be given a more "streamlined" shape.

12. DEVELOPMENT

General

It has been stated that the two most important factors in aircraft armament applications are (1) fire coverage and (2) fire power.

General Electric Turret

The first General Electric remote-controlled turret was a purely experimental installation on a Douglas A-20 consisting of a two-gun upper and a two-gun lower turret, both mounting cal. .50 machine guns, and both controlled by one double-ended periscopic sight, as shown in Figure 6-5. The area around the upper end of the periscopic sight was covered with Plexiglas. The front of the plane was protected by its fixed forward guns. The rear, protected by the turret guns, had several weak points:

While scanning in the upper hemisphere visibility was good because of the Plexiglas, for the lower hemisphere, only the 25-degree cone of vision was available and this provided an insufficient field of view.

Firing in the upper hemisphere was restricted by the large vertical area blocked out by the fin and rudder. To overcome this, Douglas installed a "tell-tale", or fluorescent indicating screen by the pilot, which shows him when the turrets are aiming at any planes in his blind spots aft.

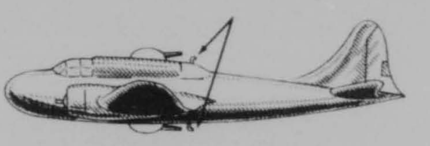

Figure 6—5. Remote Controlled Turret.

Value of General Electric Turret

This installation, though having its faults, served its purpose in developing the factors to be reckoned with in turret construction. It also served to demonstrate to the Army, on actual flight firing tests, just how practical the remote controlled turret might be.

13. PLANNED PRODUCTION

At the present time, remote-control turret systems are being produced for the following planes: The Douglas B-26 (formerly the A-26), and not to be confused with the wartime Martin B-26 light bomber, the Boeing B-29 medium bomber, the Boeing B-50 medium bomber, the Boeing B-45 heavy bomber, the North American B-47 heavy bomber, the Consolidated B-49 flying wing, the Consolidated B-36 very heavy bomber, and the Northrop F-61 night fighter.

Douglas B-26 Light (Attack) Bomber

The Douglas B-26 is a cleaned up and enlarged version of the A-20. Its primary function as an attack plane is low-altitude bombing, strafing, and fighting. The B-26 mounts a two-gun upper and a two-gun lower turret, both controlled by a double-ended periscopic sight with a rotating eyepiece. The upper turret covers the upper hemisphere except for the area interrupted by the tail surfaces, and gives an extra 5 degrees of down fire in the broadside position. The lower turret covers the lower hemisphere except where interrupted by the body of the plane, and gives a 5-degree upfire at the sides. Thus a broadside target can be tracked through the two hemispheres with overlapping fire from both turrets at the horizontal. The upper head of the periscopic sight tracks a target from the zenith down to 10-degrees below the horizontal, where the line

THIS PAGE IS DECLASSIFIED IAW EO 13526

of sight is switched to the lower head. The lower head follows on down to the nadir. On up-tracking, the lower head carries to 10-degrees above the horizontal before the changeover to the upper head occurs. This overlap of the sight hemisphere is to preclude frequent switching from one head to the other in cases of tracking near the horizontal. The field of view of each head has been increased to a cone of 50-degrees, a much more adequate field for scanning and tracking. Scanning in the upper hemisphere can also be done through the Plexiglas windows around the gunner's head. In addition to these four flexible cal. .50 guns, the B-26 will have fixed wing guns for offensive use, and the upper turret may be latched in a strafing position straight forward and fixed by the pilot. This arrangement of armament provides the B-26 with offensive striking power. At the same time the turrets provide sufficient defensive fire power and coverage such that with the plane's speed and maneuverability fighter protection should seldom be necessary.

Boeing B-29 Bomber

The B-29, the Air Forces medium bomber is an aircraft weighing over 100,000 pounds, with 8800 hp., a cruising range of 6,000 miles, and a bomb load of 10,000 pounds. It is a pressurized plane for high-altitude flying. The B-29 mounts five turrets: the upper four-gun turret in the forward section, the upper aft two-gun turret, the lower forward two gun turret, the lower forward two gun turret, the lower aft two gun turret, and the tail turret (mount) which contains two cal. .50 machine guns. On the B-29 airplane, there are five sighting stations located so as to afford the maximum unobstructed view on all sides of the airplane. A "sighting station," as the term is used in this book, refers to the actual sighting equipment, i.e., the sight and accessory equipment used by a gunner in tracking a target and in operating remotely located gun turrets. More specifically, a sighting station comprises a sight, a means of moving the sight in azimuth and elevation, a means of indicating to a gun turret the precise direction in which the sight is pointing, and a means of transmitting to the computing system variations in range and lead.

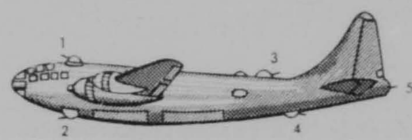

Figure 6–6. Douglas A-26 Attack Bomber.

As can be seen in Figure 6-6, the five sighting stations on the B-29 airplane are located as follows:

One on the upper structure of the ship, forward of the upper-rear turret, called the "ring sighting station."

One in the tail of the ship called the "tail sighting station."

Two located in blisters (one on each side of the ship) just forward of the rear gun turrets, and called the "right-blister sighting station" and the "left-blister sighting station," respectively.

One in the nose of the ship, called the "nose-sighting station."

The B-50 fire-control system is identical to that of the B-29.

14. THE FOLLOW UP SYSTEM

Introduction

The operation of a turret from a remotely located sighting station requires a control system in which the motion of the sight is duplicated by the turret guns. This control system is referred to as the "follow-up system," and is described in the paragraph below. In addition to the follow-up system, the complete central-station fire-control system requires auxiliary circuits such as starting circuits for the rotating machines, limit-switch circuits, backout circuits, firing circuits, transfer circuits, etc. Those circuits are as important as the follow-up system, and hence a few of them are discussed in publications dealing with specific airplanes.

Principles of Operation

One-speed system. While positioning of the

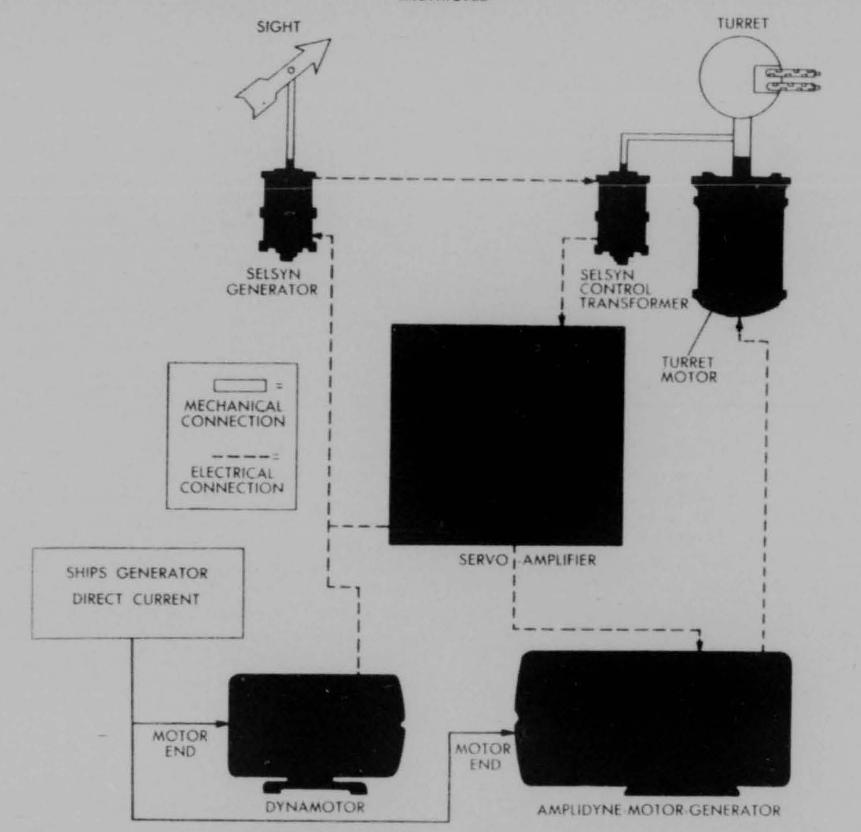

Figure 6–7. Rotor of Selsyn Generator.

gun requires control of motions in azimuth and elevation, the follow-up system is the same for both motions and, therefore, only one motion, azimuth, is discussed. The following paragraph presents a nontechnical version of the operation of the follow-up system.

In Figure 6-7, the rotor of a Selsyn generator is geared to the azimuth motion of the sight. This generator is a small electric device having windings on its rotor and stator. Geared to the azimuth motion of the turret is a Selsyn control transformer, which is similar, but not identical to the Selsyn generator. The Selsyn generator is supplied with alternating current from a small motor-generator

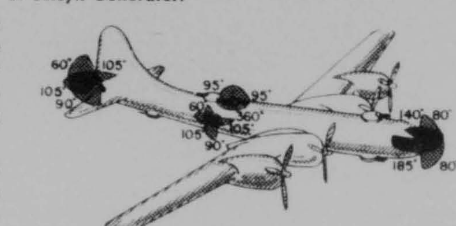

Figure 6–8. Five Sighting Stations on B-29.

set (dynamotor) and is electrically connected to the Selsyn control transformer. When so connected, the Selsyn generator transmits electrically the azimuth position of the sight

THIS PAGE IS DECLASSIFIED IAW EO 13526

to the Selsyn control transformer. The Selsyn control transformer, in turn, compares the azimuth position of the sight with the azimuth position of the turret to which it is geared. If any difference in position exists, an "error signal" appears across the terminals of the signal transformer. This "error signal" is then fed into a vacuum-tube amplifier (servo-amplifier), where it is converted into a signal capable of controlling the output of a DC generator (amplidyne generator). The output of this amplidyne generator as controlled by the signal from the servo-amplifier is fed into the turret-drive motor, causing the motor to drive the turret and the rotor of the Selsyn control transformer toward alignment with the sight. When the turret comes into alignment, the "error signal" across the signal transformer will disappear, and the output of the amplidyne generator will go to zero, allowing the turret to come to rest, aligned with the sight.

Component Parts

Power Supply. The primary source of power for the turret system and all other electric equipment is the aircraft generator, which is driven directly by the aircraft engine. The aircraft generator, and associated battery, supply the airplane with a constant source of approximately 28-volts DC.

Dynamotor. The Selsyn and the servo-amplifier used in this system require a source of alternating current. Some means of converting the direct-current power of the airplane into alternating current is necessary. The most practical way to supply the required alternating current is by use of a dynamotor, which is nothing more than a motor-generator set.

Selsyn Generator. The function of the Selsyn generator, which is coupled mechanically to the sight, is to transmit electrically the position of its rotor with respect to its stator. The rotor consists of a single-coil winding excited from the AC power supplied by the dynamotor. The stator consists of a winding so arranged that it produces an output signal which transmits to the Selsyn control transformer the position of the Selsyn generator rotor.

Selsyn Control Transformer. The function of the Selsyn control transformer is to receive an electrical signal which indicates the position of the Selsyn generator rotor and to compare the position of this generator rotor with the position of its own rotor. The Selsyn control transformer is similar in external appearance to the Selsyn generator, but its internal construction is slightly different, and they are not interchangeable.

Servo-amplifier. The "error signal" from the rotor of the control transformer is a low-power AC signal. This signal is fed into a vacuum-tube amplifier, called the servo-amplifier, which rectifies, amplifies it, and feeds it into the control field of the amplidyne generator.

Amplidyne Motor-generator. The amplidyne motor-generator consists of a DC shunt motor built on the same shaft with an amplidyne generator. The motor is energized from the airplane's power supply. The amplidyne generator is similar in operation to an ordinary DC generator, with the exception of two features: In the amplidyne generator, the output voltage builds up to its final value in a very short time, and a very small field current of only a few milliamperes, is required to produce full voltage.

Turret-drive Motor. Since the turret must be capable of rotation in either direction, i.e., clockwise or counterclockwise, the motor which drives the turret must likewise be capable of rotation in either direction. A separately excited DC motor is used because the direction of rotation can easily be reversed. With the field of the turret motor excited from the airplane's 28-volt power supply, the direction of rotation of the turret will depend upon the polarity of the output voltage of the amplidyne which is supplied to the armature of the motor. Another feature of the separately excited motor is that it has a high starting torque with relatively small armature currents.

The Two-signal System

Selsyn generators differential generators, and control transformer Selsyns are subject to a small electrical error due to manufacturing irregularities in the windings and in the

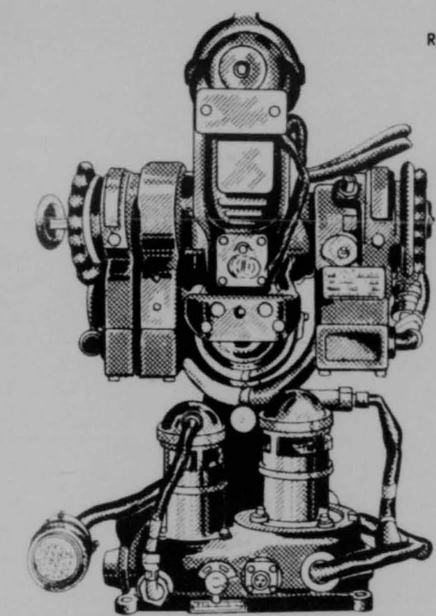

Figure 6–9. Pedestal-Type Sighting Unit Model 2CSR3B5.

magnetic structure. To obtain the high degree of accuracy desired, it is common practice to use Selsyns which are geared to rotate at speeds higher than those of the turret or sighting stations. A Selsyn is sometimes not more accurate than one-half of a degree. Such an error, of course, is too large to be tolerated in a gun-sighting system. To avoid this, two sets of Selsyns are used, each set consisting of a generator Selsyn and a control transformer Selsyn are used to control each motion. In the turret follow-up system, a one-speed Selsyn system and a 31-speed Selsyn system is used. The Selsyns in this 31-speed system are geared to rotate at 31 times the speed of the sight and turret to which they are mechanically coupled. The one-speed Selsyns are geared so that the rotors of the generators and control transformer Selsyns make one revolution for each revolution of the turret and sighting station. The system is so arranged, that, for large sight-and-turret misalignment, the one-speed Selsyn takes control and causes the turret-drive motor to drive the turret to within approximately 3-degrees of alignment with the sight. The 31-speed Selsyn system then takes control automatically, and drives the turret until the 31-speed Selsyn rotors are in correspondence. Thus, an error of ½ degree in the Selsyn system represents an actual gun alignment error of only 1/62 degree at the turret, and reduces the amount of error which would be expected from the simple one-speed system. It is, of course, possible to utilize a one-signal, 31-speed system, but when a 31-speed control is used, there are 31 positions of the turret for which the Selsyn system may indicate electrical correspondence. At only one of these 31 positions of electrical correspondence would the sight be in alignment with the turret. It is to avoid this effect that a two-signal system is used.

15. SIGHTING STATIONS

General

There are several types of sighting stations used with the central-station fire-control system. The basic operating principle of each is exactly the same. A sighting station comprises a sight, a means of indicating to a gun turret the precise direction in which the sight is pointing and a means of transmitting to the computing system variations in range and lead. On the B-29 airplane there are two types of sighting stations, ring and pedestal, located so as to afford the maximum unobstructed view on all sides of the airplane. (Figure 6-8.) The five sighting stations are well located to provide the best possible coverage from any particular gunner's station.

Retiflector Sights

In the case of the B-29 airplane, each sighting station has as one of its major parts a retiflector sight, the purpose of which is to frame the target and at the same time send a range prediction to the computer. Each sighting station on the B-29 is moved manually in azimuth and elevation by the gunner. The Selsyn system provides the means of indicating the position of the sight to the turret.

16. COMPONENTS

The first sighting station to be covered is the pedestal type (Figure 6-9), of which there are four on the B-29. Each pedestal-type sighting station is made up of four major assemblies, namely: the azimuth assembly, the elevation assembly, the retiflector sight assembly, and the gyro and support assembly. (Figure 6-11.)

17. DETAILED DESCRIPTION: THE AZIMUTH ASSEMBLY

Function

The azimuth assembly (Figure 6-10) actually forms the base for the pedestal-type sighting station. However, it also transmits signal voltages from Selsyn generators on the sighting station, through the computer to the azimuth-Selsyn control transformers on the turret or turrets. These signal voltages indicate the exact position of the sight in azimuth.

Major Parts

The major parts of this assembly are two Selsyn generators (a one-speed unit and a 31-speed unit); two gear trains, one for each Selsyn generator; and a cast-aluminum-alloy gear housing. The Selsyn units mount on the gear housing which also supports (by means of a shaft, or vertically-extended bearing support) the yoke of the elevation assembly. Also located on the gear housing are the computer-standby switch, the azimuth stowing pin, the azimuth-limit stops, the reticle-adjustment rheostat, and the azimuth-friction screw.

The 31-speed Selsyn unit is mounted in the following manner: its flanged end shield (on the shaft end) fits snugly into a rabbeted recess in the top of the gear housing. It is held securely in place by three clamps. The clamps, which fit over the edge of the Selsyn's flanged end shield, are held by three lock washers and screws which fit into tapped holes in the gear housing. (Figure 6-12.)

The one-speed Selsyn is attached to a mounting plate by similar clamp and screw assemblies. The plate is held in place on top of the gear housing by four safety-wired screws.

Gear Trains. (Figures 6-11 and 6-12.) An input spur gear on the end of the yoke shaft meshes with an identical spur gear attached to the rotor of the one-speed Selsyn generator.

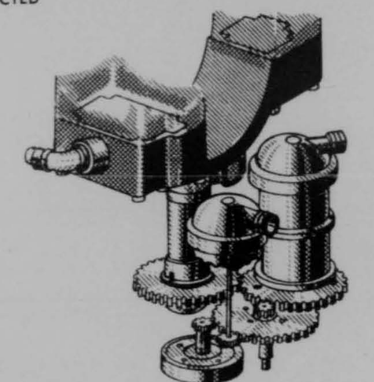

Figure 6-10. Azimuth Selsyn Gearing. Model 2CSR3B5.

Thus, as the yoke is rotated in azimuth, the rotor of the one-speed Selsyn unit makes one full revolution for every full revolution of the yoke. At the same time, the spur gear on the rotor shaft of the one-speed Selsyn serves to drive the gear train for the 31-speed Selsyn generator. This is acomplished in the following manner. The one-speed Selsyn spur gear engages a pinion on a sha. which also carries an intermediate spur gear. In turn, the intermediate spur gear meshes with a pinion on the rotor of the 31-speed Selsyn generator. A bearing plate supports the inertia-wheel shaft and pinion as well as the shaft which carries the intermediate spur gear. The gear ratio of the train is such that the rotor of the 31-speed Selsyn generator will make 31 complete revolutions for each 360-degree rotation of the yoke. The intermediate spur gear also drives a pinion whose shaft carries an inertia wheel. The "flywheel action" of this inertia wheel tends to smooth out the movement of the movement of the sighting station as it is rotated in azimuth but is designed to allow quick starts or stops. Ball-bearing assemblies assure freedom of rotation for all shafting used in the gear train.

Computer-Standby Switch

(Figure 6-12.) This is a luminous toggle-type switch which is mounted on the front of the azimuth-Selsyn gear housing. Nameplates identify it clearly and show the "in" position. The switch serves as a means of allowing the

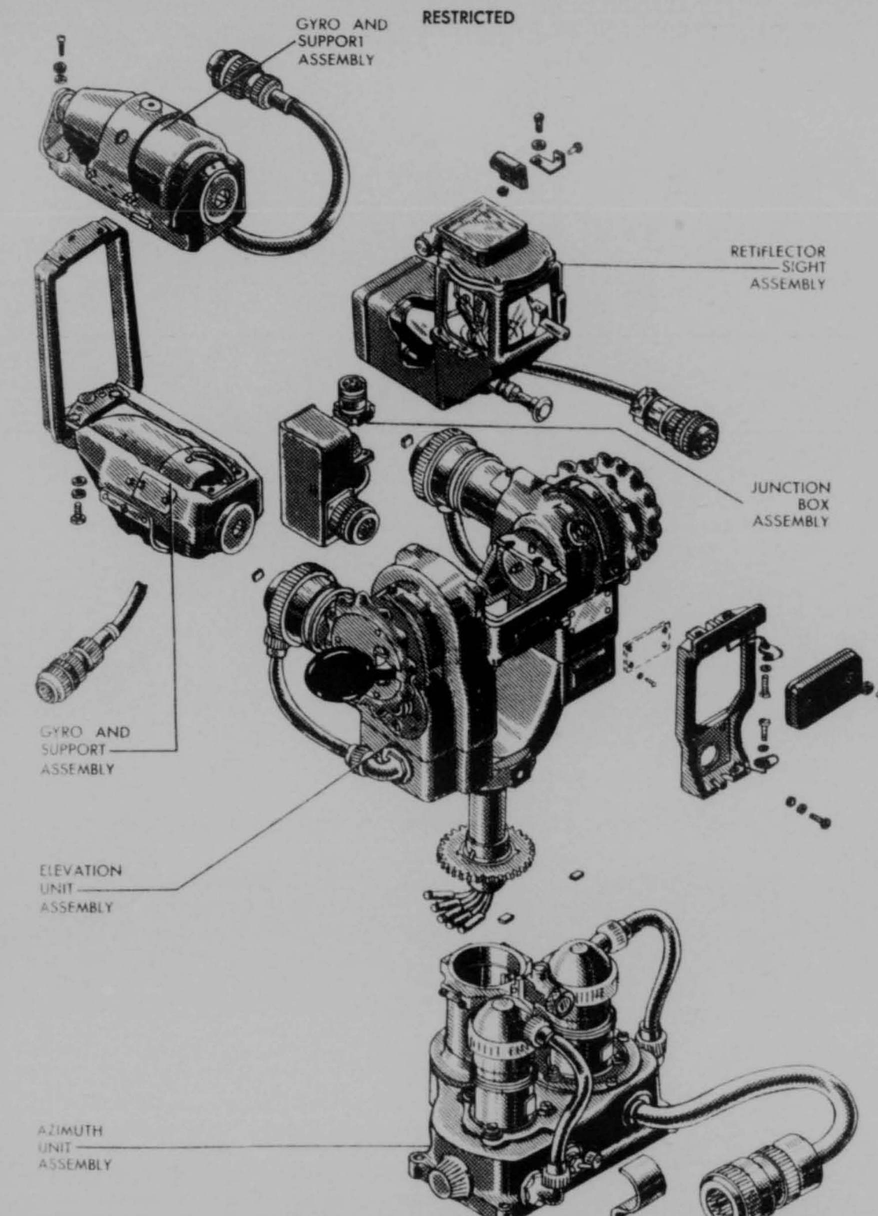

Figure 6-11. Major Parts of Pedestal Sight.

THIS PAGE IS DECLASSIFIED IAW EO 13526

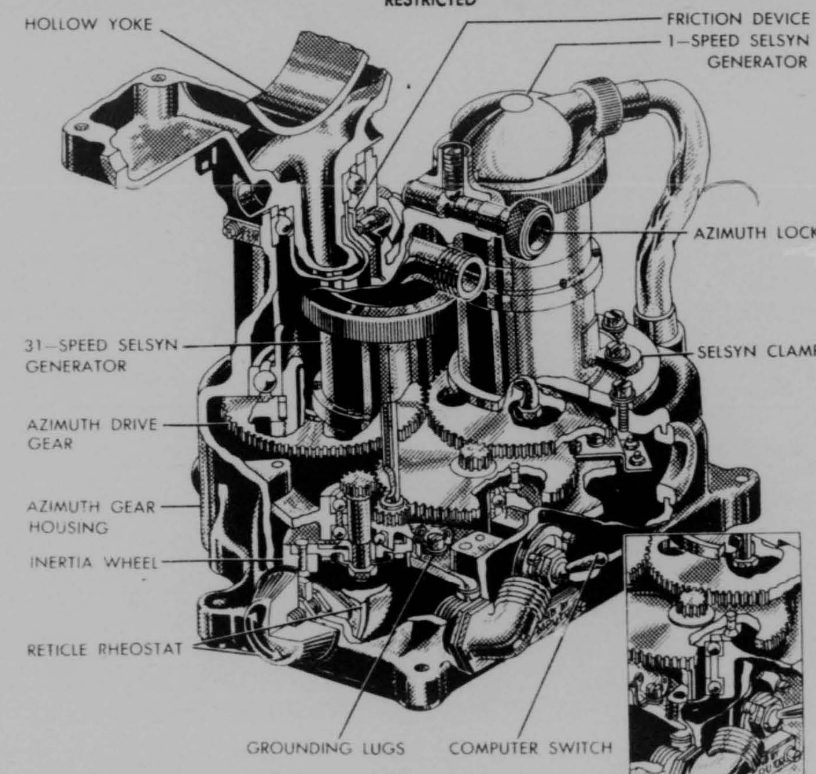

Figure 6—12. Cutaway View Azimuth Assembly Showing Gears, Shafts, etc.

Selsyn signal from the sight to by-pass the computer and go directly to the Selsyn control transformers on the turret. This switch could be used to make the system non-computing should the computer be damaged by gunfire.

Azimuth Stowing Pin

This assembly, (Figure 6-12) which is used to stow the sighting station in any one of three positions in azimuth, is located between the two Selsyn units on the front of the bearing support for the yoke. A ball, spring, and limit-screw assembly is used to hold the pin in its "out" or "in" position.

Limit Stops

The stops which limit rotation of the sighting station in azimuth are located on the same portion of the casting that houses the stow-pin assembly. Two metal clamps, one on either side (and to the rear) of the stow-pin assembly, carry rubber snubbers which engage ears on the yoke and thus stop rotation on the sight in azimuth when it has reached its limits of travel.

Reticle-adjustment Rheostat

(Figure 6-12.) This is located on the left-hand side of the gear-housing casting and is used for increasing or decreasing the brightness of the reticle image. The adjustment is made by means of a black composition knob, clearly marked with a white arrow and the words "on" and "off."

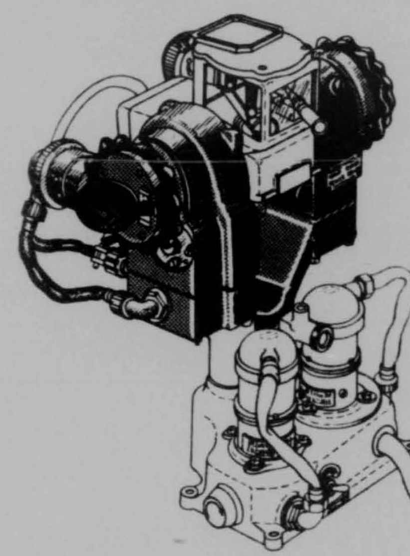

Figure 6—13. Elevation Assembly Pedestal Sight.

18. THE ELEVATION ASSEMBLY

Function

The function of this assembly (Figure 6-13) is to mount the retiflector sight and serve as a means for permitting movement of the sight in elevation. The elevation-Selsyn-generators, also located on the assembly, transmit signal voltages from the sighting station, through the computer to the elevation-Selsyn control transformers on the turret, or turrets, controlled by the sighting station. These signal voltages, indicate the exact position of the sight in elevation.

Major Parts

The major parts of the elevation-Selsyn-generator assembly are: two Selsyn generators (a one-speed unit and a 31-speed unit); two handwheels by means of which the gunner moves the sight in elevation; two gear trains for connecting the rotors of the Selsyns with the handwheels; a main yoke which carries the entire elevation-Selsyn-generator assembly; a yoke for supporting the retiflector sight; two gear boxes which mount on the main yoke; house the gear trains, and mount the Selsyn units; two triggers for firing the guns; an action switch and a range handle which are carried on the left and right handwheels respectively; two gyroscopes (not shown) which mount above and below the retiflector sight, respectively; an elevation-friction screw, which is located on the right-hand gear box; and an elevation stow pin located in the rear of the sight on the right-hand side of the main yoke.

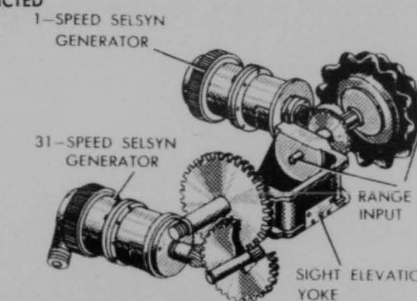

Figure 6—14. Schematic Drawing Showing 1 and 31-Speed Elevation Selsyn Drive Gearing and Range Input, etc.

Selsyn-generator Units. The elevation-Selsyn generators are identical in construction to those used on the ring-type sighting station. The only difference lies in their zero position with respect to the sighting station. The 31-speed Selsyn is mounted on the rear of the left-hand gear box (as the gunner looks into the retiflector sight) in the following manner: the shaft end of the Selsyn fits into a rabbeted recess in the gear-box casting and is held in place by three clamps, lock-washers and screws. The one-speed Selsyn generator is attached to the right-hand gear box in the same manner as the 31-speed Selsyn. Electrical connections to both of these Selsyns are made through Selsyn caps, which screw onto the Selsyn generators.

31-speed Selsyn Gear Train. This assembly (Figures 6-14 and 6-15) is housed in the left-hand gear box (as the gunner looks into the retiflector sight) and connects the left handwheel with the rotor of the 31-speed Selsyn generator. This is accomplished in the following manner. The left handwheel is mounted on the end of a hollow drive shaft, supported at either end by ball-bearing assemblies

THIS PAGE IS DECLASSIFIED IAW EO 13526

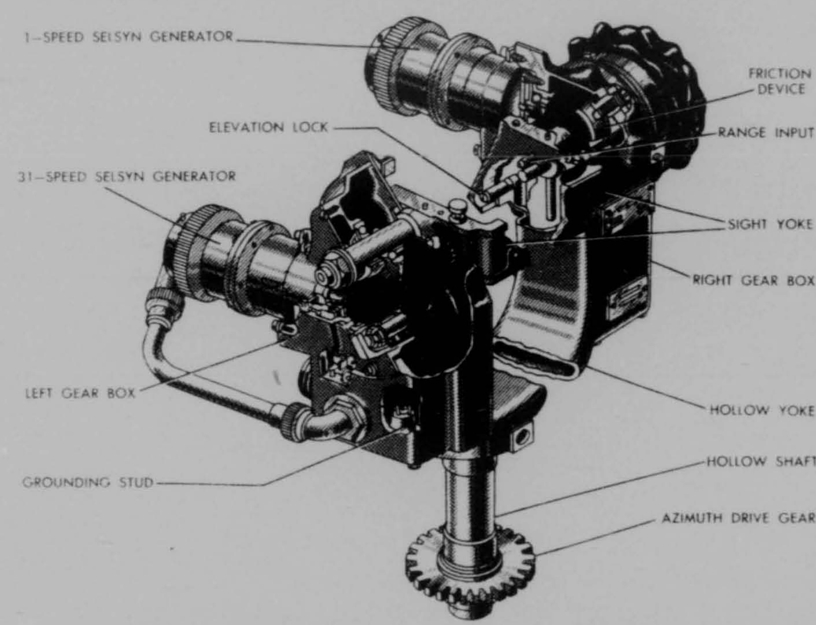

Figure 6—15. Cutaway View of Elevation Assembly Showing Drive Gearing Shafts and Bearings.

which, in turn, fit into opposite sides of the gear box. The end of this shaft opposite to the handwheel attaches to the yoke which carries the retiflector sight. Thus, as the gunner rotates the handwheel, the sight yoke (and, therefore, the retiflector sight) is raised or depressed. Inside the gear box, a large spur gear attached to the hollow drive shaft, engages a pinion on an intermediate shaft-and-gear assembly. Also mounted on this intermediate shaft is a large bevel gear which meshes with a small bevel gear on a short shaft which drives the rotor of the 31-speed Selsyn by means of a simple coupling. Thus, as the gunner elevates or depresses the sight, the gear train turns the rotor of the 31-speed Selsyn. The gear ratio of this train is such that the rotor of the 31-speed Selsyn generator makes 31 complete revolutions for each single revolution of the handwheel. Ball-bearing assemblies provide freedom of rotation for the gear shafts.

One-speed Selsyn Gear Train. (Figures 6-14 and 6-15.) As in the case of the left handwheel, the right handwheel is also mounted on a hollow shaft supported by a ball-bearing assembly which fits into a recess in the side wall of the right-hand gear box. In this case, also, the shaft extends through the side wall of the gear housing and is part of the sight yoke. Thus, the gunner can rotate this handwheel and elevate or depress the retiflector sight. Inside the gear box, the hollow shaft mounts a large bevel gear which engages directly with an identical bevel gear mounted on one end of a shaft, the other end of which carries a simple coupling. The coupling connects with the rotor of the one-speed Selsyn. Thus, because both bevel gears are identical, one complete revolution of the handwheel will cause one complete revolution of the rotor of the one-speed Selsyn.

The Main Yoke. (Figures 6-10 and 6-15.) This is a hollow Y-shaped yoke whose single

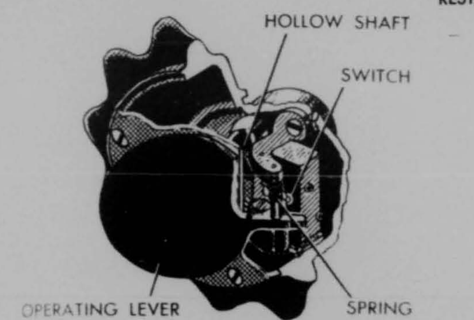

Figure 6—16. Cutaway View of Action Switch Mechanism.

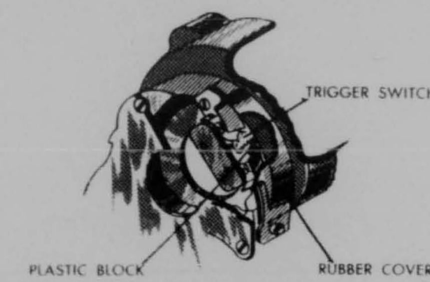

Figure 6—18. Cutaway View of Left Trigger Switch.

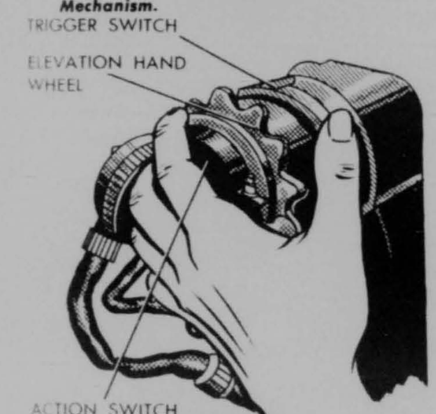

Figure 6—17. Left Hand in Place on Elevation Handwheel and Action Switch.

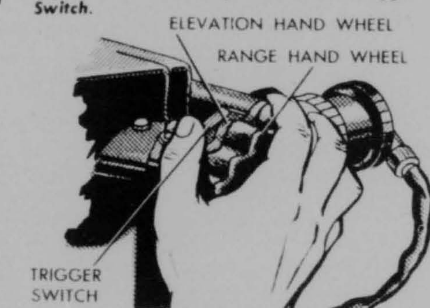

Figure 6—19. Right Hand in Place on Elevation Handwheel and Range Input Handwheel.

(lower) end is a hollow shaft which fits into the extending bearing support on the azimuth assembly. The spur gear, keyed to its lower end, engages the gear train of the azimuth-Selsyn-generator assembly so that when the yoke is rotated the azimuth gear train is set in motion. The yoke, itself, is an aluminum-alloy casting which mounts on its arms two gear boxes which carry the elevation-Selsyn generators. The wiring for the electrical units, supported by the yoke, is brought into the elevation assembly through the yoke's hollow shaft and hollow arms.

The Sight Yoke. The sight yoke (Figures 6-13 and 6-15) used to mount the sight is also a U-shaped aluminum-alloy casting. This yoke pivots between the arms of the main yoke and is supported (with the bottom of the U towards the gunner) by the two drive shafts from the right and left handwheels. Two pins on the sight-mounting surface assure proper alignment of the sight. The front of the yoke is drilled and tapped to support a front bracket which, in turn, supports one end of both gyroscope units. The mounting surface for the front bracket has two pins to assure proper alignment of the bracket and hence the gyroscopes. Mounted on the sight yoke are the stops which limit the travel of the sight in elevation. A hole in the rear-right arm of the sight yoke engages the elevation-stow pin by which the sight is stowed.

Action Switch. (Figures 6-16 and 6-17.) This disk-like switch is mounted on the left handwheel. It is held in normally open position by a spring assembly. When the gunner closes it by pressing it with his palm, (if the control box switches are properly positioned) the guns on the turret will swing into alignment with the gunner's line of sight. Wiring

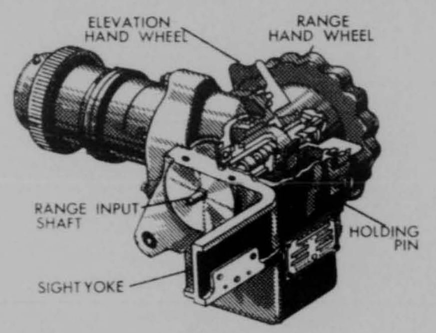

Figure 6—20. Cutaway View of Range Input Mechanism.

for the action switch is brought into the elevation assembly through the hollow yoke and reaches the action switch through the hollow drive shaft carrying the left handwheel. A slot in this drive shaft permits entry of the wiring and the fact that the sight can only be rotated a total of 150 degrees in elevation prevents undue twisting of the wiring.

Firing Triggers. (Figures 6-18 and 6-19.) The two firing triggers are mounted on the front of the right- and left-hand gear boxes in a convenient position for the gunner to press them with his thumbs. Pressure on either trigger will actuate a relay which, in turn, closes the firing circuit to the guns and, provided the gun switch on the control box is in the "fire" position, the guns will immediately begin to fire.

Range Handle. This handle is similar in contour to the right handwheel on which it is mounted. As shown in Figure 6-20, the range handle is mounted on a grooved shaft which extends through the hollow drive shaft of the one-speed-Selsyn-generator assembly and connects with the retiflector sight's gear train. The range handle is held in place by a spring-actuated pin, engaging grooves in the shaft.

Elevation-friction Screw. (Figure 6-15.) This device, which is the means by which the gunner adjusts the sighting station for freedom of movement in elevation, is located on the front of the right-hand gear-box casting. Tightening or loosening of the screw increases or decreases pressure on a metal shoe with felt liner which rides on the drive shaft rotated by the right handwheel. A lock nut

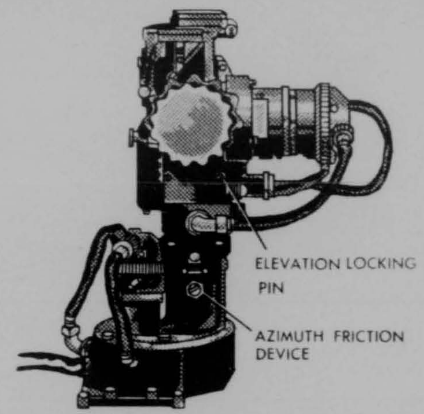

Figure 6—21. Right Hand Side of Pedestal Sight Unit Showing Elevation Locking Pin, Azimuth Friction Device.

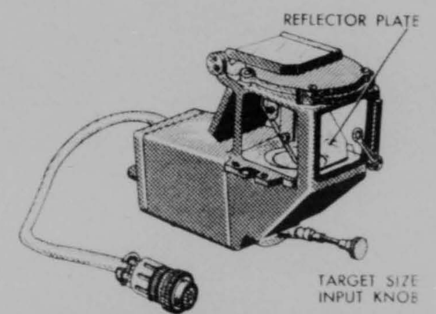

Figure 6—22. Retiflector Sight Mounted on Pedestal Sighting Unit.

holds the screw in position after the friction adjustment is complete.

Elevation-stowing Pin. (Figure 6-21.) This assembly, which is used to lock the elevation assembly when stowing the sighting station, is located at the rear of the right-hand gear box. It consists of a pin which mounts in a flange on the gear-box casting and which can be slid into a hole on the rear of the sight yoke to lock the sight yoke in the horizontal position. A ball, spring, and screw assembly (similar to that used on the azimuth-stow pin) keeps the pin in proper position.

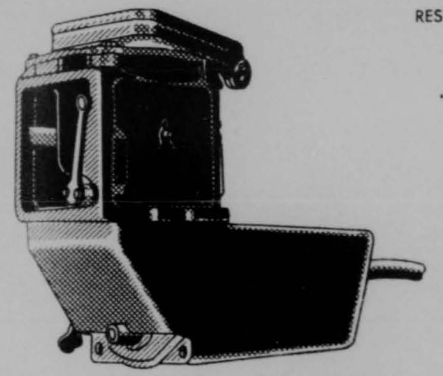

Figure 6—22A. Retiflector Sight with Blinders.

Note: The proper spring tension is set at the factory and should not be changed.

19. RETIFLECTOR SIGHT

Mounting

The retiflector sight, (Figure 6-22) is mounted on the sight yoke. (Figure 6-23.) It is identical to the sight used on the ring-type sighting station with two minor exceptions.

On the model A, C and E sights used on the pedestal-type sighting station, the assembly containing the reflecting glass and the sky filters is attached to the unit at a point 90 degrees in a clockwise direction (as shown in figure 6-22-A) from its location on the model B sight.

The target-size-input shaft is lengthened by inserting an adapter between the knurled input knob and the sight case.

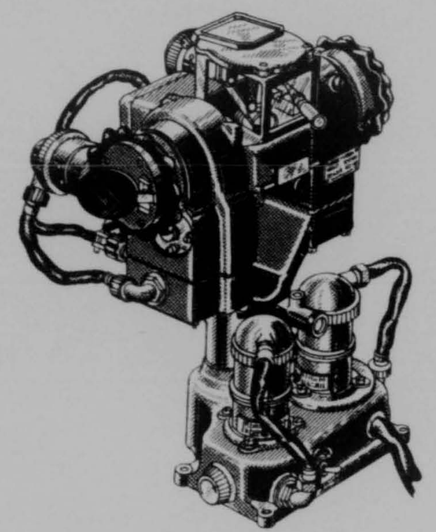

Figure 6—23. Retiflector Sight

Note: The model E retiflector sight has an 18-dot reticle for ranges below 700 yards, 12 dots for ranges above 1300 yards. The dots are slightly smaller than on previous sights. An internal range scale visible on the object glass is provided. The target size setting can be varied from 15 to 75 feet. It is interchangeable with models A and C.

SECTION II—RING SIGHTING STATION

1. THE UPPER-SIGHTING STATION
(Figures 6-24 and 6-25.)

General

The upper-sighting station, model 2CSR-3A1, is located on the upper structure of the airplane just forward of the upper-rear turret. This sighting station is called the "ring type." It takes its name from the fact that it is fastened to the structure of the airplane by means of a ring assembly which also forms a track in which the sight is moved in azimuth. When using the sight to follow the movements of a hostile airplane, the gunner is seated in a swivel seat elevated from the floor so that his eyes are slightly above the level of the fuse-

THIS PAGE IS DECLASSIFIED IAW EO 13526

Figure 6—24 Upper Gunner in Position at Ring-type Sighting Station.

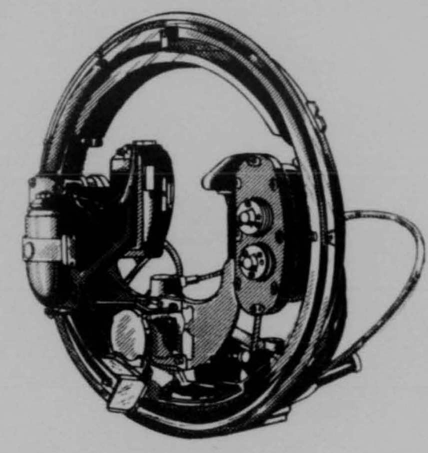

Figure 6—25. Upper Sighting Station.

lage. (Figure 6-24). He operates the sight by moving it manually in both azimuth and elevation. The gunner uses the platform on which his feet rest to facilitate rotating his swivel seat. Power to operate the various electric units on the sighting station is brought in by means of the collector-ring assembly which is located inside the base of the support for the gunner's seat.

The Blister

Covering the sighting station is a stationary, transparent dome, or "blister," which affords the gunner an unobstructed view of the entire hemisphere above the airplane.

Limits of Sight Movement

The upper-sighting station can be rotated continuously in either direction in azimuth, and 95 degrees in elevation from the vertical to 5 degrees below the horizontal.

2. BASIC PARTS OF THE UPPER-SIGHTING STATION
(Figure 6-26.)

The upper-sighting station is composed of eight major parts or assemblies. These are defined as follows:

The Ring Assembly

This consists of two rings, an outer and an inner ring. The inner ring, which supports the retiflector sight and its various accessories rides on the outer ring which serves as a means of mounting the sighting station on the airplane structure. The ring assembly is also the means of permitting the sight to swing in azimuth.

The Control Unit and Junction Box

This device, by which the gunner actually operates the sight, attaches to the inner ring and is composed of the following parts: the range grip, the action switch, the trigger, the interphone button, the reticle-lamp adjustment knob, the computer switch, and the azimuth and the elevation stowing pins.

The Azimuth Selsyn-generator Assembly

This is the means of transmitting to the turrets, signal voltages which indicate the position of the sight in azimuth.

The Elevation Selsyn-generator Assembly

This assembly transmits to the turrets, signal voltages which indicate the position of the sight in elevation.

The Yoke Assembly

This assembly mounts the sight, and is pivoted between the azimuth and elevation Selsyn-generator assemblies.

The Retiflector-type Sight

This is a direct-vision type of sight through which the gunner looks when tracking his target.

The Gyroscopes

There are two single-action gyroscopes, one for azimuth and one for elevation. These are mounted on the right-hand arm of the yoke. The gyroscopes serve as a means of transmitting to the computer the necessary electrical corrections for lead.

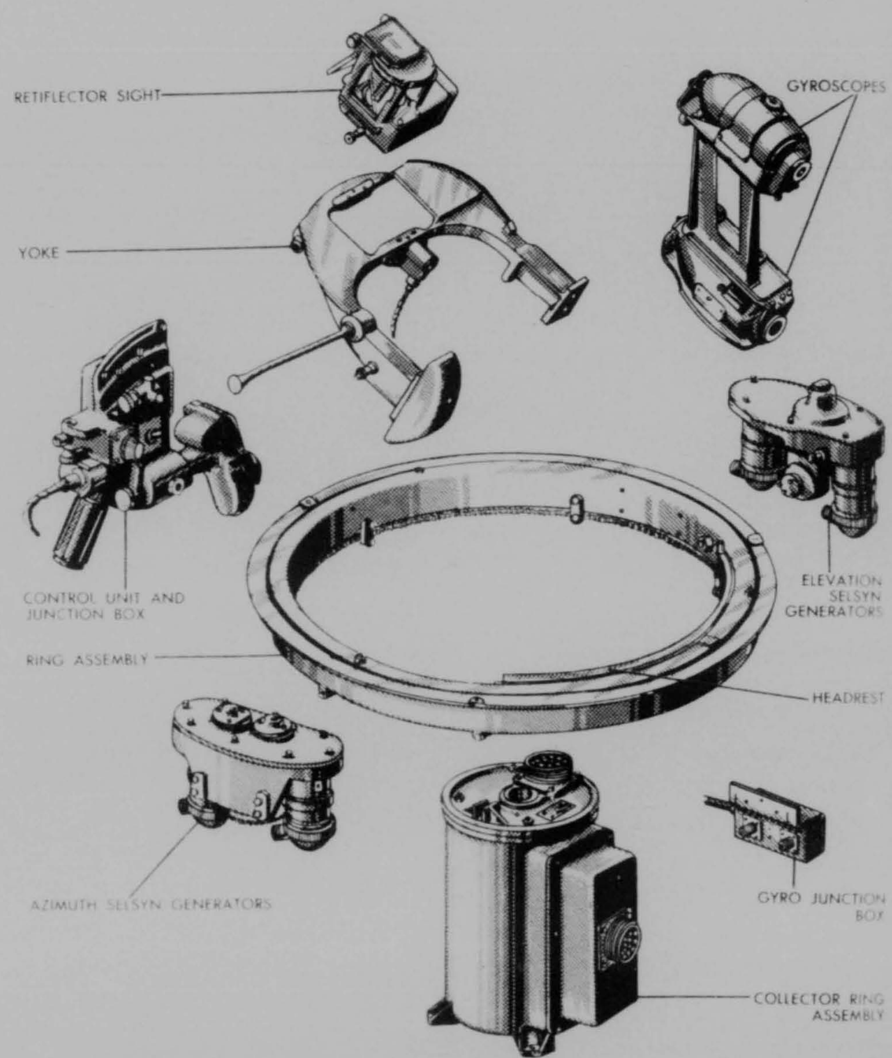

Figure 6—26. Major Parts, Ring-Type Sighting Station.

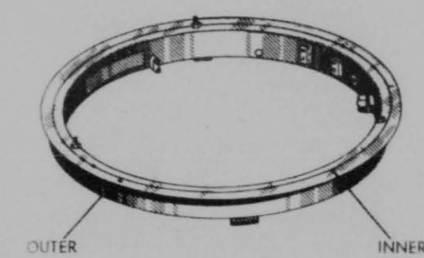

Figure 6—27. Outer and Inner Rings Assembled.

Collector Assembly

The collector assembly is housed inside the support which carries the gunner's seat. It serves as a means of bringing power from the airplane's electrical system to the sighting station.

3. THE RING ASSEMBLY
(Figure 6-27.)

As in the case of the turret, the ring assembly on the upper-sighting station essentially comprises two rings, one of which turns inside the other by means of radial and trust bearings. The outer ring is the means of fastening the sight to the airplane structure while the inner ring supports the rest of the sighting station sight and much of the sight's accessory equipment.

The Outer Ring

This is a ring which is Z-shaped in cross-section (Figure 6-28.) The upper flange is drilled to take the mounting bolts which fasten the sighting station to the airplane's structure. The lower flange has teeth cut on its inner periphery. These teeth are engaged by the drive gear on the azimuth Selsyn-generator assembly.

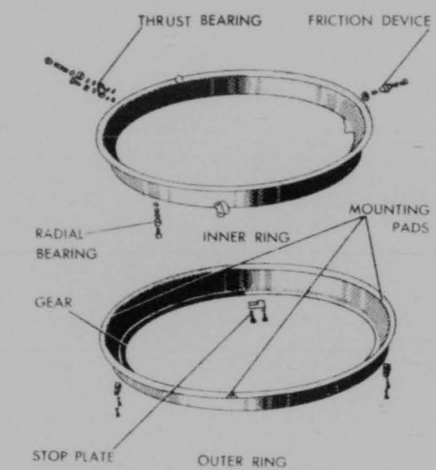

Figure 6—28. Outer and Inner Rings Separated.

The Inner Ring

This is a ring which has an inverted-L cross-section (Figure 6-28. The flange (upper) portion of the ring mounts three radial bearings. The side portion of the ring mounts the following parts: five double thrust bearings, the azimuth-friction device, the azimuth and elevation Selsyn-generator assemblies and the control and junction-box assembly.

Ring Bearings

Ball bearings mounted on short shafts,

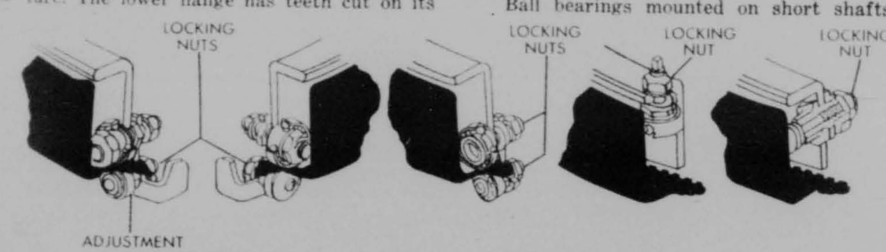

Figure 6—29 Sectional View of Rings Showing Bearings and Friction Device.

bolted to the inner ring, ride on machined surfaces on the outer ring. Five thrust bearings support the inner ring within the outer ring. Three radial bearings center the inner ring within the outer ring and serve to maintain the alignment between the two rings.

Each thrust bearing assembly consists of an upper and lower ball bearing. The upper bearing rides on the top of the inside flange of the outer ring. The lower bearing rides on the under side of the same flange. (Figure 6-29 The upper bearing in each assembly carries the weight of the sighting station, and the lower bearing prevents upward motion. The spacing between upper and lower bearings can be adjusted to maintain the proper clearance between the lower bearings and the under side of the flange. One of the thrust bearings (Figure 6-29) is located on the ring back of the elevation Selsyn-generator assembly. These two bearings are equipped with brackets having sections turned at right angles to prevent complete rotation of the sighting station in azimuth without rotation of the gunner's seat. This is to aid the gunner in maintaining the most effective sighting position.

A third bearing of similar construction but without the right-angle bracket is located to the right of the control unit and junction box assembly on the inner ring. All three of these thrust-bearing assemblies are adjusted by loosening the locking nut, turning the adjustment and then tightening the locking nut. The shaft is eccentric, thus turning the adjustment raises or lowers the lower bearing to give the clearance desired.

Two additional thrust bearings (Figure 6-29) are located on the inner ring above the point where the control unit and junction-box assembly is mounted. These give additional support to the inner ring at the point where the gunner is likely to apply stress to the ring These two thrust-bearing assemblies are also adjustable. In this case, however, both the upper or lower bearing of each assembly can be adjusted. The lower bearing is adjusted in the same way as the lower bearings previously described. The upper bearing is adjusted by loosening the lock nut on the bearing shaft, turning the shaft (which is eccentric) with a screwdriver, and then tightening the nut to hold the adjustment.

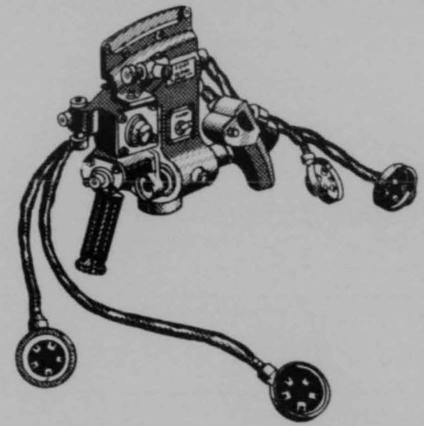

Figure 6—30. Control Unit and Junction Box.

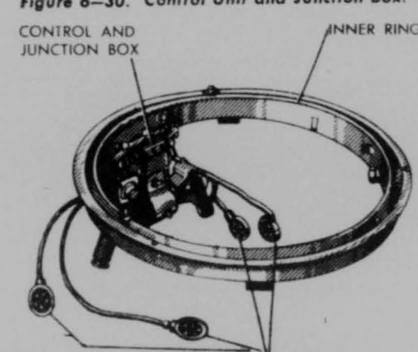

Figure 6—31 Control Unit and Junction Box Mounted on Inner Ring.

The centering of the inner ring is accomplished by three radial bearing assemblies equally spaced and mounted on the horizontal section of the inner ring. (Figure 6-29d.) These bearings also have eccentric shafts to permit radial positioning and accurate centering of the inner ring with the outer.

Friction Device

Figure 6-29 shows an adjustable spring-loaded friction device mounted on the inner ring to aid in controlling motion in azimuth. The amount of friction can be adjusted by turning the shaft with a screwdriver. The friction setting can be maintained by tightening the local nut on the shaft.

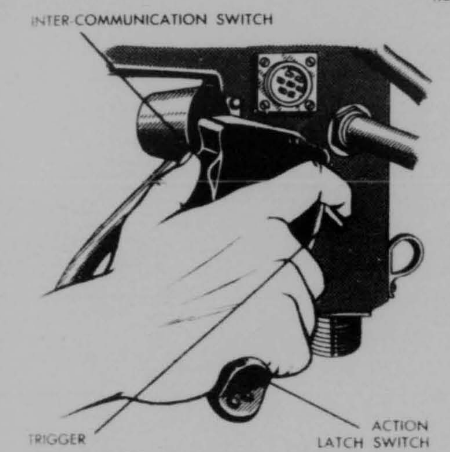

Figure 6—32. Right-Hand Grip Showing Action Switch, Intercommunication Switch and Trigger Switch.

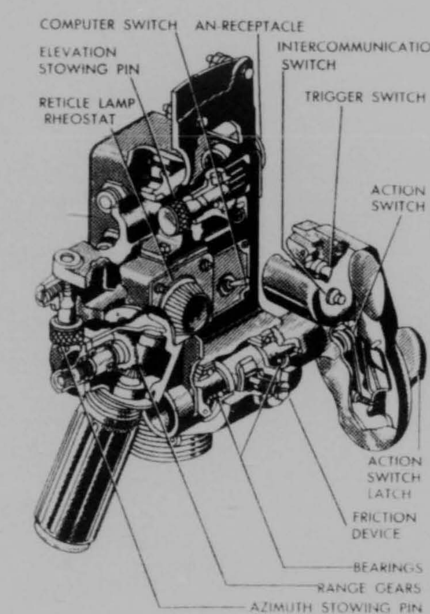

Figure 6—33. Cutaway View of Control and Junction Box Assembly Showing Shaft Bearings, Friction Device and Range Adjustment Gearing.

4. CONTROL UNIT AND JUNCTION-BOX ASSEMBLY

Control of the line of sight in azimuth and elevation is effected through the right-and-left hand grips which form parts of the control and junction-box assembly. (Figure 6-30.) This assembly is attached to the inner ring as shown in Figure 6-31.

Right-hand Grip

(Figure 6-32.) An action switch to apply power to the gun turret, or turrets, is located on the right-hand side of the grip. The gunner holds the switch closed against a spring by depressing the switch lever with the side of his hand. His hand fits between the grip and lever, and not over the lever. Located at the top of the grip is a trigger which is operated by the first or index finger. Also on the grip, and in position to be operated by the thumb, is a push-button switch for the inter-communication circuit of the plane.

Left-hand Grip

This is the range adjusting grip. It is connected to a flexible shafting by means of the gearing shown in Figure 6-33. The flexible shafting is connected to the retiflector sight.

Housing

(Figure 6-33.) The housing is an aluminum alloy casting, which carries two ball bearings supporting a shaft on which are mounted the right-hand grip and the left-hand (or range-adjusting) grip together with gearing and a flexible shaft connection to the retiflector sight. This range grip also serves as a connection point for a link or rod connection to the yoke. The casting also supports an adjustable friction device which bears upon the shaft midway between bearings. This device aids in smoothing the operation of the sight in ele-

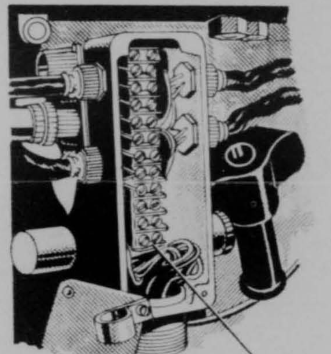

Figure 6–34. Junction Box Side of Control and Junction Box Assembly.

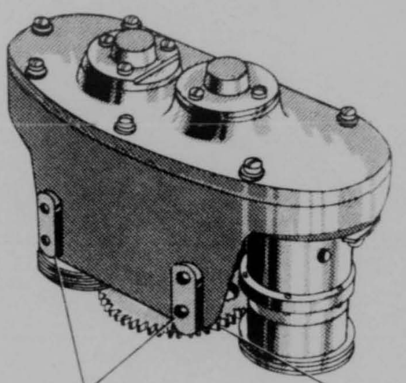

Figure 6–35. Azimuth Selsyn Generator Assembly Showing Mounting Pads and Drive Gear, Ring-Type Sighting Unit.

vation. The casting also provides a mounting for a computer stand-by switch and for a combined switch and rheostat for the sight's reticle lamp.

Junction Box

All electrical connections for the sighting station are brought from the collector assembly (located under the gunner's swivel seat) to a terminal board mounted in the housing. (Figure 6-34.) From the terminal board, connections are carried to the various electrical units on the sighting station.

Stowing Pins

There is an azimuth stowing pin to lock the yoke assembly in the horizontal position, and an elevation stowing pin to lock the inner ring at "forward," "broadside," or "aft" position in azimuth. (Figure 6-33.)

5. AZIMUTH SELSYN-GENERATOR ASSEMBLY

(Figures 6-35, 6-36, and 6-37.)

Function

The azimuth Selsyn-generator assembly is bolted to the inner ring of the sighting station

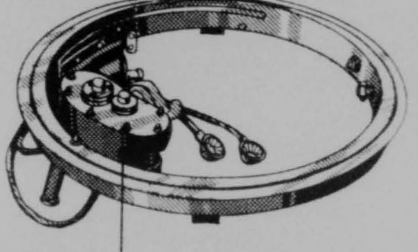

Figure 6–36. Azimuth Selsyn Generator Assembly Mounted on Inner Ring.

(Figure 6-36), at the left of the gunner's head as he looks through the retiflector sight. The purpose of this assembly is to send signal voltages from the sighting station indicating the position of the sight in azimuth. The assembly also provides a tail-bearing mounting for the left-hand side of the yoke assembly by means of which the yoke assembly is pivoted. (Figure 6-38.)

Major Parts

This assembly consists of a one-speed and a 31-speed Selsyn generator, a cast-aluminum-alloy housing to which the Selsyn generators are attached, and a gear train which engages

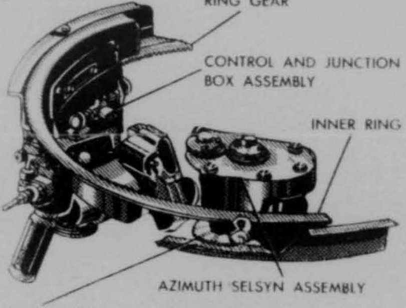

Figure 6–37. Cutaway to Show How Main Drive Gear Engages Internal Gear on Stationary Outer Ring.

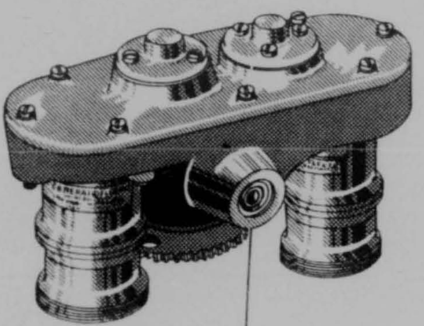

Figure 6–38. Yoke Side of Azimuth Selsyn Generator Assembly.

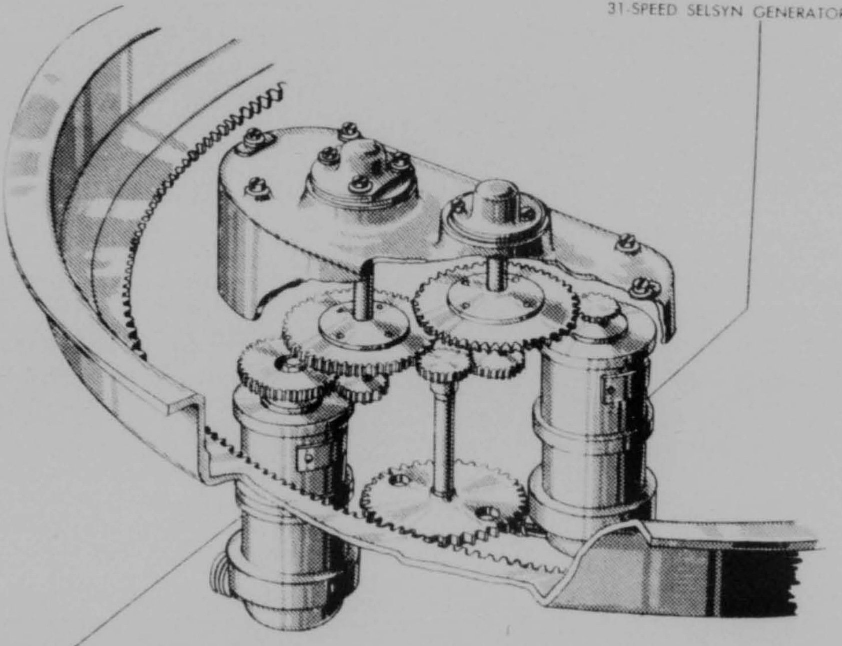

Figure 6–39. Schematic Drawing of Azimuth Selsyn Units Geared to Stationary Outer Ring Gear.

THIS PAGE IS DECLASSIFIED IAW EO 13526

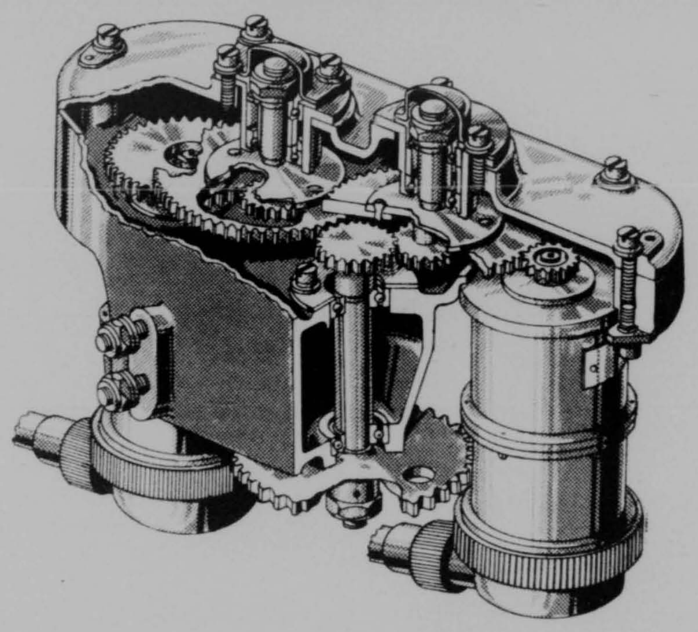

Figure 6—40. Cutaway View of Azimuth Selsyn Units, Showing Gears, Shafts, and Bearings.

the stationary internal gear on the outer ring. The gear train is located within the housing.

Selsyn-generator Units. The mechanical construction and the electrical operation of the Selsyn generators, as well as the reasons for the use of duplicate units are given under this section. Each of the Selsyn generators is mounted vertically on the under-side of the gear housing. The flange of each Selsyn-generator end shield is held in a rabbeted recess of the housing by three clamps. Each clamp is held to the housing by a screw.

Gear Train. In Figure 6-39, the gear train which connects the rotors of the Selsyn generators to the stationary internal gear of the outer ring is shown schematically. The gearing which drives the one-speed generator rotor is shown as part "a" in Figure 6-39 to distinguish it from the gearing, which drives the 31-speed generator rotor, shown as "b" in Figure 6-39. The main drive gear and shaft are common to both. This gearing causes the rotor of the 31-speed generator to turn 31 times faster than the rotor of the one-speed generator as the sight is moved in azimuth.

Housing. Figure 6-40 shows the housing with the Selsyn generators attached. The housing has been cut away to show the internal construction of the entire assembly. In this view, the bearing construction which supports the gearing can be seen. Note how the Selsyn generators are held by the clamps in the rabbeted recess in the housing.

Electrical Connections. Power is brought into the rotor and taken off the stator of each Selsyn generator by means of the cable attached to each Selsyn cap. The cap is held to the Selsyn unit by means of a threaded and flanged collar. Although the caps are shown attached to the Selsyn unit in Figure 6-40, actually the caps are attached to the control unit and junction box by means of the cable and are considered a part of that assembly.

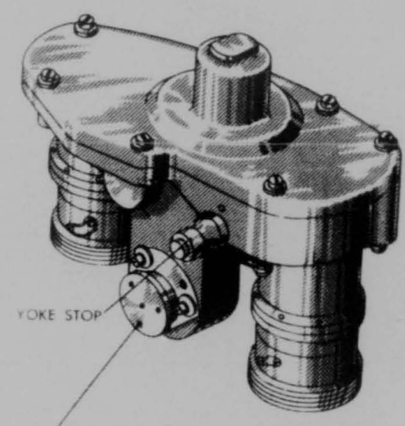

Figure 6—41. Elevation Selsyn Generator Assembly, Yoke Side, Showing Coupling to Yoke and Yoke Stop.

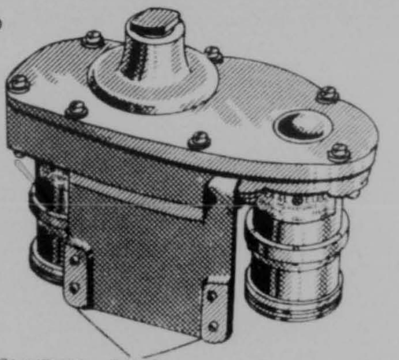

Figure 6—42. Elevation Selsyn Generator Assembly, Showing Mounting Pads.

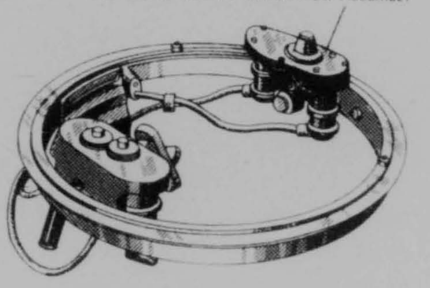

Figure 6—43. Elevation Selsyn Generator Assembly, Mounted on Inner Ring.

6. ELEVATION SELSYN-GENERATOR ASSEMBLY

(Figures 6-41, 6-42 and 6-43.)

Function

The elevation Selsyn-generator assembly is bolted to the inner ring of the sighting station (Figure 6-41), to the right of the gunner's head as he looks into the retiflector sight. The purpose of this assembly is to send signal voltages from the sighting station, indicating the position of the sight in elevation.

Major Parts

This assembly consists of a one-speed and a 31-speed Selsyn generator, a cast-aluminum housing to which the Selsyn generators are attached, and a gear train which connects the rotors of the Selsyns with the yoke of the sighting station.

Selsyn-generator Units. The elevation Selsyn generators are identical to the azimuth Selsyn generators, and are attached to the housing in the same fashion.

Gear Train. In Figure 6-44, the gear train which connects the rotors of the Selsyn generators with the yoke assembly of the sighting station is shown schematically. The gearing which drives the one-speed generator rotor is shown as "a" to distinguish it from the gearing which drives the 31-speed generator rotor, shown as "b". The plate, which attaches to the yoke assembly, and the bevel gearing is common to both 1- and 31-speed gearing. This gearing causes the rotor of the 31-speed generator to turn 31 times faster than the rotor of the one-speed generator as the yoke assembly is moved in elevation.

Housing. Figure 6-45 shows the housing with the Selsyn generators attached. The housing has been cut away to show the internal construction of the entire assembly. The yoke assembly is attached to the plate, and is pivoted at this point. As the yoke is turned, its motion is carried through the gearing to the

THIS PAGE IS DECLASSIFIED IAW EO 13526

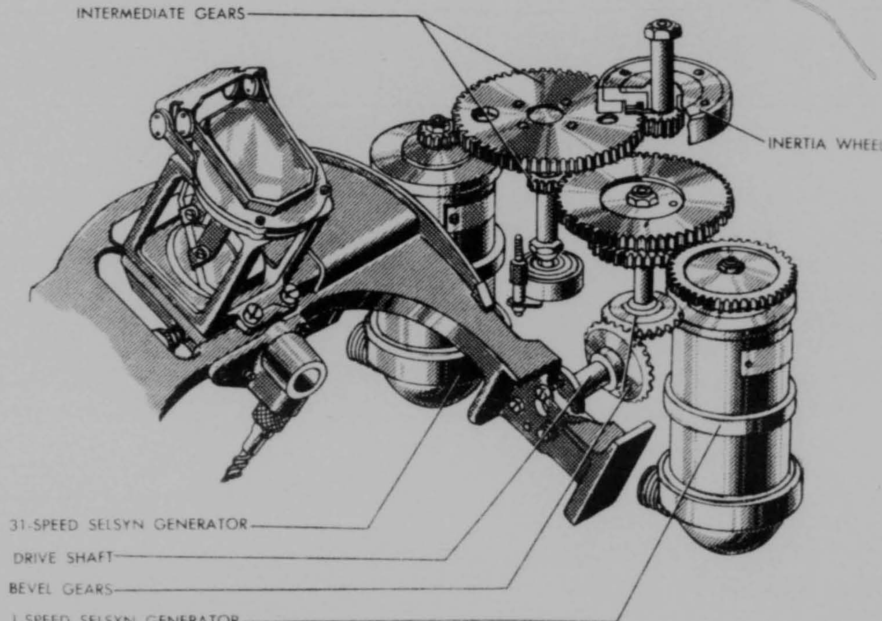

Figure 6–44. Elevation Selsyn Generator Assembly Gearing.

Selsyn generator rotors. This view shows the details of the bearings which support the gears, and the manner in which the Selsyn generators are attached to the housing. The Selsyn generators are held by the clamp in the rabbeted recess in the housing so that the Selsyn units can be "zeroed."

Inertia Wheel. Within the housing, and connected to the gear train is an inertia wheel. This wheel smooths the motion of the sight in elevation through its fly-wheel action. Figures 6-44 and 6-45 show how the inertia wheel is connected to the gearing. Note that this connection is made through a clutch. This is to permit the gunner to slew quickly, to move the sight rapidly when a new target is sighted. During normal use, the inertia wheel helps prevent jumpy tracking.

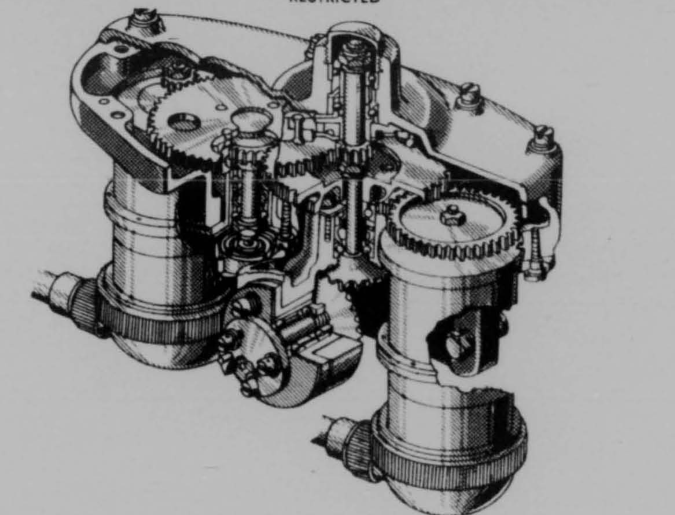

Figure 6–45. Elevation Selsyn Units, Showing Gears, Shafts, and Bearings.

Electrical Connections

Power is brought into the rotor and taken off the stator of each Selsyn generator by means of the cable attached to each Selsyn cap. The cap is held to the Selsyn unit by means of a threaded and flanged collar. Although the caps are shown attached to the Selsyn unit in Figure 6-45, actually the caps are attached to the control unit and junction box by means of the cable and are considered a part of that assembly.

7. YOKE ASSEMBLY

(Figure 6-46.)

It is necessary that the retiflector sight be so mounted as to permit motion in elevation as well as in azimuth. Also, the mounting must not interfere with the gunner's line of sight. These objectives are conveniently accomplished through the use of a yoke-shaped aluminum-alloy casting. The sight is mounted on the center of the closed end of the yoke. The yoke assembly is mounted between the two Selsyn-generator assemblies. (Figure 6-47.) Because the yoke is pivoted at its mounting points, the closed end on which the retiflector sight is mounted is free to move up and down.

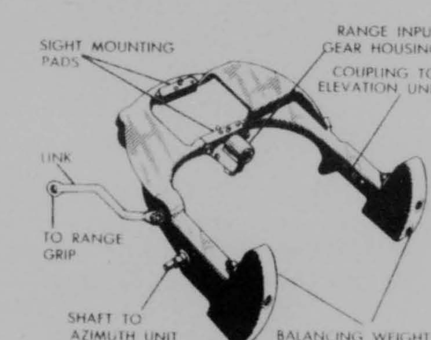

Figure 6–46. Yoke Assembly, Ring Type Sighting Station.

Counterbalancing weights are used at the open end of the yoke.

The yoke is connected to the elevation Selsyn generator assembly as shown in the schematic view in Figure 6-48. As the yoke is moved in elevation, its motion is translated to the Selsyn rotors by the gear train. The manner in which the gunner moves the yoke and thus his sight in elevation, is shown in the

THIS PAGE IS DECLASSIFIED IAW EO 13526

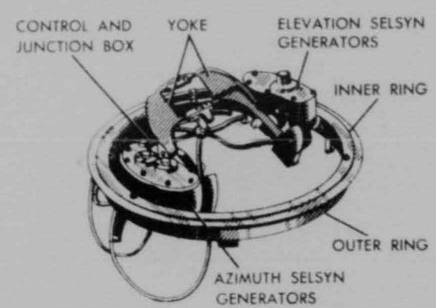

Figure 6—47. Yoke Assembly Mounted on Sighting Station.

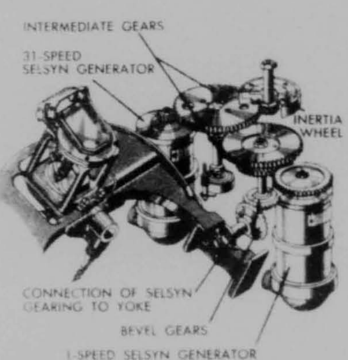

Figure 6—48. Yoke Connected to Elevation Selsyn Generator Assembly.

schematic view in Figure 6-50. Here the control unit and junction box assembly with the gunner's control grips is shown together with the yoke and the mechanical linkage between the control grips and the yoke. The parts concerned with the elevation motion are shown in "a" of Figure 6-50. As the gunner moves the control handles, the yoke is elevated or lowered by means of the mechanical link connected between the yoke and the movable boss on the control unit and junction box assembly. Movement of the control handles moves the boss. The yoke can be moved through 95 degrees from vertical to 5 degrees below the horizontal.

Figure 6-50 also shows how the gunner supplies the retiflector sight with its "range input", and input which when passed on to the computer enables that equipment to compute the range of the target. When the gunner twists the range grip, he controls the diameter of a circle of dots which appear in his sight. This control is effected by the gearing in the range grip and the flexible shafting connected to the sight (shown mounted on the yoke). Parts concerned with range input are shown in "b" in the, diagram. (Figure 6-49.)

One of the single-action gyroscopes (elevation) is mounted on brackets above and parallel to the right-hand arm of the yoke, and the other (azimuth) is mounted on brackets just below and parallel to the right-hand arm of the yoke. The gyros thus move with the yoke assembly as it moves in both azimuth and elevation.

THIS PAGE IS DECLASSIFIED IAW EO 13526

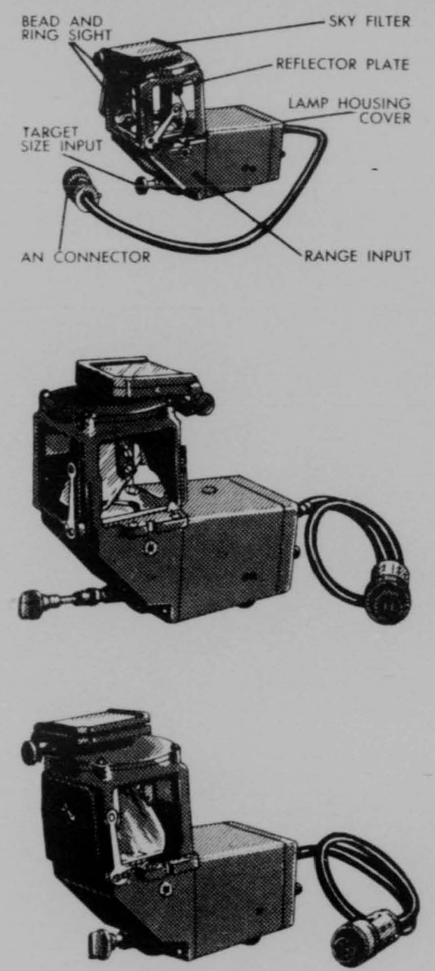

Figure 6–51. (A & B). Retiflector Sight, Models B, C and D or F.

8. RETIFLECTOR SIGHT

The retiflector sights used on all sighting stations are manufactured for the General Electric Company by the Bell and Howell Company. For detailed information on the models used, reference is made to Figure 6-49, 51, 51A, 51B, and 52.

Major Parts

Optical System. Figure 6-51 shows the major parts of the retiflector sight. This is a partially exploded view showing the parts forming the optical system of the sight. These parts are a double-filament reticle lamp which is the light source for the reticle image; a small indicating lamp which lights when the computer is out of the system; a condensing lens; a filter; the reticle assembly, consisting of range-, neutral-, and target-reticle assemblies (which form the reticle image); a 45-degree mirror which turns the formed reticle image upward; a cover plate which encloses the reticle box, but permits passage of light, a reflector plate on which the reticle image appears and through which the gunner looks; and a Magnin mirror which collimates or makes parallel the light rays which form the reticle image.

Sky Filters and Ring-and-bead Fixture. Sky filters are provided to cut down glare and thus increase the brilliancy of the reticle image during daylight flights. The filters are hinged so that they can be swung out of the line of sight during night flights. A ring-and-bead fixture is provided for emergency use.

Electrical Elements. A potentiometer controlled by movement of the range-reticle assembly provides the computer with an electrical signal representing the range of the target. The reticle lamp is built with two independent filaments to guard against burn out. A filament-selector switch to turn on one or the other filament is located on the removable cover of the lamp housing. The intensity of the light from the filament lamp can be varied by turning the reticle-lamp rheostat on the control and junction-box assembly (Figure 6-33).

Operation

Figure 6-53 shows the optical system schematically. In the interest of simplicity, only the center dot and one of the reticle image dots are shown in this diagram. The light from the reticle lamp passes through an orange-colored filter (which gives the reticle image its characteristic color), the condensing lens and through an indicator disk with a circular opening the size of the maximum reticle image.

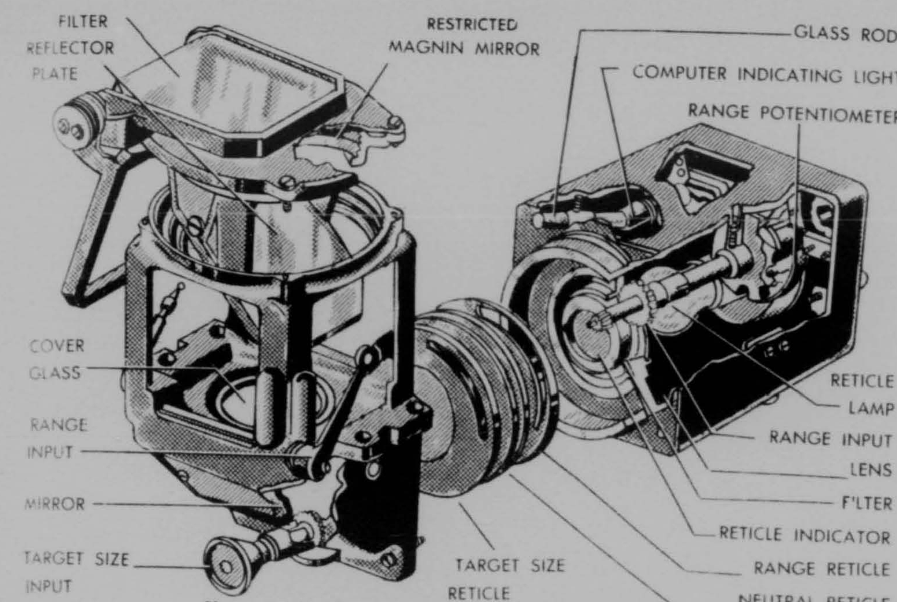

Figure 6–52. Partially Exploded View of Retiflector Sight.

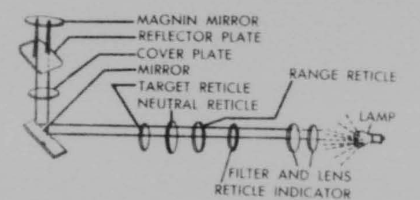

Figure 6–53 Schematic Diagram of Optical System of Retiflector Sight.

This disk serves the same purpose as a mask. However, there is an opening cut into the inside diameter of the disk to permit passage of light through the target size figures.

The light now passes through the reticle assembly where it is broken up into the dots which form the reticle image. In addition, the target size numeral is formed.

The formed reticle image is reflected upward by the 45-degree mirror through the cover plate to the reflector plate. Here about 80 percent of the light passes through the plate to the Magnin mirror. This mirror is so shaped and located, with respect to the reticle

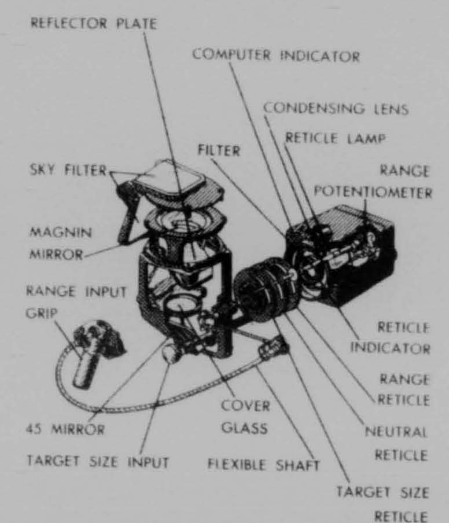

Figure 6–54 Schematic Illustration of Retiflector Sight.

THIS PAGE IS DECLASSIFIED IAW EO 13526

assembly, that the light rays from the reticle mirror are collimated, or made parallel, and reflected back to the reflector plate. Again, about 80 per cent of the light passes through, and 20 per cent of the light is reflected toward the gunner's eye. These rays form a virtual image of the reticle at infinite distance, or at infinity. Any object in line with the center of this reticle image will appear in the same position, irrespective of the distance of the gunner's eye from the reflector plate. A slight movement of the gunner's eye up or down and from side to side will not change the relative position of target and reticle image. This is one of the chief advantages of the reflecting-type sight as compared with such sights as the ring-and-bead sight.

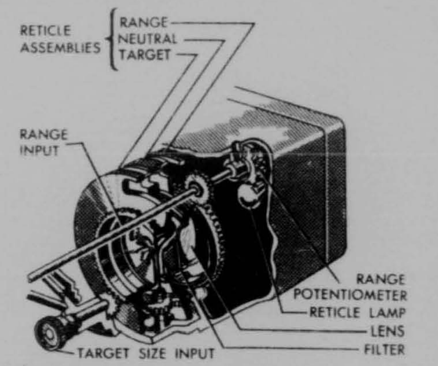

Figure 6—55. Cutaway View of Reticle Assemblies Showing Detail of Gearing Between Reticles.

Reticle Assembly

Figure 6-54, a schematic view of the reti-flector sight, shows the reticle assembly with the three reticles pulled apart, and with the range- and target-size inputs included. The complete reticle assembly consists of a range-reticle assembly, a neutral-reticle assembly, and a target-reticle assembly. The three reticles break down the light from the reticle lamp into a circular pattern of dots which is the reticle image. Each of the reticles is pierced with a series of slots which permit the passage of a portion of the light from the lamp. Thus as the light passes through the reticles, a portion is masked out at each reticle until only the dots forming the reticle image (and the target size numeral) remain. The relationship of each reticle to the others (i.e., each set of slots to the others) is what determines the diameter of the reticle image. As can be seen in Figure 6-55, the slots of the target-reticle assembly are curved. Those of the range reticle are similar, but curve in the opposite direction. The slots of the neutral reticle are straight. Each reticle has a hole in its center to permit the passage of light to form the center dot of one reticle image. The diameter of the reticle image is varied by the gunner when he changes the angular relationship of the three reticles with respect to each other.

The gunner can vary the position of the target-reticle assembly by turning the target-size input knob. In actual practice he sets target size just before aiming at his target and then allows the target reticle to remain in position. The gearing from the target size input knob to the target reticle assembly is shown in Figure 6-54.

The gunner varies the position of the range-reticle assembly by turning the range input grip on the sighting station. The gearing and shafting connections shown translate this motion into a motion of the range reticle.

The neutral-reticle assembly is located between the target-reticle assembly and the range-reticle assembly and is connected to both by differential gearing. Thus when either one or the other of the outside reticle assemblies is moved, the neutral reticle assembly is moved proportionately.

In Figure 6-55, the reticle assembly is cut away, and the detail of the gear arrangement at the reticle assembly is shown. The three reticles are close together, so that their masking action on the light from the filament lamp gives a clear-cut reticle image. The three reticles ride on the inner surface, or circular bore, of the housing. When either of the outer reticles is moved, the teeth cut on the inside surface of their flanges turn the pinion which is held in the neutral reticle, turning the neutral reticle.

When the range-input gearing turns the range reticle, it also turns the slider of the

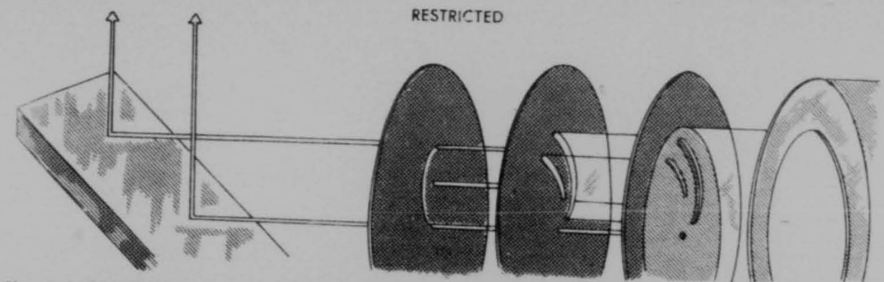

Figure 6—56. Schematic View of Reticles Showing How Sight Dots of Reticle Image Are Formed.

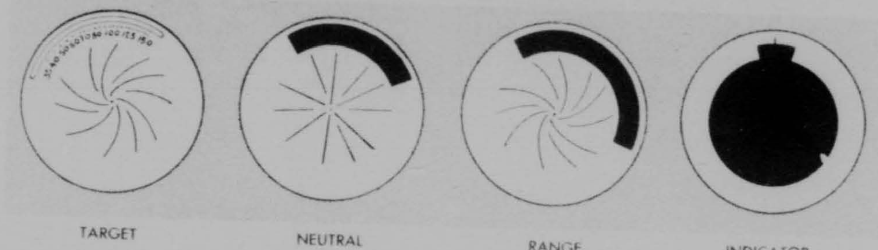

Figure 6—57. Individual Reticles and Reticle Indicator.

potentiometer, which in turn sends the range correction to the computer.

Figure 6-56 shows how the reticles act to mask out portions of the light from the reticle lamp until only the dots forming the reticle image remain. For the sake of illustration, only the center dot and one of the dots in the reticle image circle are shown.

Actually, there are eleven dots forming the reticle image when the diameter of the reticle image circle is large, and five when the diameter is small.

The light from the lamp passes first through the reticle indicator, a disk whose inner diameter is slightly larger than the maximum reticle-image diameter. Then the portion which comes through the center opening falls upon the range reticle. Here all light except that passing through the curved slots and the center dot is blocked. At the neutral reticle the curved segments of light cross the straight reticle slot. Where they cross, light is permitted to pass through. This step forms dots of light. However, more dots are formed than are wanted, thus as these dots fall on the target reticle, only those which intersect a slot in the target reticle get through. In this way the proper dots to form the reticle image are selected. Changing the position of any reticle changes the relationship of the slots and changes the selection of reticle-image dots.

Figure 6-57 shows how the reticles and the reticle indicator are laid out. The keystone-shaped opening in the reticle indicator permits passage of light for the target size indication. The narrow slot above this opening passes light which becomes the index mark on the reflector plate. The wide curved opening in the range and neutral reticles pass the light for the target size indication. The numbers for target size are on the target size reticle.

The short slots on each reticle account for the change from eleven reticle image dots to five when the reticle image is small in diameter.

Figures 6-58 to 6-61 show the inter-relation of the reticle slots of the three disks. The letters represent the slots of the three disks: (a) for the target-size disk, (b) for the neutral disk, and (C) for the range-adjustment disk.

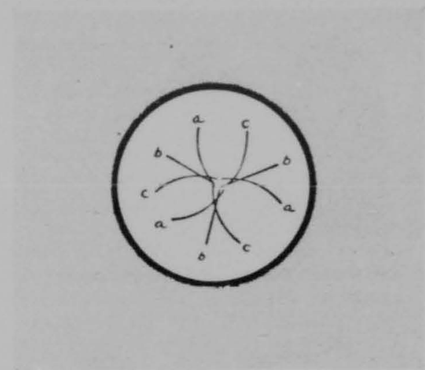

Figure 6—58. 3-Reticle Circle Dots. Target Size Setting 60 Feet.

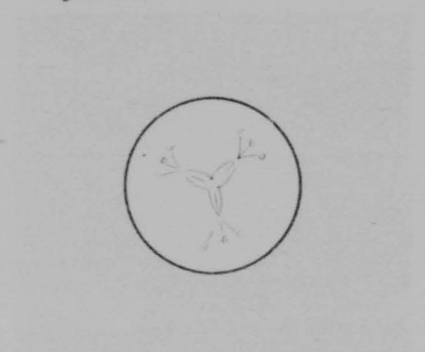

Figure 6—59. 3-Reticle Circle Dots. Target Size Setting 60 Feet.

In order to simplify the drawings, only three intersecting slots have been selected from each of the three disks.

Figure 6-58 shows the manner of intersection where the range disk is set to span a sixty-foot target which is at a considerable distance. In this case the reticle image will be small in diameter, because the slots have common intersection points near the centers of the disks. It should be noted that all three slots must intersect at a common point to permit the passage of light.

Figure 6-59 shows the triple intersection point (where slots of all three disks intersect) at a greater radius from the center, such as would be required to span the same sixty-foot target when much nearer to the sight. Near

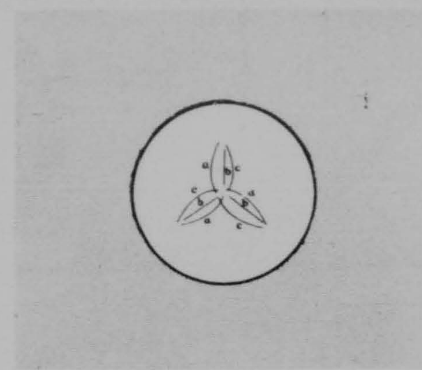

Figure 6—60. 3-Reticle Circle Dots. Target Size Setting 60 Feet.

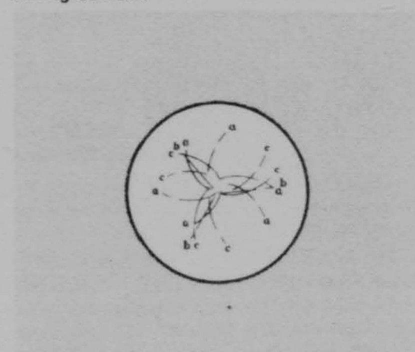

Figure 6—61. 3-Reticle Circle Dots. Target Size Setting 60 Feet.

the center of this drawing are three double intersections from the slots of the target and range disks. These are blanked off by the neutral disk, and consequently no light passes through them.

Figure 6-60 likewise shows the intersections with the range-adjustment disk turned to give the maximum diameter possible such as would be required to span a sixty-foot target quite near the sight.

Figure 6-61 shows adjacent slots at each of the three positions previously used for the target and range disks. It will be noted that a number of double intersections occur, but that the triple intersections are limited to three points on the circumference of a circle which would represent a range setting between those

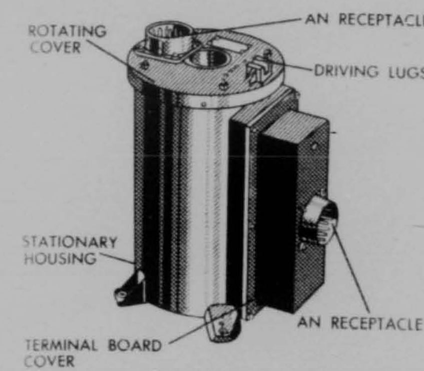

Figure 6—62. Collector Ring Assembly and Junction Box.

of Figure 6-59 and 6-60. This setting most nearly approaches a condition of incorrect indication. If carried out using all slots, it will indicate the reason for using the five short slots shown in each disk, Figure 6-56.

9. COLLECTOR RING ASSEMBLY

This assembly (located under the gunner's seat Figures 6-62 and 6-63) is used to bring in the 33 electrical connections which are required between the ring-type sighting station and the system. A device of this kind is needed in order that the sighting station may remain free to rotate continuously in either direction without limitations of movement or twisting of the control connections. Figure 6-64 shows the exterior of the collector ring assembly designed for such an application.

Operation

When the gunner swings his sight around in the sighting station, he also must swing his seat around somewhat in order to be always sighting forward. In doing this, a mechanical connection from his seat acting on two driving lugs on the top cover of the contact ring assembly (Figure 6-63) rotates the assembly within the housing to a corresponding position. Since the contact rings are complete cylinders, the stationary brushes maintain con-

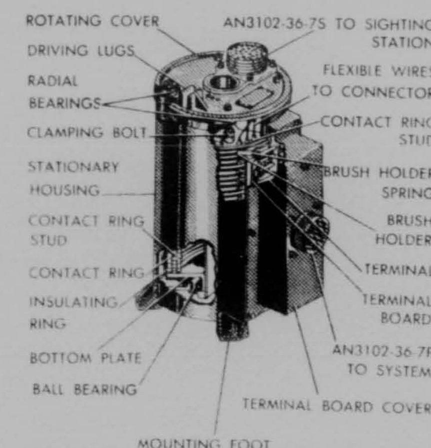

Figure 6—63. Cutaway View of Collector Ring Assembly.

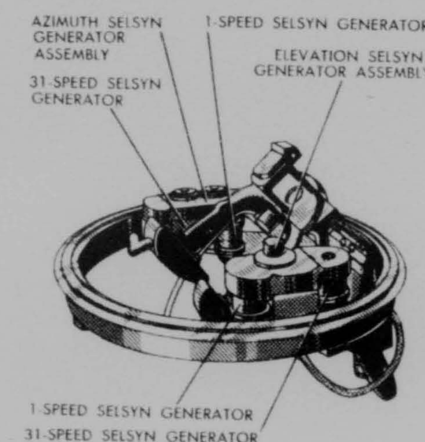

Figure 6—64. Selsyn Generators Mounted on Sighting Station.

tact and continuity of the circuits without limitation on the number or direction of rotations. Likewise, excessive twisting of the connections and limitations of rotation are avoided.

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION III—CONTROL SYSTEM UNIT (SELSYNS)

1. BASIC COMPONENTS

The Selsyn system comprises a Selsyn generator mounted on a sighting station, the generator being electrically connected to a Selsyn control-transformer mounted on the turret. The Selsyn generator is energized by 400-cycle alternating current from the dynamotor. The Selsyn generator, in turn, transmits energy to the Selsyn control-transformer. For this reason, the generator is sometimes referred to as a "Selsyn transmitter." Since the Selsyn control-transformer receives the electrical signal from the generator it is sometimes called a "Selsyn receiver." The Selsyn units make an electrical comparison of the relative positions of the sighting stations and turret. If the sighting station has been moved, the operation of the Selsyn units is such that the Selsyn control-transformer provides a signal which indicates the direction and amount the turret must be moved by the drive motor to bring it back into alignment with the sighting station.

Figure 6—65. Selsyn Generator.

Since both the sighting station and turret move in two different directions, azimuth and elevation, separate Selsyn generators and control-transformers are provided to indicate movement in both these planes. Moreover, in order to provide for accurate alignment of the turret with the sighting station, two sets of Selsyn generators and control-transformers are used in both the azimuth and elevation systems. For example, Figure 6-64 shows four Selsyn generators mounted on a ring sight, two for use with the azimuth Selsyn system and two for use in the elevation system. In the elevation system, one Selsyn generator is geared to rotate once for every revolution of the ring sight and is known as the "1-speed Selsyn generator" while the other is geared to rotate 31 times for every revolution of the sighting station and is known as the "31-speed Selsyn generator." Similarly, the azimuth system is provided with 1- and 31-speed Selsyn generators.

Actually, both the azimuth and elevation Selsyn systems operate in the same manner so that in the following description of the Selsyn generators and control-transformers only one system will be discussed by way of example.

2. SELSYN GENERATOR

As shown by Figure 6-65, a Selsyn generator is a small electrical device which somewhat resembles a motor but which functions similarly to a transformer. Although the Selsyn generator is geared to the sighting station, it is not used to produce a torque to rotate the sighting station. Rather, the purpose of the gear drive is simply to change the position of the Selsyn rotor in accordance with a change in position of the sighting station so that an electrical indication of the position of the sighting station is sent to the control-transformer on the turret.

The Selsyn generator comprises, in general, a stator carrying a three-coil winding, a rotor carrying a single winding which revolves inside the stator, an end-shield forming part of the housing for the elements, and a cap for making electrical connections with the Selsyn. (Figures 6-66 and 6-67.)

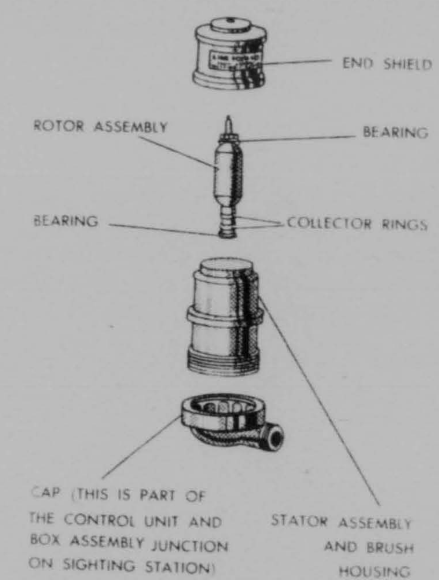

Figure 6—66. Exploded View Selsyn Generator.

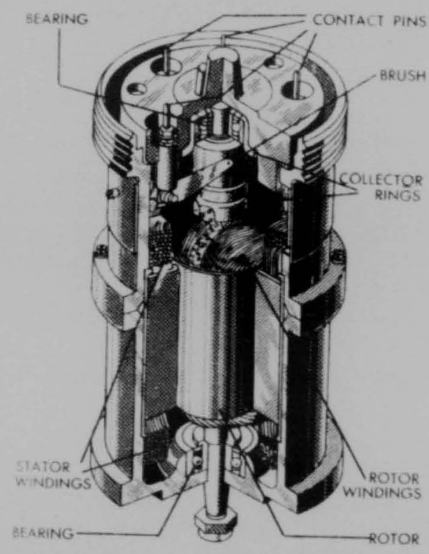

Figure 6—67. Sectional View of Selsyn Generator 2J1F1.

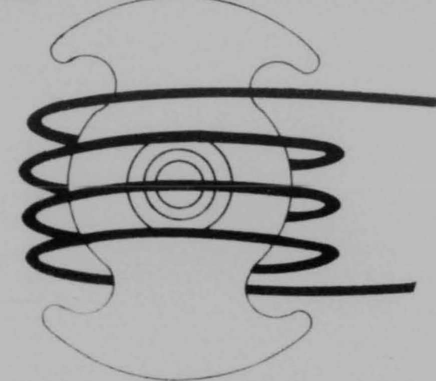

Figure 6—68. Schematic View of Selsyn Generator Rotor.

The stator comprises three windings assembled within a slotted laminated core which is press-fitted into the end-shield. A lead from one end of each of the three windings extends to contact pins carried by the insulated brush holder at the end of the Selsyn. The respective contact pins connected to the stat or windings are identified as "S_1," "S_2," and "S_3." The other ends of the windings are connected together internally in the Selsyn.

The rotor of the Selsyn generator comprises a single coil wound on a laminated iron core. (Figure 6-68.) Opposite ends of the rotor are supported in ball bearings carried by the brush holder and end-shield, respectively. The ends of the rotor winding are brought out to spaced collector rings carried by the rotor shaft. Brushes electrically connected to contact pins carried by the brush holder ride on the collector rings and provide an electrical connection to the rotor. The contact pins connected to the rotor winding are identified as R_1 and R_2 respectively.

The rotor of the Selsyn generator is energized by the 400-cycle alternating current from the dynamotor. This produces a magnetic flux in the rotor winding which, in turn, by transformer action produces a voltage in each of the three windings of the stator. The rotor is geared to the sighting station so that as the sighting station is manually moved, the rotor likewise moves varying the voltage in the stator coils.

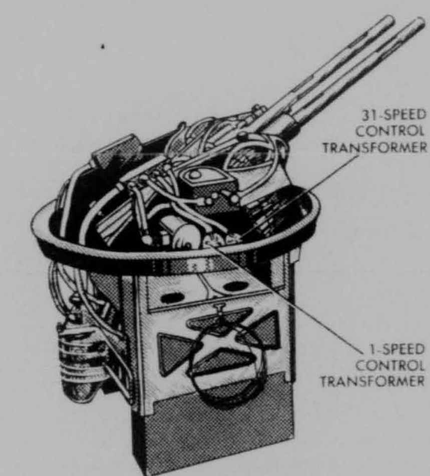

Figure 6–69. Elevation 1 and 31-speed Selsyn Control Transformers Mounted on Turret.

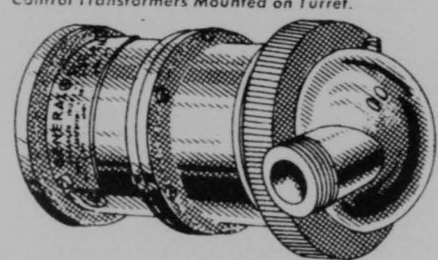

Figure 6–70. Selsyn Control Transformer Model No. 2J1G1.

3. SELSYN CONTROL TRANSFORMER

The turret carries Selsyn control-transformers in number and arrangement corresponding to the Selsyn generators on the sighting station. One- and 31-speed Selsyn control-transformers are provided for both the azimuth and elevation Selsyn systems. (Figure 6-69.)

A Selsyn control-transformer (Figure 6-70) is a small electrical device which, in outward appearance, closely resembles the Selsyn generator. It consists of the same basic elements (Figure 6-71)—stator, rotor, end-shield and connecting cap, which are assembled in the same manner as the Selsyn generator. (Figure 6-67.) Actually, the electrical characteristics of the Selsyn control-transformer differ considerably from those of the Selsyn generator so that these elements are not interchangeable in the system. One of the apparent differences is in the shape of the rotor. The Selsyn control-transformer is provided with a laminated round rotor carrying a single winding (Figure 6-72). Electrical connections to the Selsyn control-transformer are made through contact pins identified R_1, R_2, S_1, S_2, and S_3, the same as for the Selsyn generator.

The three stator windings of the control-transformer are electrically connected to the stator windings in the Selsyn generator so that the voltages appearing in the windings of the Selsyn generator are reproduced in magnitude and polarity in the stator of the Selsyn control-transformer. The resulting

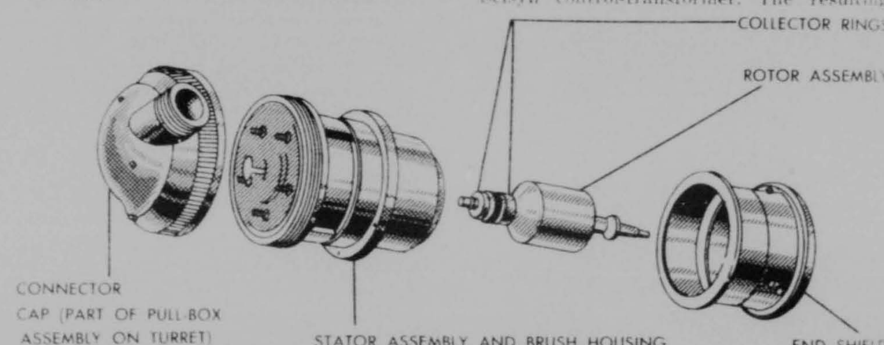

Figure 6–71. Exploded View of Selsyn Control Transformer.

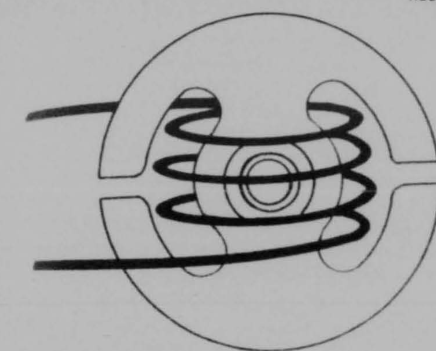

Figure 6–72. Schematic View of Selsyn Control-Transformer Rotor.

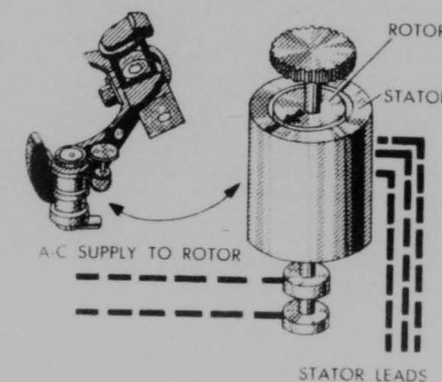

Figure 6–73. Schematic View of Selsyn Generator Geared to Sighting Station.

magnetic flux in the control-transformer stator induces a voltage in the rotor by transformer action which is the signal voltage fed to the servo-amplifier.

4. OPERATION OF SELSYN SYSTEM EXPLAINED IN SCHEMATIC FORM

Figure 6-73 shows a Selsyn generator in schematic outline, geared to a sighting station. The broken lines indicate the 400-cycle alternating current from the dynamotor fed through the collector rings to the rotor of the Selsyn generator. The three broken lines represent the electrical connections from the stator of the Selsyn generator. When the sighting station is moved, the rotor of the Selsyn generator is moved through the gearing. (Figure 6-74.) This causes the rotor to vary the voltage in each of the three stator windings and consequently across the three leads from the stator windings.

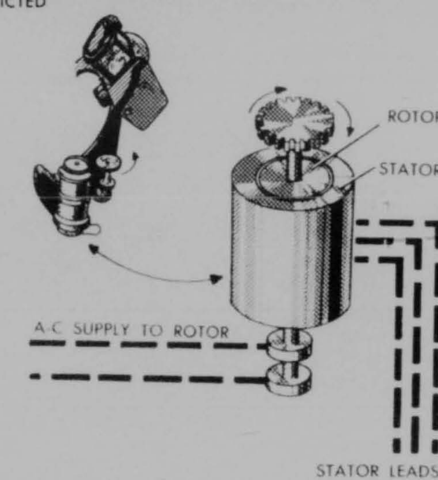

Figure 6–74. Movement of Sighting Station Driving Selsyn-Generator Rotor.

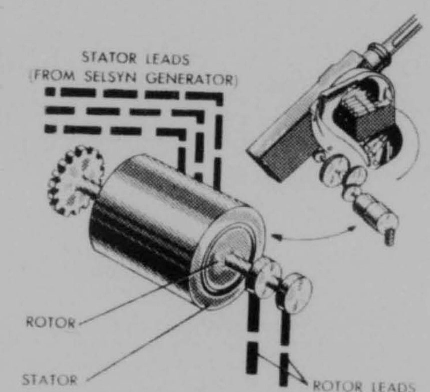

Figure 6–75. Schematic View of Selsyn Control Transformer (Rotor Geared to Turret).

Figure 6-75 shows a Selsyn control-transformer geared to the turret. As the turret moves, the rotor of the Selsyn control-trans-

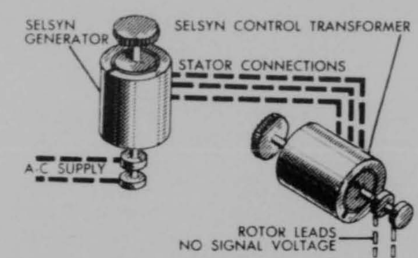

Figure 6—76. Schematic View of Selsyn Generator Connected to Selsyn Control Transformer.

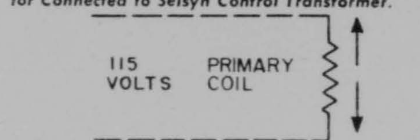

Figure 6—77. Coil Energized with an Alternating Current.

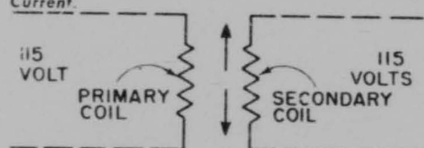

Figure 6—78. Voltage Induced in Secondary Coil from Primary Coil.

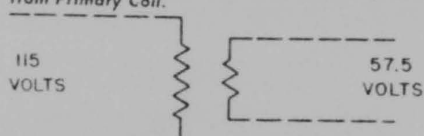

Figure 6—79. Reduced Voltage in Secondary Coil Having Reduced Number of Turns.

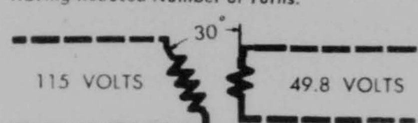

Figure 6—80. Varying Position of Primary Coil to Reduce Voltage in Secondary Coil.

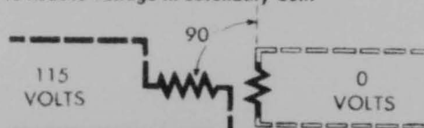

Figure 6—81. Positioning Primary Coil to Reduce Voltage in Secondary Coil to Zero.

former is likewise moved by the gear train. It should be noted that the Selsyn control-transformer does not drive the turret to any particular position; the means for driving the turret is the turret-drive motor. The three broken lines indicate the electrical connections to the stator from the Selsyn generator. The two heavier broken lines indicate the voltage output from the rotor of the Selsyn control-transformer, in the event that sight and guns are out of alignment.

The manner in which the Selsyn generator and control-transformer are connected together is shown in Figure 6-76. The stator windings are shown electrically connected by the broken lines. The Selsyn generator is continuously sending an electrical signal which is representative of the position of the sighting station along the broken lines to the Selsyn control-transformer. The Selsyn control-transformer compares this signal with its own position representing the position of the turret. If the turret is in alignment with the sight, no voltage signal appears at the control-transformer rotor as is indicated by the broken blank lines in Figure 6-76. However, if the turret and sighting station are not in alignment, a voltage signal will appear at the collector rings of the control-transformer rotor. As will appear later, this voltage signal is fed to the servo-amplifier. The manner in which this voltage signal is developed in the Selsyn control-transformer is set forth in the paragraph to follow.

5. ELECTRICAL OPERATION OF SELSYN SYSTEM

When an alternating current is passed through a winding, a magnetic field, or flux, is created around the coil which takes a direction parallel to the coil (Figure 6-77). In the Selsyn system this coil, which corresponds to the rotor of the Selsyn generator, is energized by the 115-volt 400-cycle alternating current derived from the dynamotor.

If another identical coil is brought into the magnetic field of the first coil, a voltage is said to be induced in the second coil. This is known as the transformer action. When the two coils are identical, the voltage induced in the secondary coil will be substantially the

same as that appearing in the primary coil (Figure 6-78). However, if the number of turns in the secondary coil is reduced, for example, to one-half the number of turns in the primary coil, the voltage in the secondary coil will be reduced by one-half and will amount to 57.5 volts (Figure 6-79). This is the maximum voltage induced between the terminals of any two coils in the stator of the Selsyn generator.

Another means of varying the voltage in the secondary coil is to rotate the primary coil relative to the secondary so that the coils are no longer parallel. This will reduce the voltage in the secondary coil and the value of the voltage will depend upon the angle through which the primary coil is moved. The voltage may be determined by multiplying the maximum voltage in the secondary by the trigonometric cosine of the angle (Figure 6-80). When the primary coil is moved through an angle of 30 degrees the voltage induced in the secondary is 49.8 volts.

If the primary coil is rotated to a position at right angles to the secondary coil, then the secondary coil will link none of the magnetic flux of the primary coil so that the voltage in the secondary will drop to zero (Figure 6-81). In this way the voltage in the secondary coil may be varied from a maximum of 57.5 to zero volts by simply turning the primary coil. In a similar way the voltage between the terminals of any two coils of the Selsyn-generator stator is varied from a maximum of 57.5 volts to zero simply by turning the rotor in accordance with movement of the sighting station.

If desired, the secondary coil may be moved with respect to the primary coil with the same result. When this is done the voltage through the secondary coil will vary according to the angular positions of the coil. In Figure 6-82, the secondary coil has been moved at right angles to the primary coil so that zero voltage is induced in it.

The basic principles thus far set forth are utilized in the operation of the Selsyn system. In Figure 6-83, the primary and secondary coils have been associated with the turret and sighting station which are separated from one another by any desired distance, thirty-five in

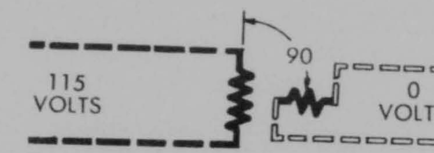

Figure 6—82. Positioning Secondary Coil to Reduce Voltage in Secondary Coil to Zero.

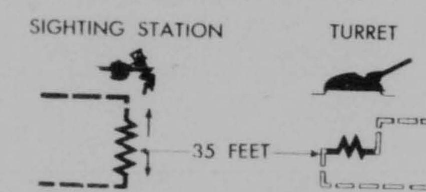

Figure 6—83. Schematic View of Primary and Secondary Coil (Applied to Sighting Station and Turret).

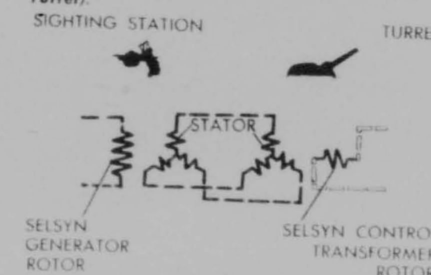

Figure 6—84. Primary Coil (Generator Rotor) and Secondary Coil (Control-Transformer Rotor) Interconnected by Selsyn Stators.

the example given. The primary coil will hereinafter be referred to as the "rotor" of the Selsyn generator mounted on the sight, and the secondary coil as the rotor of the Selsyn control-transformer mounted on the turret. When sight and guns are in alignment, these rotors are electrically at right angles to each other so that no voltage signal is induced in the control-transformer rotor (secondary coil). If the sighting station is moved to rotate the generator rotor so that it is no longer at right angles, a voltage signal would be induced in the control transformer rotor, were it not for the fact that it is thirty-five feet away. Some means must be provided to transmit the position of one rotor to the other. These means are the stators of the Selsyns.

In Figure 6-84, the Selsyn's stators have

THIS PAGE IS DECLASSIFIED IAW EO 13526

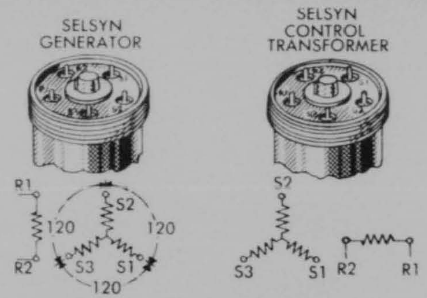

Figure 6—85. Generator and Selsyn Control Transformer with Windings Identified.

been electrically connected together, as indicated by the broken lines. Now if the Selsyn rotor on the sighting station is moved it will vary the voltages between the terminals of the three coils of the stator, and these voltages will appear in the stator of the control-transformer reproducing the flux or magnetic pattern of the generator stator. In this way the position of the generator rotor is transmitted to the rotor of the control transformer.

6. ELECTRICAL SYMBOLS OF SELSYNS

Figure 6-85 illustrates the electrical symbols for a Selsyn generator and Selsyn-control-transformer. In each case the three windings of the stator coils have been indicated as spaced 120 degrees apart and the windings identified as S_1, S_2, and S_3 corresponding to the contact pins of the Selsyns. In the case of the Selsyn generator the rotor winding R_1 and R_2 is shown as perpendicular to a line drawn between terminals S_1 and S_3. In the case of the control transformer the rotor R_1 and R_2 is shown parallel to a line drawn between terminals S_1 and S_3.

The positions of the rotors shown (Figure 6-85) are standard reference symbols used to represent the electrical positions of the Selsyns when the turret and sighting station are in alignment. (Figures 6-84 and 6-85, for comparison.) Moreover the windings on the rotors and stators are always identified with the letters shown and in the positions shown, when the Selsyns are in their electrical reference or zero position. The proper procedures for zeroing the Selsyns is described later.

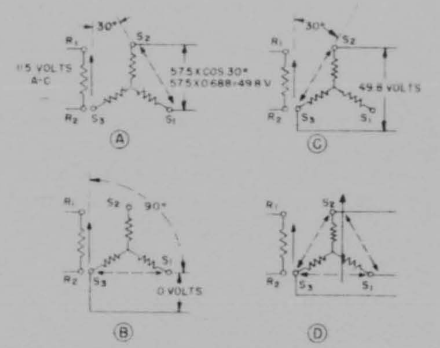

Figure 6—86. Voltages Between Windings of Selsyn Stator with Rotor in Zero Position.

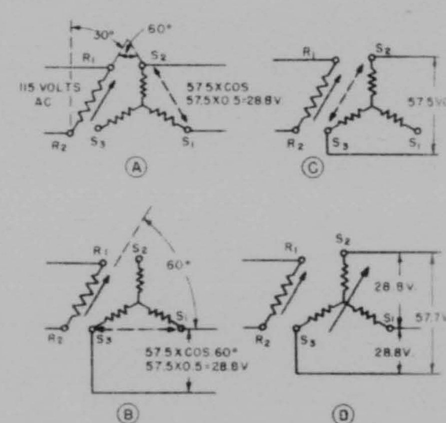

Figure 6—87. Voltages Between Windings of Selsyn with Rotor Moved to 30 Degrees.

It has been stated that as the rotor of the Selsyn generator moves, the voltages in the windings of the stator coils vary to indicate the position of the rotor. Figure 6-86 illustrates the manner in which the voltages in the windings of the Selsyn generator may be computed for the zero position of the rotor. The Selsyn generator is designed so that the maximum voltage obtained between any two windings of the stator is 57.5 volts when 115-volt 400-cycle alternating current is applied to the rotor. This condition is obtained when the rotor is parallel to the magnetic flux path between any two windings or terminals. The flux direction between S_1 and S_2 is shown by the dotted diagonal line between S_1 and S_2 which is the resistant of the magnetic flux in each of the coils. Since the resultant flux between S_1 and S_2 is not parallel to the rotor R_1 and R_2 but at an angle of 30 degrees thereto, the voltage across S_1 and S_2 will not be 57.5 volts but rather

57.5 X cosine 30 degrees
57.5 X .866 = 49.8 volts.

The voltage between S_1 and S_3 is
57.5 X cosine 90 degrees
57.5 X 0 = 0 volts

The voltage between S_3 and S_2 is
57.5 X cosine 30 degrees
57.5 X .866 = 49.8 volts

The resultant of the magnetic flux in all the windings is a net resultant flux in the stator, parallel to the flux in the rotor. The direction of this resultant flux is illustrated by the black arrow in Figure 6-86.

If the generator rotor is now moved clockwise 30 degrees (Figure 6-87), the voltage between the stator terminals will change to move the resultant flux in the stator 30 degrees. This means that the direction of the resultant flux between S_1 and S_2 is now at an angle of 60 degrees to the rotor so that the voltage between S_1 and S_2 is now

57.5 X cosine 50 degrees
57.5 X .5 = 28.8 volts

In a similar way, it will be seen from Figure 6-87 that the voltage between S_2 and S_3 is 28.8 volts. The voltage between S_1 and S_3 is a maximum of 57.5 volts because the direction of the resultant flux between these points is parallel to the direction of the rotor flux so that maximum flux is linked. The result of the flux changes in the stator windings is to move the resultant direction of flux through the stator 30 degrees clockwise parallel to the rotor flux.

In this way, the direction of resultant flux in the stator follows movement of the rotor in either direction. If now the flux direction in the generator stator is transferred to the stator of the Selsyn control-transformer, the rotor of the control-transformer will now be the position of the generator rotor.

7. ELECTRICAL CONNECTIONS BETWEEN SELSYN GENERATORS AND SELSYN CONTROL-TRANSFORMERS

The stators of the Selsyn generator and control-transformer are shown electrically connected. When the generator rotor is energized with 115-volt 400-cycle alternating current, voltages in both the stator windings are the same and the direction of the resultant magnetic flux in both stators will be the same as indicated by the arrows. The direction of flux in the control-transformer stator is at right angles to the rotor so that no voltage signal appears across the rotor terminals R_1 and R_2. This means that the turrent and sighting station are in alignment because the system is set up and the Selsyns zeroed with their rotors in the electrical position.

8. HOW THE SELSYN SIGNAL VARIES IN MAGNITUDE WITH AMOUNT OF SIGHT MOVEMENT

If the sighting station is moved so that the rotor of the Selsyn generator moves clockwise 30 degrees, the direction of flux in the control-transformer stator is likewise moved 30 degrees. This means that a portion of the control-transformer stator-flux links with the control-transformer rotor so that a voltage appears across the rotor terminals R_1 and R_2. Due to the characteristics of the control-transformer rotor, the maximum voltage output signal is aproximately 57.5 volts which occurs when the direction of flux in the stator is parallel to the rotor. (When the direction of flux is at right angles the voltage output in the rotor is zero.) However, since the flux direction is at an angle of 60 degrees to the rotor, the voltage output signal of the control-

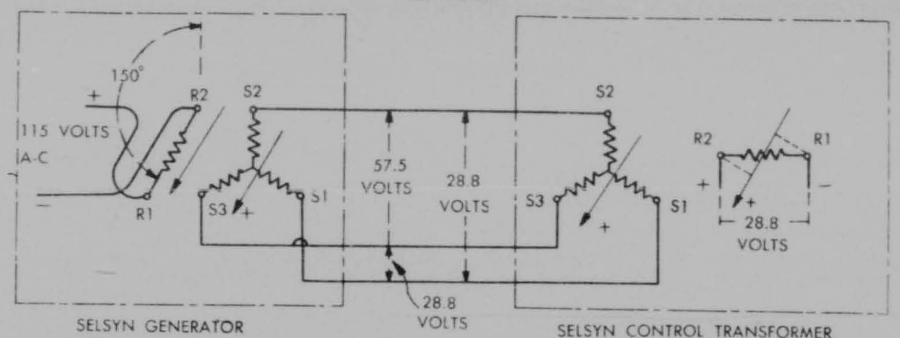

Figure 6—88. How Counterclockwise Movement of Generator Rotor Affects Magnitude and Polarity of Voltage in Control-transformer Rotor.

transformer rotor will amount to

57.5 volts X cosine 60 degrees
57.5 X .5 = 28.8 volts

In this way it will be seen that the magnitude of the voltage-output signal of the Selsyn control-transformer varies directly with the magnitude of the angle through which the sighting station has been rotated. This voltage signal is varied because the rotor of the Selsyn generator on the sighting station is rotated to change the voltage in the Selsyn stators whenever the sighting station is moved.

9. HOW THE POLARITY OF THE SELSYN SIGNAL CHANGES WITH THE DIRECTION OF SIGHT MOVEMENT

The signal voltage from the control-transformer must not only be capable of determining the amount of sight movement, it must also give an indication of the direction of movement. This is accomplished by changing the polarity of the signal voltage in accordance with the direction of movement.

The 400-cycle alternating current has been stopped at that instant on the portion of the cycle when terminal R_1 of the rotor is positive (+) and terminal R_2 negative (—). At this same instant the magnetic flux bath, represented by the directional arrow, will have a + polarity opposite the + end of the rotor. The polarity of the flux represented by the directional arrow will be duplicated in both Selsyn stators and also link the control-transformer rotor. As the + end of the arrow is nearest terminal R_1 of the control-transformer rotor, this terminal R_1 will have a + polarity. (The polarity of R_1 and R_2 may also be determined by projecting a line from the terminals at right angles to the flux directional vector and determining which projected line is nearer the + end of the arrow.) For a 30-degree clockwise rotation of the generator rotor the voltage signal from the control-transformer is 28.8 volts with terminal R_1 of + polarity.

In Figure 6-88 the generator rotor has been rotated 150 degrees counterclockwise by moving the sighting station. This position brings the generator rotor parallel to the position when it was rotated 30 degrees clockwise. This means that the voltages appearing in the stator windings are the same so that the voltage signal from the control-transformer rotor is the same. Although for both positions of the generator rotor, the output signal is 28.8 volts, the Selsyn system distinguishes between the two positions by changing the polarity of the signal. Assuming the alternating current stopped at the same portion of the cycle when terminal R_1 of the generator rotor is positive (+), then when the rotor is moved to the 150-degree position, the + end of the flux direction arrow will be pointed in the opposite direction in Figure 6-88, from that shown by Figure 6-87 because the + end is opposite the + terminal R_1 of the generator rotor. However, the + end of the flux directional arrow is now near-

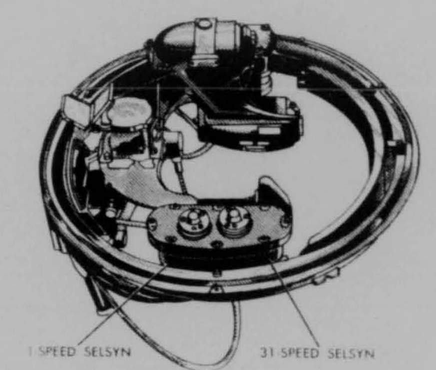

Figure 6—89. Location of 1 and 31-speed Selsyn Generators on Sighting Station.

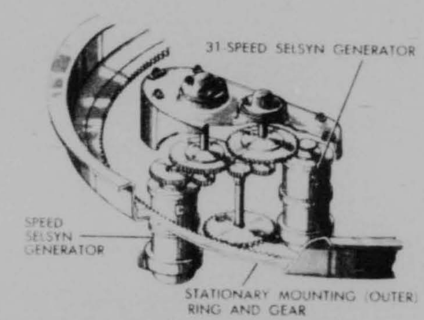

Figure 6—90. Schematic View of Selsyn Gearing on Sighting Station.

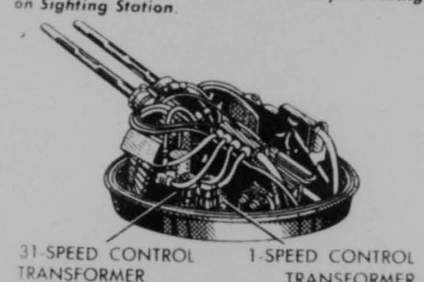

Figure 6—91. Location of 1 and 31-speed Selsyn Control Transformers on Turret.

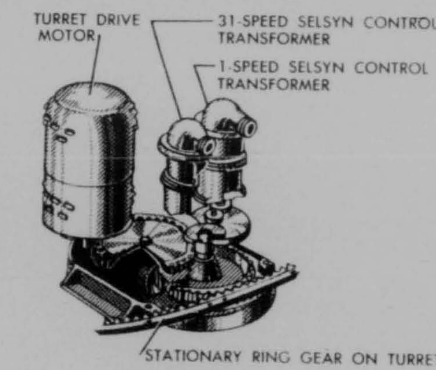

Figure 6—92. Schematic View of Selsyn Gear Train on Turret.

est the R_2, terminal of the control-transformer rotor so that R_2 is positive (+). Thus the polarity of the voltage signal output from the control-transformer varies depending upon the direction of movement of the sighting station even though in certain instances the magnitude of the voltage may be the same.

10. 1- AND 31-SPEED SELSYN SYSTEM

Selsyn generators and control-transformers are subject to small electrical errors due to manufacturing tolerances. Since the turret system must be extremely accurate, certain of the Selsyn units are geared to rotate at speeds higher than those of the turret or sighting stations. Figure 6-89 shows the sighting station with a Selsyn generator mounted thereon to rotate 31 times for every revolution of the sight. The gear train for driving the Selsyn generator is shown by Figure 6-90. If an error of one-half degree occurred in the Selsyn system the actual error at the turret would be 1/62 degree due to the reduction gearing. In addition to the 31-speed Selsyn generator, the system includes a 1-speed Selsyn generator. Figures 6-89 and 6-90, also show a Selsyn generator mounted on the sighting station and geared to rotate once for each revolution of the sight.

In a similar manner the turret is provided with 1- and 31-speed Selsyn control-transformer, Figure 6-91. These control-trans-

THIS PAGE IS DECLASSIFIED IAW EO 13526

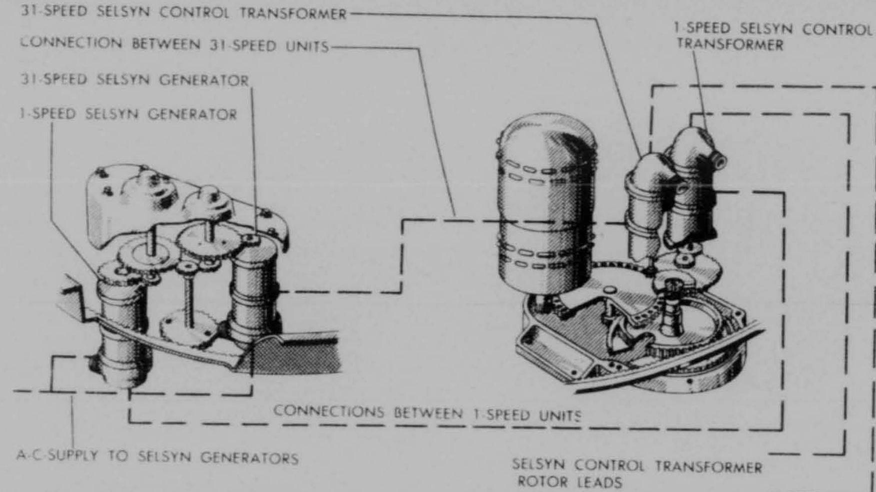

Figure 6–93. Schematic View of Electrical Connections Between 1 and 31-speed Selsyns on Sighting Station and Turret.

formers are driven through the gear train illustrated by Figure 6-92. It should be noted that 1- and 31-speed Selsyn units are used in both the azimuth and elevation Selsyn systems. This means that the sighting station carries a total of four Selsyn generators and the turret four Selsyn control-transformers.

The manner in which the 1- and 31-speed Selsyn units on the sighting station and turret are interconnected is illustrated schematically by Figure 6-93. The corresponding 1- and 31-speed Selsyn stators are electrically connected, as indicated by the broken lines. Both the 1- and 31-speed Selsyn generators on the sighting station are energized by 115-volt 400-cycle alternating current from the dynamotor. Separate 1- and 31-speed Selsyn signal output voltages are obtained from both the 1- and 31-speed Selsyn control-transformers. Both the 1- and 31-speed signals are fed to the servo-amplifiers which selects the signal to be used. If the turret is out of alignment with the sight by more than approximately three degrees the 1-speed Selsyn signal will control the turret through the servo-amplifier. Within three degrees of correspondence the 31-speed signal has control.

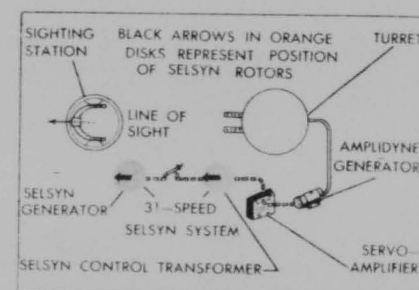

Figure 6–94. Schematic Representation of 31-speed Selsyn Units in Alignment.

11. WHAT HAPPENS WHEN ONLY THE 31-SPEED SELSYN SYSTEM IS USED

In Figure 6-94, a sighting station and turret have been illustrated in schematic outline together with a controlling 31-speed Selsyn system, servo-amplifier and amplidyne. The Selsyn generator and control-transformer are represented by shaded disks. The electrical connection between them is opened or closed by a knifeblade switch. In Figure 6-98 the turret and sighting station are in alignment.

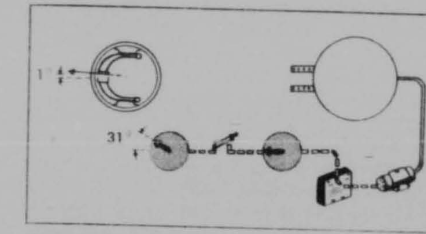

Figure 6–95. Rotation of 31-speed Selsyn Generator When Sighting Station is Moved One Degree.

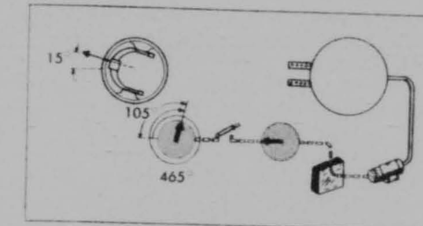

Figure 6–96. Rotation of 31-speed Selsyn Generator When Sighting Station is Moved 15 Degrees.

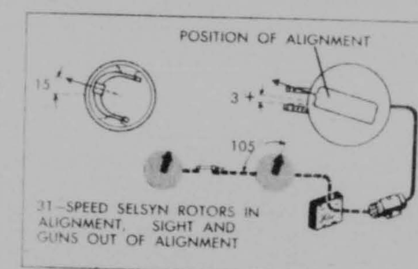

Figure 6–97. Movement of Turret When Electrical Connection Between 31-speed Selsyn Units is Closed.

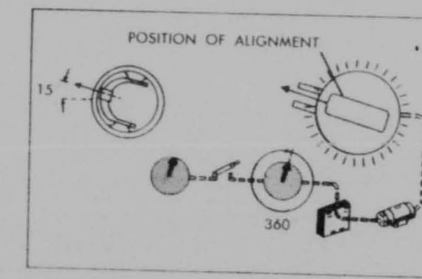

Figure 6–98. Movement of 31-speed Selsyn Control-transformer Rotor When Gun is Moved into Alignment with Sight.

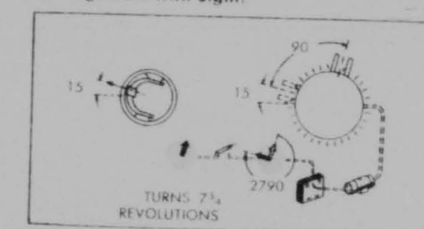

Figure 6–99. Movement of 31-speed Selsyn Control-transformer When Turret is Moved 90 Degrees out of Alignment with Sighting Station.

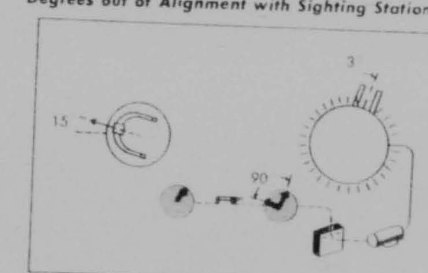

Figure 6–100. Movement of Turret Further out of Alignment When Electrical Connection Between 31-speed Selsyn Units is Closed.

In Figure 6-95 the sighting station has been moved one degree which rotates the 31-speed Selsyn generator 31 degrees. Since the switch is open, no signal is sent to the Selsyn control-transformer and the turret does not move. Figure 6-96 shows the position of the Selsyn generator when the sighting station has been moved 15 degrees. It will be seen that the Selsyn generator has moved one complete revolution of 360 degrees plus an additional 105 degrees. If the switch in the Selsyn system circuit is then closed the turret will be moved to drive the Selsyn control transformer into alignment with the Selsyn generator, or 105 degrees. (Figure 6-97). However, it is apparent that since the Selsyn control-transformer rotates 31 times for each revolution of the turret, the turret moves only approximately three degrees $\left(\frac{105}{31} = 3\right)$ to bring the

THIS PAGE IS DECLASSIFIED IAW EO 13526

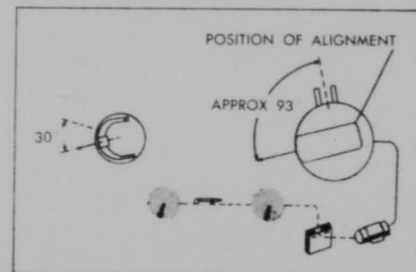

Figure 6—101. Turret Following Movement of Sighting Station but out of Alignment.

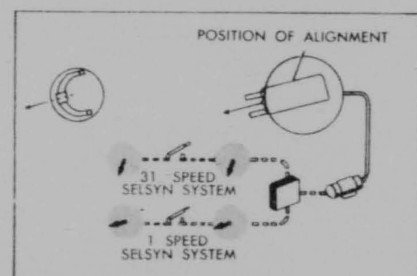

Figure 6—102. Schematic View of Both 1 and 31-speed Selsyn Systems.

Selsyn rotors into alignment. Thus with only the 31-speed Selsyn system operating it is possible for the Selsyn rotors to be in alignment electrically, at the same time that the turret and sighting station are out of alignment.

In Figure 6-98 the switch has been opened and the turret manually moved into alignment with the sighting station. Since the Selsyn rotors revolve 31 times for each revolution of the sight and turret, there are 31 points at which the Selsyn rotors in the system will be in alignment, but only one point where the turret and sight are in alignment. The 31 points at which the Selsyn rotors will line up are indicated by the lines radiating from the turret. It will be seen that one of the disadvantages of using only the accurate 31-speed Selsyn system is that the Selsyn rotors may be in alignment when the sight and turret are out of alignment.

In Figure 6-99 the turret guns have been moved manually 90 degrees out of alignment, with the switch in the Selsyn circuit open. This moves the Selsyn control-transformer 2790 degrees or $7\frac{3}{4}$ revolutions from the position shown by the dotted arrow to that shown by the black arrow. If the switch is now closed it will be found that the Selsyn control transformer will be driven 90 degrees by the turret into correspondence with the Selsyn generator but that at the same time the turret will be moved approximately three degrees farther out of alignment as indicated in Figure 6-100. The Selsyn system is now in alignment but the turret and sight are approximately 98 degrees out of alignment. If the sighting station is moved slowly, it will be found that the Selsyn rotors will rotate in alignment but that the turret and sight will remain 93 degrees out of alignment (Figure 6-101). Thus with a 31-speed Selsyn system only, it is possible to track a target with the turrets and sighting station out of alignment. The above mentioned difficulties encountered in using a 31-speed Selsyn system only, are overcome by the use of a 1-speed Selsyn system.

12. HOW THE 1-SPEED SELSYN SYSTEM ASSISTS THE 31-SPEED SYSTEM

In Figure 6-102 a 1-speed Selsyn system has been added to the Selsyn control and is indicated schematically by the shaded disks. A switch controls the 1-speed system. Also the guns have been manually moved into alignment with the sighting station so that both the 1- and 31-speed Selsyn systems are in alignment.

With both switches open the turret is manually moved 90 degrees out of alignment with the sighting station. As shown by Figure 6-103 the 31-speed Selsyn control-transformer will be rotated 2790 degrees and the 1-speed control-transformer 90 degrees so that both Selsyn control-transformers are out of alignment with their respective Selsyn generators. Now if the switches are closed it will be found that the servo-amplifier selects the 1-speed Selsyn system to take control and drive the turret to within about three degrees of alignment (Figure 6-104). With the 1-speed system there is only one position of alignment between the Selsyn units, and correspondingly only a single position of alignment between the turret and sighting station. After the turret and sighting station have been brought almost into alignment the servo-amplifier transfers control to the 31-speed Selsyn system (Figure 6-105) to bring the turret and sight accurately into alignment.

The 1-speed Selsyn system eliminates the possibility of the turret and sight lining up on any one of the 31 positions of correspondence which exist between the Selsyns in the 31-speed system except the one in which the sight and guns are also in alignment. Actually, the speed of response of the turret to movements of the sighting station is so fast that usually the turret and sight are within three degrees of alignment during normal tracking speeds so that the 31-speed Selsyn system only is used. The 1-speed system is brought into operation when the sight is moved quickly as when "slewing" the turret into position.

13. DYNAMOTOR

The aircraft dynamotor is a combination motor-generator with a common magnetic field and a two-winding armature (rotor assembly). It converts the 27-volt direct-current input into a 115-volt, 400-cycle, alternating-current output. Four units produce the 400-cycle power needed by the Selsyn generators and control-transformer and the servo-amplifiers of the system. The four dynamotors are allotted to the upper, nose, right-and-left-blister, and tail sighting stations respectively.

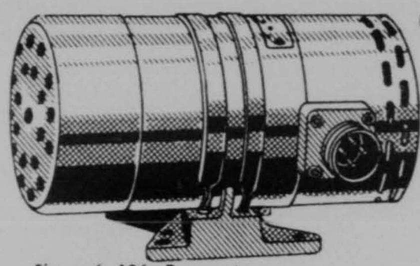

Figure 6—106. Dynamotor.

Component Parts

(Figures 6-106, 107, 108 and 109.) The dynamotor consists of a stator assembly, end covers, a rotor assembly, two brush riggings, a fan, and an AN connector.

Stator Assembly. The stator assembly consists of a steel shell, a yoke which is pressed into the shell, six pole pieces which are bolted to the field yoke, and six series-connected shunt windings. The complete assembly is strapped and bolted to a cast-aluminum base.

End Covers. The ends of the stator assembly are protected against damage by two sheet-aluminum covers. The commutator-end cover, with round ventilating holes in the end, is attached to the commutator-end shield. The collector-end cover is supported by the stator shell.

Rotor Assembly. The rotor assembly consisting of two balancing disks, armature core, armature windings, commutator, collector, and shaft is supported by the commutator-and-collector-end bearings. The bearings are supported by the commutator-end end shield and the collector-end end shield. Four clamp studs fasten the two end shields to the stator assembly. To complete the rotor assembly, the shaft is threaded and machined on the collector end to provide for the mounting of a nut, lock washer, fan, key, shim washers, and spring washer.

Brush Riggings. (Figure 6-110.) The commutator-end brush rigging is supported by the commutator-end end shield and consists of a circular brush yoke which can be shifted for the proper brush position, four spring-supported brush holders, and four brushes. The rigging is connected to pin B in the connector and to the stator assembly. The collector-end brush rigging, supported by the collector-end end shield, consists of a circular brush yoke, two brush spring-supported holders, and two brushes. The rigging is connected to pins A and C in the connector.

Fan. A fan is mounted on the rotor shaft at the AC end of the dynamotor, between the brush rigging and the end cover.

Connector, Capacitor and Resistor. An AN connector to provide a means for quickly connecting and disconnecting the dynamotor, a capacitor to reduce radio interference, and a resistor to add additional resistance in the

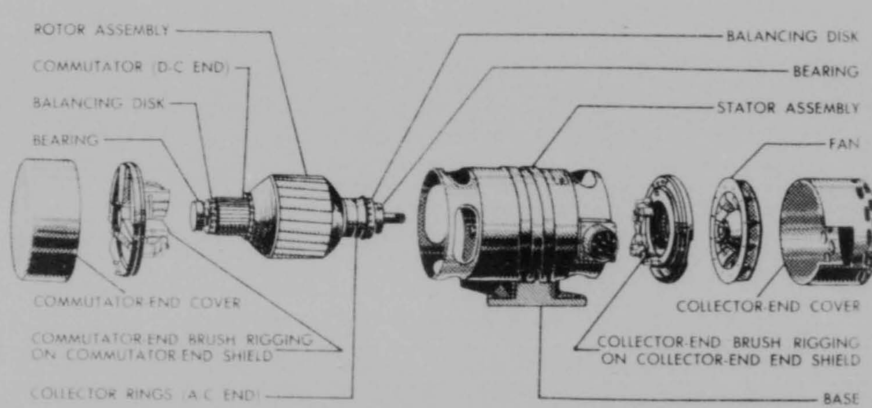

Figure 6—107. Dynamotor, with Major Parts Exploded.

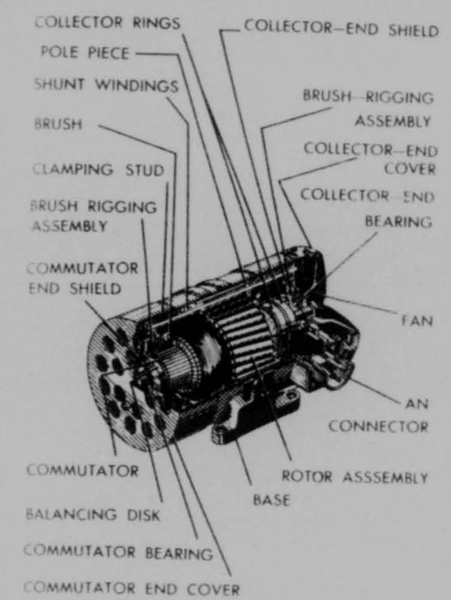

Figure 6—108. Dynamotor, Three Quarter View.

motor circuit complete the assembly. The capacitor is located on the commutator brush-rigging assembly; the resistor is located on the collector brush-rigging assembly.

14. OPERATION

(Figure 6-111.) An understanding of the dynamotor can be obtained from the schematic view of the rotor and field winding. In this view the direct-current input is represented as solid line and the alternating-current output is represented as broken line. Note that this view shows schematically the commutator-end (DC) brushes, the commutator, the field winding, the AC and DC windings of the rotor, the collector rings, and the collector-end (AC) brushes.

The dynamotor is really a DC motor and an AC generator with two sets of armature windings revolving in a common field. Power comes to the dynamotor from the 28-volt airplane system and energizes the field windings and the DC armature windings. Since all electric motors operate on the condition that a conductor (armature windings) carrying an electric current through a magnetic

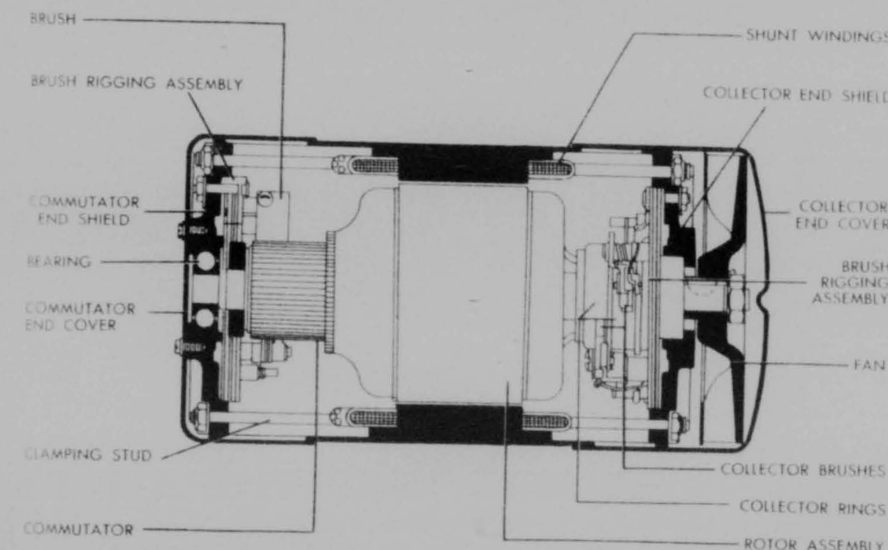

Figure 6—109. Dynamotor, Cross Section View.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Figure 6—110. Dynamotor Brush-Rigging Assemblies Mounted on End Shields.

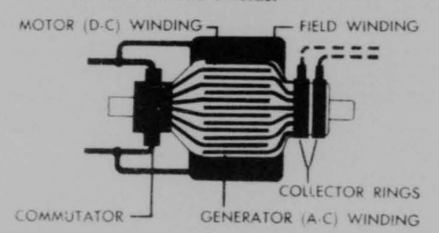

Figure 6—111. Dynamotor Schematic View

field (produced by the field winding) tends to move at right angles to the field, the "motor windings" of the dynamotor convert electrical energy into mechanical energy, causing the armature to rotate. Because the AC armature windings are also on the same armature, they are rotated as well.

The motor of the dynamotor is compound-wound, combining series and shunt characteristics. This is to provide quick starting and a reasonably constant speed while running. The series field winding has only a single turn; voltage drop across the winding is less than 0.5 volt. Thus the shunt field winding is connected across a 26.5 volt line, and current in the shunt winding and the resultant magnetic field is practically constant. The strength of the field being constant, makes the speed practically constant over a wide range of load.

The AC armature windings, revolving in the magnetic field, generate 400 cycles, 115 volt alternating current power. It is true that all electric generators operate on the principle

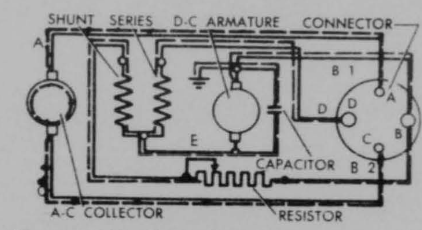

Figure 6—112. Connection Diagram for Dynamotor.

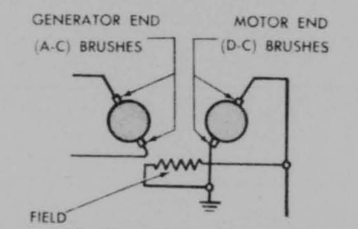

Figure 6—113. Electrical Symbol for Dynamotor.

that an armature conductor moved across a magnetic field generates a voltage. Thus as the AC (generator) windings are rotated in the magnetic field, they generate alternating current, which is taken off by the collector-end brushes. Since no electrical connection is made between the DC (motor) windings and the AC (generator) windings on the rotor, the generated voltage is proportional to the speed (practically constant) and the field strength (practically constant). The generated frequency is also exactly proportional to the speed. To sum up, two characteristics mark the dynamotor:

A generated voltage that is proportional to the input voltage and

A generated frequency that is fairly constant.

Dynamotor Connections

(Figures 6-112 and 6-113). Power is brought to the dynamotor through the AN connector. The diagram (Figure 6-112) shows the dynamotor connections.

SECTION IV—TURRET DRIVE MOTOR AND TWO GUN TURRETS

1. AMPLIDYNE MOTOR-GENERATOR

Upper-forward, Lower-forward, Upper-rear, and Lower-rear Turrets

An amplidyne motor-generator (often called the "amplidyne") is simply a special type of motor-generator set. In a conventional motor-generator, a motor driven by one type of electricity, drives a generator which generates a different type of current from that originally supplied to the motor. The amplidyne motor-generator used in the central-station fire-control system has the motor and the generator mounted in a single housing. The motor, driven by the direct-current supply from the airplane, drives the rotor of the generator. This amplidyne is a direct-current generator which amplifies, or multiplies the less-than-one-watt input to its control field (generator stator) into the more-than-500 watt output of its armature (generator rotor). The energy for this tremendous increase between input and output is obtained from the mechanical energy of the generator rotor, which is driven by the motor.

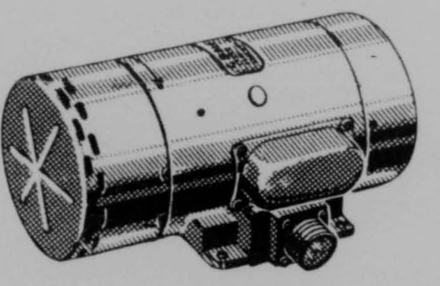

Figure 6—115. Eight Amplidyne Motor-Generator.

Rating

There is complete data on the eight amplidyne motor-generators (Figure 6-115) used in the azimuth and elevation control circuits for the upper-forward turret, lower-forward turret, upper-rear turret, and lower-rear turret. (Reference should be made either to the amplidyne nameplate or the following information.)

INPUT (MOTOR)	
Volts, direct-current	27
Amperes, direct-current	44
OUTPUT (GENERATOR)

Speed, rpm.	8300

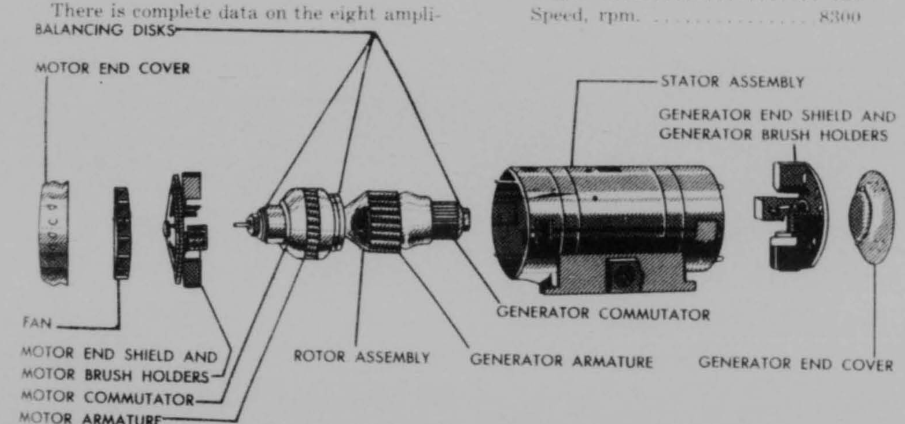

Figure 6—116. Amplidyne Motor-Generator with Major Parts Exploded.

THIS PAGE IS DECLASSIFIED IAW EO 13526

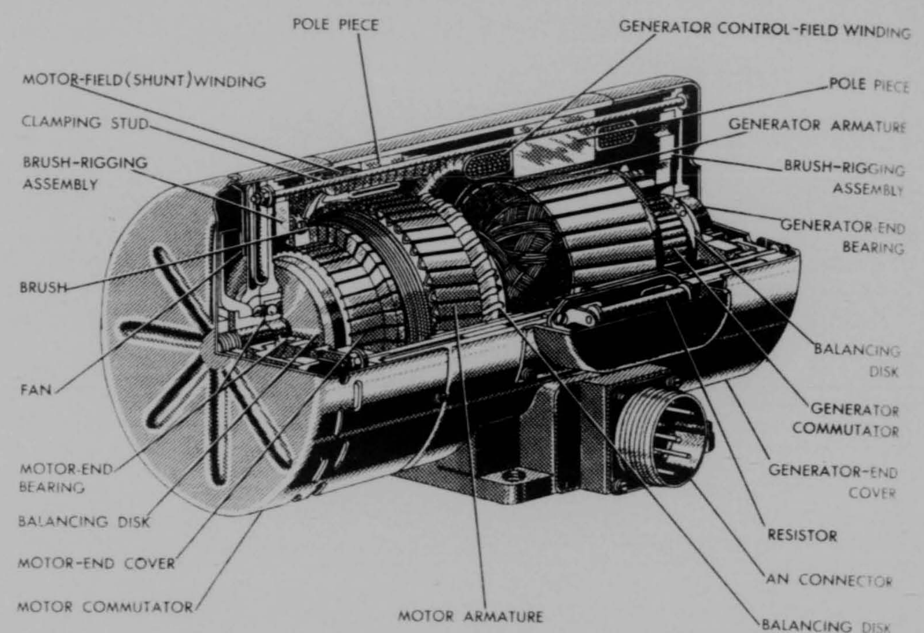

Figure 6—117 Amplidyne Motor-Generator, Three Quarter View.

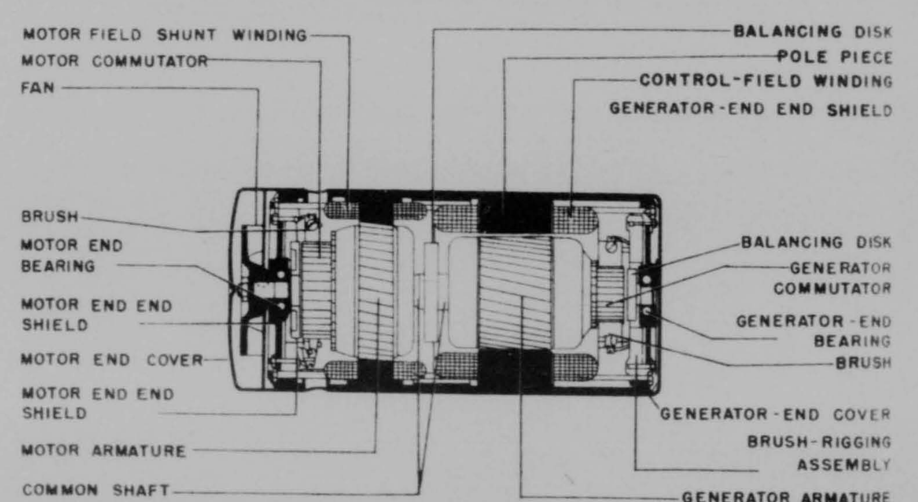

Figure 6—118. Amplidyne Motor-Generator, Cross Section View.

Component Parts

(Figures 6-116, 117 and 118.) The amplidyne motor-generator consists of a stator assembly; a rotor assembly; a brush rigging assembly for the generator end; and a brush-rigging assembly for the generator end; a fan; and two end covers, the motor end cover and the generator end cover.

Stator Assembly. The motor end of the stator assembly consists of a steel shell, eight pole pieces, eight series-connected shunt windings, and eight series-connected series windings. The generator end consists of the steel shell supporting two pole pieces and three separate series-connected windings: the series-quadrature field, the compensating field, and the control field.

End Covers. The ends of the stator are protected against damage by two sheet-aluminum covers: the motor-end cover, with ventilating slots in the sides, and the generator-end cover, with round ventilating holes in the end.

Rotor Assembly. The rotor assembly consisting of three balancing disks, a motor-armature core with a winding and a large-diameter commutator, a generator-armature core with a winding and a small-diameter commutator, and a shaft, is supported by the motor-and-generator-end bearings. The bearings are supported by the motor-end end shield and the generator-end end shield. Four clamp studs fasten the two end shields to the stator assembly. To complete the rotor assembly, the shaft is threaded and machined on the motor end to provide for the mounting of a nut, lock washer, fan, key, shim washers, and spring washer.

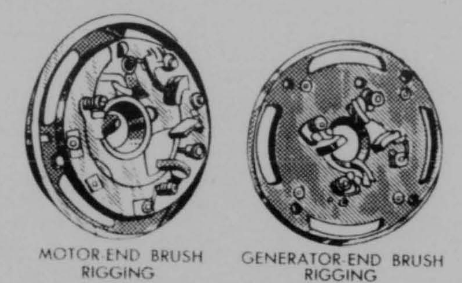

Figure 6—119. Brush-Rigging Assemblies Mounted on End Shields.

Brush-rigging Assemblies. (Figure 6-119.) The motor-end brush rigging is supported by the end shield and consists of a circular brush yoke which can be shifted for the proper brush position, six spring-supported brush holders, and six brushes. The rigging is connected to the stator assembly by a gray wire. The generator-end brush rigging, supported by the generator-end end shield, consists of a circular brush yoke, four spring-supported brush holders, and four brushes. This rigging is connected to the connector by a red wire and to the stator assembly by a yellow wire and two gray wires.

Fan. A fan is mounted at the motor end of

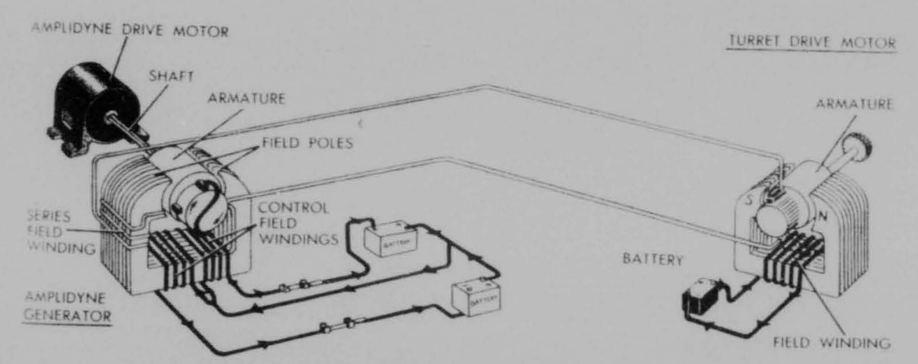

Figure 6—120. Amplidyne Turret Drive Motor Connections—Schematic View.

THIS PAGE IS DECLASSIFIED IAW EO 13526

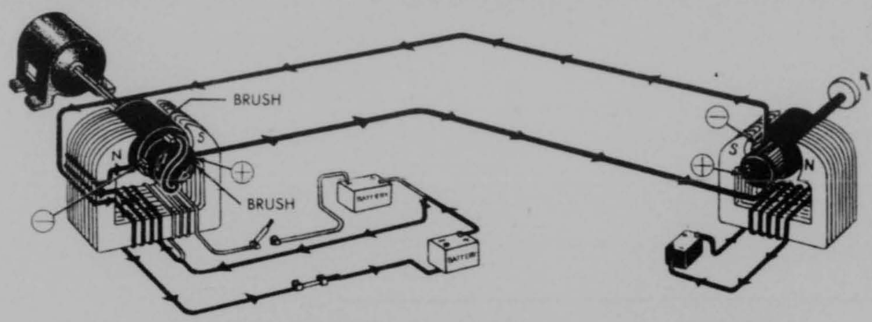

Figure 6–121. Amplidyne Turret Drive Motor Connections—Schematic View.

the rotor assembly shaft, between the end cover and the motor-end end shield.

Connector, Capacitor and Resistor. An AN connector to provide a means for quickly connecting and disconnecting the amplidyne, a capacitor to reduce radio interference, and a resistor to add additional resistance to the compensating winding complete the assembly. The capacitor is located under the cover plate opposite the connector assembly. The resistor is located under the cover plate just above the connector assembly.

Operation

The function of the amplidyne is to supply power for the turret-drive motor. The power to the drive motor must be direct current, capable of a wide variation in voltage. It also is necessary to reverse the direction of current flow. Polarity of the direct current must be reversed in order to drive the turret motor in the direction desired. In describing the operation of the amplidyne, the electrical principles by which it works will not be explained, but rather how it is controlled by the Selsyn-amplifier circuits, and how it, in turn, controls the turret-drive motor.

In Figure 6-120 there is a schematic representation of the amplidyne turret drive motor circuit. The turret-drive motor is shown at the right. In looking at the amplidyne generator it can be seen that it is similar in schematic construction to the turret drive motor. The amplidyne generator has an armature with its commutator, brushes, field poles, and control-field windings. It will be noted that the control-field winding is divided into two halves. In addition there is a compensating-field winding, and two brushes. These brushes, which are connected, are known as "short-circuited brushes."

The compensating-field winding and the short-circuited brushes are characteristic of the amplidyne generator but these will not be considered in an explanation of this system. They are important only in giving the amplidyne generator its unusual electrical characteristics.

The armature shaft of the amplidyne generator is shown connected to the amplidyne drive motor. Actually this motor and the amplidyne generator are built into one assembly and mounted as a single unit.

The amplidyne drive motor is actually connected to the airplane's direct-current supply which makes it run at a constant speed, always in the same direction, driving the amplidyne generator armature continuously clockwise as shown by the arrows on the generator commutator.

With the armature leads of the separately excited turret-drive motor connected to the amplidyne generator brushes, it can be seen that the driving of the turret motor will depend upon the direct-current voltage generated by the amplidyne-generator armature.

This amplidyne generator is no more than a direct-current generator in which the direct-current voltage produced within the constantly rotating armature depends upon the direction and amount of the magnetic path

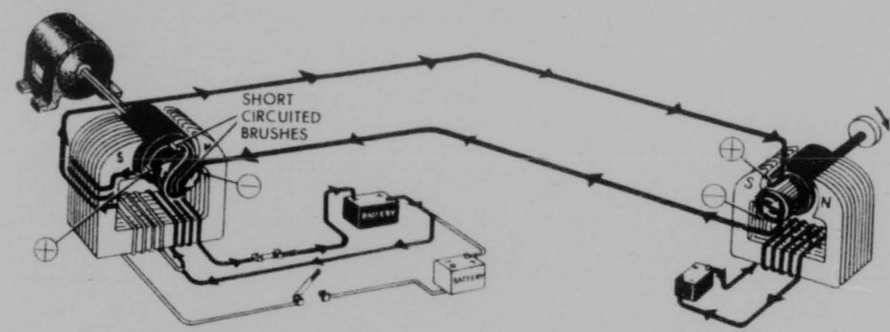

Figure 6–122. Amplidyne Turret Drive Motor Connections—Schematic View.

produced between the field poles by the control-field windings.

The amplidyne is made with two control-field windings. The control-field windings are wound on the field poles in such a way that if current (shown as arrows) through one winding is the same as current through the other winding, then the ends of the field poles are both magnetically north N which does not allow the rotating armature to generate a voltage since a magnetic path will not cross between like magnetic poles. Since there is no armature voltage generated, there is no power to the turret drive motor.

These two control-field windings may be compared to two teams playing "tug-of-war": when both teams pull the same, the rope stands still; if one team pulls harder than the other, the rope moves toward it. In Figure 6-121 there is more current, more pull through the left control-field winding and less or none through the right.

This makes the left field pole north N and the right field pole south S and thus gives a magnetic path between the unlike poles. A voltage is now generated in the amplidyne armature with the right brush positive and the left brush negative, causing the turret motor to turn counter-clockwise.

If the right winding gets more current than the left one, then the left brush becomes positive and the right brush negative, making the turret motor turn clockwise. See Figure 6-122.

Note: The central-station fire-control system using the amplidyne is concerned only with the balancing and unbalancing of the opposite control fields in the amplidyne.

The amplidyne generator is especially suited to the central-station fire-control system because this type of generator permits the use of a very small field current (represented by the arrows in Figure 6-122 to give a relatively large current represented by the arrows) from the generator armature. This proportion of armature current to field current is much higher than for ordinary generators, so from this it is evident that the amplidyne has a very high "amplification."

Amplidyne Symbol

The symbol for the amplidyne generator used in electrical diagrams is shown in Figure 6-123. Note the two control-field windings, the amplidyne armature, the compensating-field winding, the brushes (with the characteristic tie between two of them to indicate that they are short circuited) the shaft, and the drive motor. In the top view, the control-fields are shown balanced; in the two lower views, first one then the other control-field is shown with the greater amount of current.

Amplidyne Motor-generator connections

Power is brought to the amplidynes through an AN connector. This connector has seven pins, which are connected. See Figures 6-124 and 6-125.

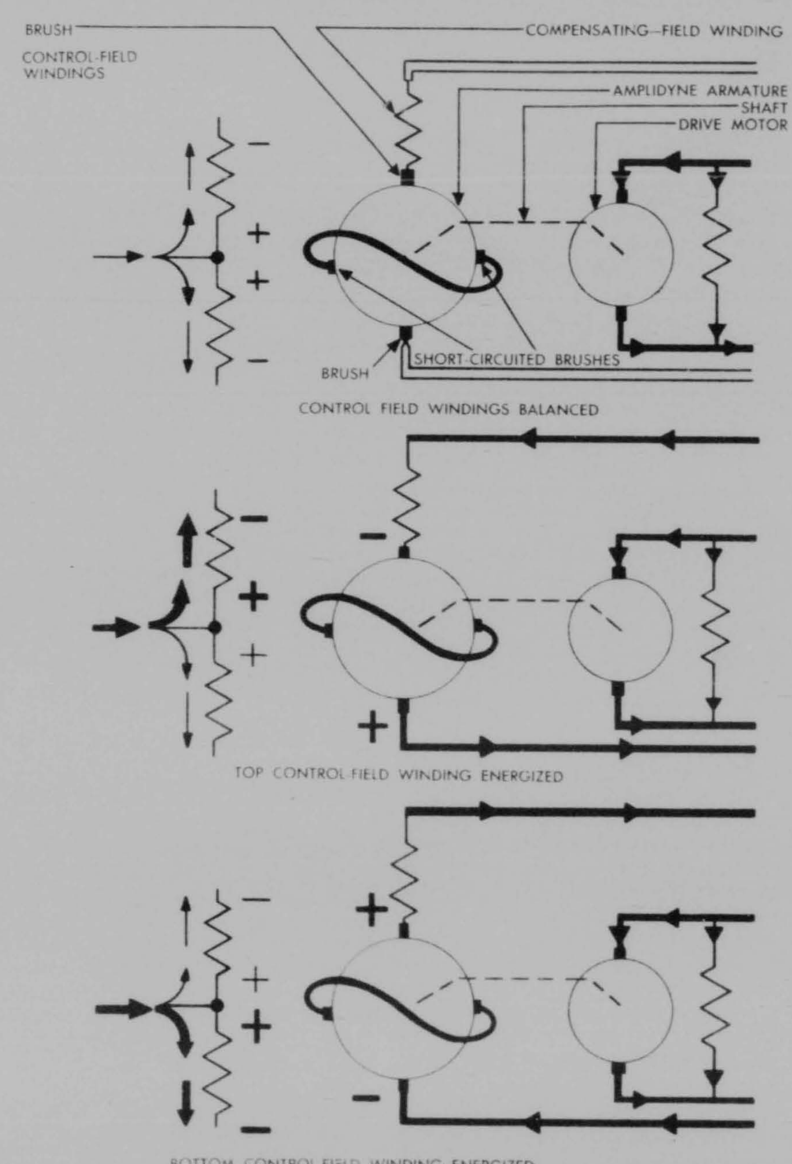

Figure 6—123. Electrical Symbol Representing Amplidyne Motor-Generator.

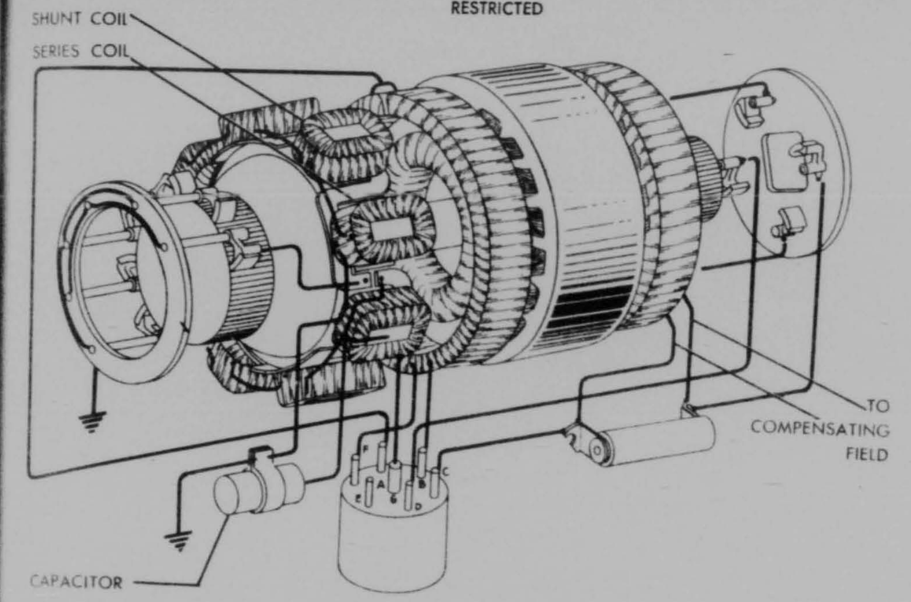

Figure 6—124. Amplidyne—Schematic View.

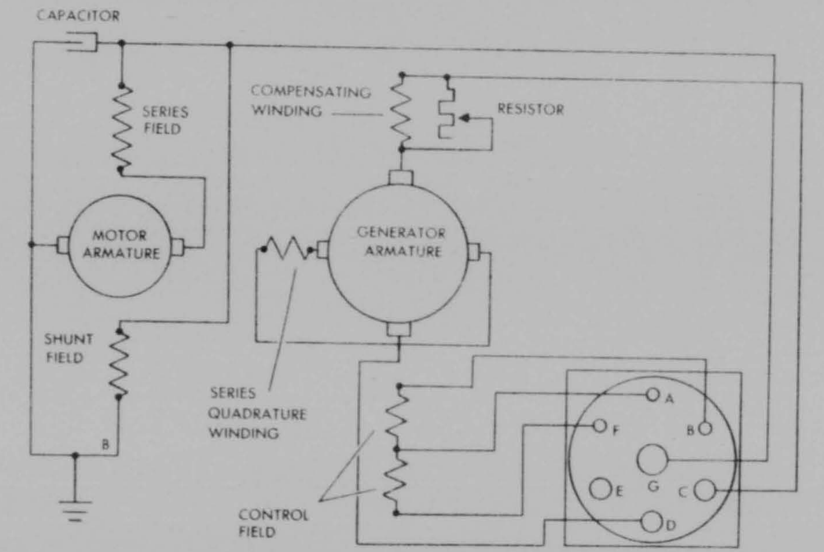

Figure 6—125. Connection Dingram for Amplidyne

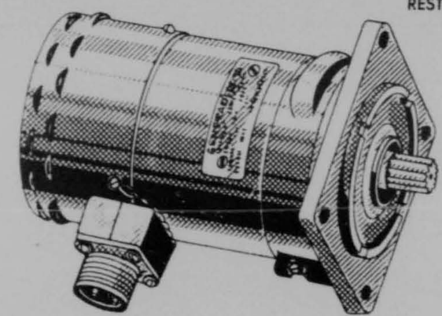

Figure 6—126. Assembled View Turret-Drive Motor.

2. DRIVE MOTORS

Lower-forward, Upper-aft, and Lower-aft Turrets

To parallel the line of fire with the line of sight, the turrets are moved in either azimuth or elevation by turret-drive motors. Since the outer rings of any of the four turrets is stationary with respect to the airplane, and the azimuth drive motor is mounted vertically on the inner-ring assembly, rotation of the motor causes rotation of the turret within the fuselage. The complete turret including dome, guns, ammunition frame, and ammunition, rotates in azimuth as a unit. And, since the pinion of the elevation-drive assembly mates with a gear sector on the gun saddle, rotation of the elevation drive motor causes the guns to elevate or depress depending on the direction or rotation. Thus, by a combination of azimuth and elevation turret-drive motors, the guns can be directed at any point in a hemisphere.

Rating

There is complete data on the direct-current motors (Figure 6-126) for the azimuth and elevation drive assemblies on the upper-forward turret, lower-forward turret, upper-aft turret, and the lower-aft turret. Reference should be made either to the motor nameplate or to following information.

INPUT

Volts, direct-current	28
Amperes, direct-current	2.3
Rotor assembly (armature)	
Volts, direct-current	60
Amperes, direct-current	8.3
OUTPUT	
Horsepower	0.5
Speed, rpm	4000

Structure. (See Figures 6-127, 128 and 129.)

Stator Assembly. The stator consists of a shell containing the field poles and field windings. The four pole pieces are bolted to a steel yoke which is pressed into the stator shell. The stator windings are assembled with the poles as their core.

Rotor. The rotor consists of a shaft on which are mounted the punchings with windings, the commutator, a balancing disk, and the ball bearings.

Commutator. The commutator consists of wedge-shaped bars of copper insulated from each other by strips of mica. These are assembled onto a steel support, and the entire unit is then pressed onto the shaft. Each end of

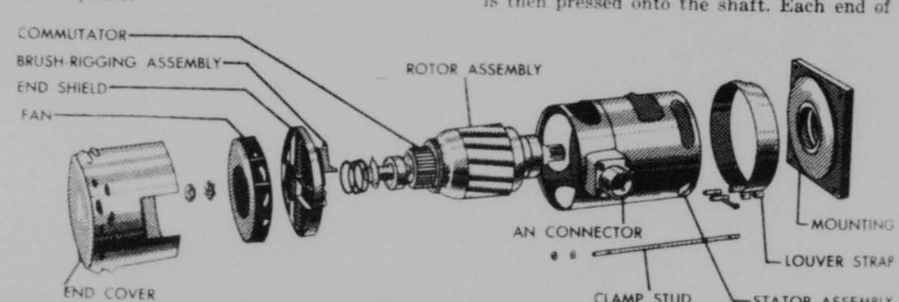

Figure 6—127. Turret-Drive Motor, Major Assemblies.

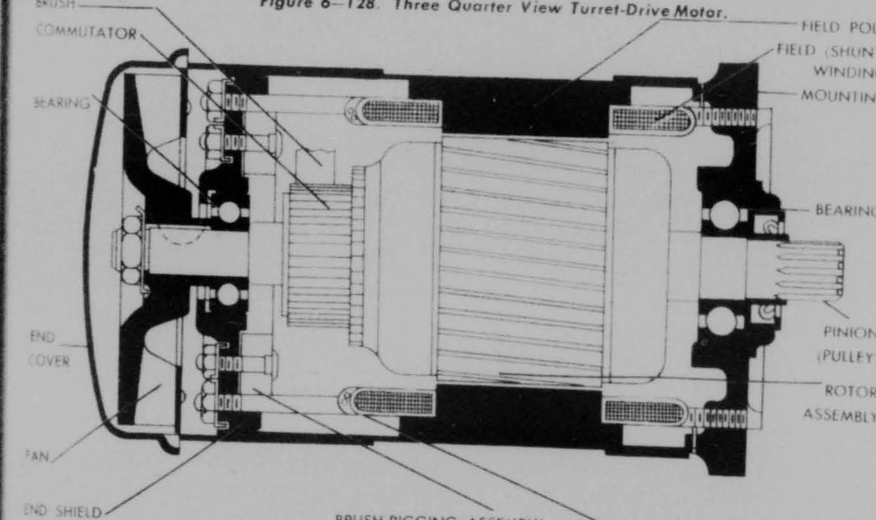

Figure 6—129. Cross Section View Turret-Drive Motor.

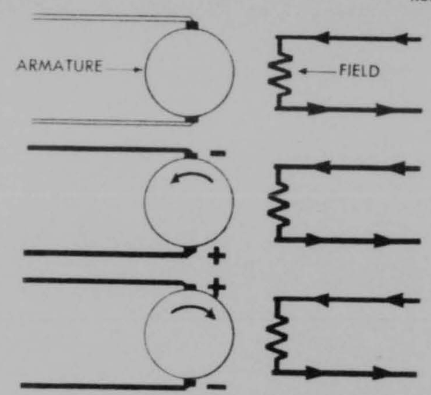

Figure 6—130. Turret Drive Motor Symbol.

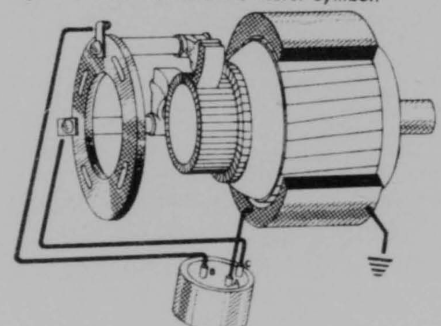

Figure 6—131. Schematic View. Connections for Turret Drive Motor.

each armature-winding coil is soldered to one of the commutator bars.

Bearings. The bearings are mounted one on either end of the rotor shaft, and fit into bearing housings in the end shields. The bearings are of the shielded, ball-bearing type.

End Shields. The end shields are fastened to the stator assembly by means of long clamp-stud bolts extending the length of the stator shell.

End-play Control. The rotor end play is controlled by means of shim washers and a spring washer located in the bearing housing of the commutator-end end shield. The spring washer allows the rotor shaft to expand and contract without danger of binding when hot, developing excess endwise motion when cold.

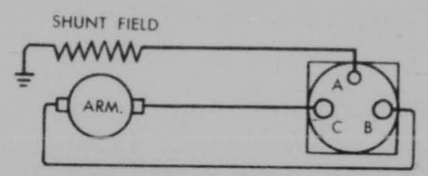

Figure 6—132. Diagram of Electrical Connection for Turret Drive Motor.

The end play may be adjusted by inserting or removing shim washers.

Brush Rigging. The brush rigging, together with the commutator, provides the means by which electrical connection is made between the stationary stator and the movable rotor. The brush rigging consists of an insulating yoke to which the brush holders are attached. The brushes are fastened in these brush holders by means of screws. They are kept in contact with the commutator bars by means of torsion springs which maintain a pressure against the brush holders. The brush yoke is mounted on the inner side of the commutator-end end shield by means of screws. Connection to the brush rigging is made by means of terminals mounted on the brush yoke.

External Connections. The connections from the power source to the stator windings and brush rigging are made by means of a receptacle mounted on the stator shell.

Operation

The model 5BA50LJ2A motor is a separately excited shunt-wound motor. This means that the field windings and armature windings are connected in parallel with each other and that current for the two windings is supplied from different sources.

Direction of Rotation. A reversal of rotor rotation in a direct-current motor may be accomplished by changing the relative direction of current flow through the field or armature windings. This is accomplished by changing the polarity of the connections to the armature windings.

Speed of Rotation. Separately-excited shunt-wound motors are useful in applications where variable speed control is desired.

The driving of a gun turret is such an application. The shunt-field voltage is supplied by a constant voltage from the plane generator and the armature voltage is supplied by the controlled variable-voltage source, the amplidyne motor-generator. Since the output of the amplidyne motor-generator may be varied both in polarity and in voltage, the direction of rotation and speed is controlled over a range of from zero to several thousand rpm.

Turret Motor Symbol

The schematic representation of the turret drive motor (Figures 6-131 and 6-132) will show how it can be controlled by the Selsyn-amplifier-amplidyne circuits. In actual practice on electrical diagrams, such schematic representation would take unnecessary space, so an electrical symbol for the motor is used. The turret-motor symbol is shown in Figure 6-130. In the top view, the field represented is energized by the aircraft generator at a constant voltage (27 volts). There is no voltage to the armature; therefore the motor does not turn. The two lower views (Figure 6-130) simply show the armature energized, with the top brush negative, and then with the top brush positive, and an indication of a reversed direction of rotation as the polarity is changed.

Turret Motor Connections

Power is brought to the turret drive motor through an AN connector. This connector has three pins marked respectively "A," "B," and "C."

Pin A is connected to the main DC supply of the airplane, and to the positive side of the motor field winding Figures 6-131 and 6-132). The negative side of the field is connected to ground.

Pins B and C are connected to the amplidyne output and to the brushes of the turret drive motor (Figure 6-131).

SECTION V—FOUR GUN TURRET, TAIL MOUNT, AND CONTROL BOXES

1. FOUR-GUN UPPER-FORWARD TURRET

General

The upper-forward turret is located in the forward crew nacelle.

Armament

Four cal. .50 machine guns. Each gun is furnished with approximately 925 rounds of ammunition carried in four ammunition cases designed to fit the contour of the frame assembly.

Approximate Dimensions

The over-all diameter across the dome is 48 inches. The over-all diameter across the ammunition cases is $41\frac{11}{64}$ inches. The overall height of the turret is $67\frac{11}{64}$ inches.

Approximate Weight in Pounds

The approximate weight of the turret fully loaded is 1,938 pounds.

Limits of Turret Movement

This turret rotates continuously through 360 degrees in azimuth and between —5 and +90 degrees in elevation. Power and control signals are introduced into the turret by a collector assembly which prevents the incoming cable from becoming twisted as the turret rotates. Guns are moved into alignment with the sight by an azimuth drive which rotates the guns in a horizontal plane, and by an elevation drive which moves the guns in a vertical plane.

Basic Parts of Upper-forward Turrets

(Figure 6-133.) The upper-forward turret

Rings, Supports, and Drives

(Figure 6-133.) The main assemblies of the rings, supports, and drives are the ring assembly on which the entire turret is mounted, the saddle-support assembly which supports the saddle assembly, and the drive assemblies which electrically drive the turret into alignment with the sighting station.

Ring Assembly. (Figure 6-134.) The purpose of the ring assembly is to secure the turret to the fuselage of the airplane and to furnish a mount on which the turret can continuously rotate through 360 degrees in azimuth.

Components. The main components of the ring assembly (Figure 6-134) (12) are: an outer ring (6), inner ring (5), radial and thrust bearings (7 and 8) together with adapter and baffle assemblies which are attached to the ring assembly, but are not considered components.

Outer Ring and Azimuth Gear. (Figure 6-135.) The outer-ring assembly is a Z-shaped aluminum-alloy drawn ring, the upper flange of which is bolted to the airplane's fuselage so that the outer ring (1) remains stationary. The azimuth ring gear (2) is bolted to the lower flange and meshes with the main gear of the azimuth drive, which drives the turret in azimuth. A 32-bearing assembly bolted to the periphery of the outer ring ride in a track riveted to the inner ring. Protecting the inner turret from dirt, rain, and other foreign mat-

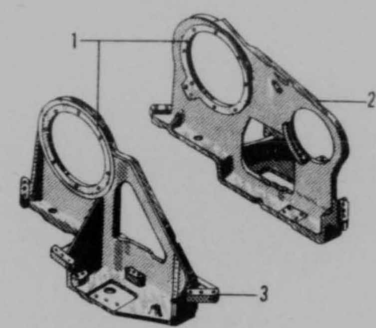
1. ANCHOR PIN 2. UPPER FLANGE OF ADAPTER

Figure 6—138. Adapter Assembly.

ter, is a felt seal, cemented on the upper-flange of the outer ring, filling the space between the inner and outer ring.

Inner-ring Assembly. (Figure 6-136.) This assembly is made of aluminum-alloy and is concentric with the outer ring. A stainless steel channel (3), riveted to its outer circumference guides the radial and thrust bearings that are bolted to the periphery of the outer ring. Five T-shaped aluminum pieces (1), riveted to the inner circumference (2) of the assembly, secure the saddle support assemblies which are bolted to its flange.

Radial Bearing Assembly. (Figure 6-137.) Sixteen radial bearings (4) are bolted between the sixteen thrust bearings (3) around the periphery of the outer ring (6). The radial bearings restrict the horizontal movement of the turret with respect to the outer ring. The tolerance between the track and the bearings must be sufficient to permit free operation of



1. TRUNNION BEARINGS
2. RIGHT-HAND SADDLE SUPPORT
3. LEFT-HAND SADDLE SUPPORT

Figure 6—139. Saddle Supports.

the turret and yet must prevent mechanical play.

Thrust-bearing Assembly. (Figure 6-137.) Sixteen thrust bearings (3) bolted around the periphery of the outer ring (6), absorb all vertical loads upward or downward including normal gravity loads plus additional loads due to diving and climbing, with guns in various positions. Sudden vertical loads caused by turbulent wind conditions, are also absorbed by the thrust bearings.

Adapter and Baffle Assemblies. (Figure 6-138.) The adapter is an aluminum-alloy assembly secured by its lower flange to the top of the inner-ring assembly. Twenty-three equally-spaced anchor pins (1), adapter facilitates installing the dome without catching on other components of the turret. Two steel baffles, attached to the bottom of the inner-ring assembly, cover the azimuth ring gear and prevent the ammunition from catching on the ring gear. They also prevent damage to the ring gear from the cal. .50 shell cases as they are fed to the gun. The adapter and baffle assemblies, attached to the ring assembly are not considered part of the ring assembly.

Saddle Supports (Figure 6-139.)

The saddle-support assemblies are aluminum-alloy castings mounted on the flange of the inner-ring assembly. The trunnion bear-

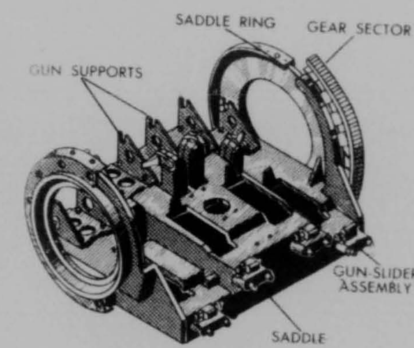


Figure 6—140. Saddle Assembly.

ings (1) support the saddle assembly within steel inserts and allow free movement of the guns in a vertical plane. The left-hand saddle support (3) mounts the azimuth drive assembly. The right-hand saddle support (2) mounts the elevation drive assembly, and the contour-follower mechanism. An ammunition booster assembly is attached to the outside of each saddle support.

Saddle Assembly (Figure 6-140.)

Function. The saddle assembly is supported between the left and right-hand supports, and mounts the four cal. .50 machine guns. Guns are elevated or depressed by the elevation drive, which engages the gear sector attached to the right-hand side of the saddle assembly. To allow ammunition to enter without restriction, the two center guns are mounted 2½ inches higher than the two outer guns.

Components

Gear Sector. (Figure 6-140.) The guns are elevated or depressed when the elevation drive pinion rotates and moves the gear sector. The gear sector is bolted and doweled to the saddle.

Supports. (Figure 6-141.) A recoil adapter fits over the barrel of each gun and mounts it to the saddle. The adapter is bolted to the gun support and absorbs most of the shock.

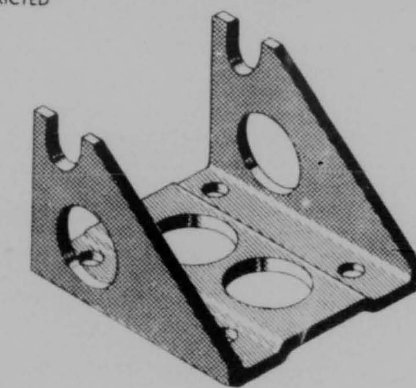

Figure 6—141. Gun Support.

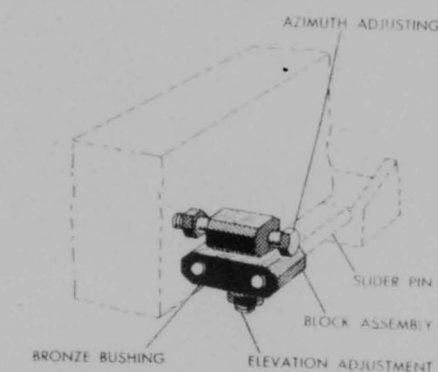

Figure 6—142. Gun Slider Assembly.

Gun-slider Assembly. (Figure 6-142.) The rear of each gun is mounted to the saddle assembly by a gun-slider assembly. This assembly consists of a block assembly with two bronze bushings, and elevation and azimuth adjustments. Two steel sliderpins are pressed in the rear of the saddle casting. The block assembly and bronze bushings which are attached to the gun, fit over the slider pins and ride fore and aft with the recoil action of the guns. Azimuth and elevation adjustments which permit alignment of the guns, are made by turning the adjusting screws on the block assembly. These adjustments are necessary when boresighting the guns.

Rotating Stop. This is a rectangular-shaped

RESTRICTED

piece of metal secured to the right side of the saddle just inside the gear sector. It engages a stop assembly on the saddle support, restricting the vertical travel of the guns at zenith.

Saddle-ring Assembly

(Figure 6-140.) The saddle rings are aluminum fittings mounted on the front of the saddle trunnions. They are designed to retain the upper and lower parts of the gun enclosure. The enclosures are attached to the saddle-ring assembly by means of fasteners.

Azimuth Drive Assembly
(Figure 6-143.)

Function. This assembly, located on the left-hand saddle support, positions the guns in azimuth. An electric motor (1) drives a set of speed-reduction gears that mesh with the azimuth ring gear (4). The Selsyn control-transformer rotors are connected through a second gear train to the drive motor and transmit a gun-position signal.

Components

Drive Motor. The azimuth drive motor is rated at ½ horsepower, and is a "separately-excited" motor that rotates either clockwise or counterclockwise according to the signal from the amplidyne generator. Input voltage from the amplidyne generator controls the motor's speed. A solenoid-operated brake, located at the base of the motor, prevents rotation of the drive motor armature when the motor is not energized. When the motor armature is locked by the brake, the turret cannot rotate in azimuth. The brake can be released manually by two spring-loaded levers, one located on each side of the motor.

Gear Assembly. (Figure 6-143.) The purpose of the power-gear assembly is to transmit power from the drive motor (10) through a set of speed-reduction gears to the main drive gear (6) and to the Selsyn drive (5). The main drive gear meshes with the azimuth ring gear (4) and turns the turret in azimuth. The Selsyn-gear system is located above the power gear assembly and is driven by a driving gear attached to the main shaft of the power gearing.

Power Gearing. (Figure 6-143.) The power-gearing assembly consists of a gear case, cover Selsyn mounting plate (3) and a gear train with four gears which is designed to reduce the motor speed. The power gearing is located in the lower part of the gear case. Power is transmitted from the drive-motor armature-shaft to the motor mating-gear (9) which is attached to the pinion (8), and is supported vertically in two bearings. The pinion transmits power to the intermediate gear (7) which is bolted and doweled to the main shaft and meshes with the azimuth ring gear (4), completing the power gear train.

Selsyn Rotor Position Gearing. (Figure 6-143). The Selsyn gearing is located in the top section of the gear case. The Selsyn drive gear (5) is keyed to the main shaft and is machined with two rows of gear teeth. The top row of teeth meshes with the 31-speed Selsyn gear which is keyed to the Selsyn rotor. The gear ratio is increased at this point to increase the speed of the Selsyn rotor to 31 revolutions for every revolution of the turret. The lower row of teeth on the Selsyn drive gear (5) meshes with the Selsyn idler gear which is secured to the hub gear. The 1-speed Selsyn gear engages the hub gear and turns the Selsyn rotor once for every revolution of the turret in azimuth. The Selsyn control-transformers indicate by means of an electrical control signal, the azimuth location of the guns in relation to the azimuth location of the line-of-sight.

Elevation Drive Assembly
(Figure 6-144.)

(1) **Function.** This assembly, located on the right-hand saddle support, positions the guns in elevation by means of an electric motor (1) and a set of speed-reduction gears which mesh with the elevation gear sector. Two Selsyn control-transformers are mounted horizontally on the elevation drive assembly. Their operation is identical to that of the Selsyn control-transformers on the azimuth drive.

Components

Drive Motor. (Figure 6-144.) The elevation- and azimuth-drive motors are identical.

Gear Assembly. (Figure 6-144.) The gear assembly consists of a gear case (2) and cover

(6), a Selsyn mounting plate, clutch assembly (7), and a speed-reduction-gear train. The elevation power-gear assembly transmits power from the elevation drive motor (1) to the elevation gear sector through the speed-reduction gears and clutch assembly (7). The two elevation Selsyn control-transformers are driven by two Selsyn drive gears on the main pinion-gear shaft.

Power Gearing. (Figure 6-144.) The elevation power gearing reduces the motor speed and increases its driving torque. Power is transmitted from the motor-armature-drive to the clutch gear and through a clutch assembly (7) to the pinion bevel gear (9). The pinion bevel gear drives the intermediate gear and the intermediate gear assemblies (11). The intermediate gear assembly (11) consists of a planetary system which meshes with the minor pinion gear, and a second pinion bevel gear driving interrupter drive shaft. The minor

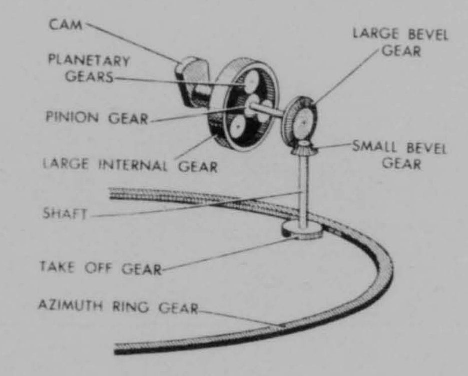

Figure 6–146. Schematic Drawing of Contour Follower Mechanism.

pinion meshes with the last reduction gear which is on the same shaft as the main pinion gear (5). The main pinion gear meshes with the elevation gear sector completing the power gear train.

Selsyn Rotor Position Gearing. (Figure 6-144). The Selsyn control-transformers are mounted on the Selsyn mounting plate by two clamps and screws. The Selsyn drive gears are keyed to the main and pinion shaft. The top gear meshes with the 31-speed Selsyn gear which is secured to the rotor shaft of the Selsyn control-transformer. The lower Selsyn drive gear meshes with the Selsyn idler gear and drives the hub gear which is attached to the idler gear by three screws. The hub gear meshes with the 1-speed Selsyn gear and transmits motion to the rotor shaft of the 1-speed Selsyn control transformer.

Selsyn,Control Transformers. The elevation Selsyn control transformers are identical in operation and construction to the azimuth Selsyn control transformers.

Stop Assembly

Function. The stop assembly restricts the upward motion of the guns at their maximum travel limit. The travel in elevation is limited to 90 degrees zenith by a fixed stop. The permissible downward travel of the guns varies with the turret azimuth position and is controlled by the contour-follower assembly.

THIS PAGE IS DECLASSIFIED IAW EO 13526

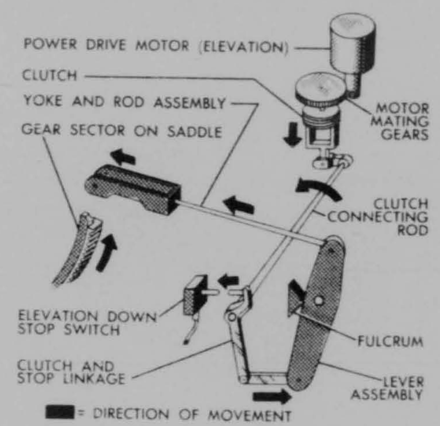

Figure 6–147. Schematic Drawing of Clutch Mechanism.

Components

Zenith Stop Assembly. The zenith stop assembly consists of an aluminum block with a rubber buffer which is attached to the (right-hand) saddle support. A similar block without the rubber buffer is attached to the saddle The fixed stop engages the stop on the saddle and restricts the upward motion of the guns.

Contour Follower
(Figures 6-145 and 6-146)

Function. The purpose of the contour follower is to limit the downward travel of the guns in all azimuth positions and to prevent the line of fire from pointing at the upper-gunner's sighting station. When the guns approach their maximum travel downward, the elevation gear sector (Figure 6-145) engages the yoke and rod assembly (1) which is attached to the upper part of the lever assembly (9). As the guns continue their downward travel, the rod assembly pulls the top part of the lever assembly forward. The lever rides on a cam (3) which changes position as the turret moves in azimuth. The bottom of the lever assembly is connected to the clutch-mechanism assembly (8) which restricts the downward travel of the guns. A clutch assembly and a limit switch (4) work simultaneously with the clutch mechanism to disengage the power drive from the gear train and to break the power and firing circuit in the down direction only.

Components

Yoke and Rod Assembly. (Figures 6-145 and 6-147). The yoke and rod assembly (1, Figure 6-147) consists of a steel rod attached to the top of the lever (9) assembly and a yoke that engages the elevation gear sector (2) as the guns approach their maximum downward limit.

Contour Follower Mechanism. (Figure 6-146). The contour follower mechanism consists of a speed-reduction gear train with a cam splined to the large internal gear. The cam acts as a movable fulcrum point for the lever assembly and changes position as the azimuth position of the turret changes. The contour-follower take-off gear engages the azimuth ring gear and transmits the motion of the turret in azimuth through two bevel gears to a pinion gear. The pinion engages three planetary gears which drive the large internal gear.

Lever Assembly. (Figure 6-145.) The clutch mechanism is fastened to the lower end of the lever assembly. It consists of a system of springs and shafts which has three functions:

To limit the downward movement of the guns by means of a fixed stop.

To absorb within a total movement of ½ inch the downward inertia of the guns before hitting the fixed stop above.

To simultaneously operate the elevation-drive-clutch lever mechanism, which operates the elevation limit switch and disengages the elevation drive clutch. The limit switch simultaneously breaks the firing circuits, engages the elevation-drive-motor brake, and breaks the power circuit. As the elevation drive clutch is relaxed, disengaging the motor from the drive. Thus the large inertia of the motor is not transmitted through the gear train to the fixed stop.

Left and Right Booster Assemblies
(Figure 6-148)

Function. Boosters are used to assist in the feeding of the ammunition. The ammunition is lifted from the ammunition case by the booster motor-power sprockets (4) and shaft

6. AMMUNITION GUIDE

Figure 6–148. Booster Assembly.

assembly and fed into the guns. Each gun is fed by a separate sprocket and shaft assembly. Each booster assembly has two sets of sprockets (4) and one motor (5).

Components

Bracket Assemblies. (Figure 6-148.) The bracket assemblies (1) are bolted to the saddle supports, and mount the gear assemblies (3), power motors (5), and the sprocket assemblies (4).

Gear Assembly. (Figure 6-148.) The gear assembly (3) is designed to reduce the speed of the drive motor (5) and to drive the sprocket assemblies (4). Power is transmitted from the drive motor armature shaft to the motor-mating gear and to the pinion gear which is attached to the same shaft. The pinion gear meshes with the drive gear which drives the lower sprocket shaft. An intermediate gear meshes with the upper sprocket shaft. Free-wheeling within the gear assembly allows the sprocket to turn, when ammunition is being fed into the gun, and acts as a brake when the sprocket tends to turn in the opposite direction.

Sprocket Assemblies. (Figure 6-148.) Two rubber sprockets (4) are attached to each

drive shaft. They are designed to fit the contour of the cal. .50 ammunition. The sprocket assemblies are driven by an electric motor (5) through a speed-reduction gear train. The sprocket assemblies rotate, when the firing circuit closes, lifting ammunition from the ammunition cases and feeding it into the guns. The rubber sprockets are designed so that ammunition can slide over them to prevent jamming when ammunition is fed too fast. The upper and lower guides (6) keep the ammunition in place. The upper sprocket and shaft assembly on each booster assembly feeds the center gun, and the lower sprocket feeds the outside gun.

Cal. .50 Machine Gun and Accessories

(Figure 6-149)

Function. The four cal. .50 machine guns operate automatically from recoil action. The first cartridge is injected into the gun by an automatic gun charge (1) which actuates the cocking mechanism by compressed air. The gun charger (1) also ejects dud shells. A recoil adapter (5) is mounted on the gun in the front, and a gun-slider assembly (2) in the rear. A gun heater (8) is installed on each gun to prevent freezing of the gun. A rounds-counter actuator (4), which consists of a small snap-action switch which opens and closes a circuit to the rounds counter every time a shot is fired, is mounted on the two center guns. The gun accessories also include a link chute (3), feed guide (6), and a cartridge positioner (7).

Components

Gun Charger. (Figure 6-150.) The gun charger (6) cocks the gun (2), injects the first shell into the gun and fires the gun. It also clears the gun of defective ammunition in case of misfire.

Recoil Adapter. (Figure 6-150.) The recoil adapter screws on the barrel jacket of the gun and contains two mounting bolts. An intermediate gear meshes with the upper drive gear and drives the upper sprocket shaft. Free wheeling within the gear assembly allows the sprocket to turn, when ammunition is being fed into the gun, and acts as a brake when the sprocket tends to turn in the opposite direction.

Sprocket Assemblies. (Figure 6-148.) Two rubber sprockets (4) are attached to each drive shaft. They are designed to fit the contour of the cal. .50 ammunition. The sprocket assemblies are driven by an electric motor (5) through a speed-reduction gear train. The sprocket assemblies rotate, when the firing circuit closes, lifting ammunition from the

ammunition cases and feeding it into the guns. The rubber sprockets are designed so that ammunition can slide over them to prevent jamming when ammunition is fed too fast. The upper and lower guides (6) keep the ammunition in place. The upper sprocket and shaft assembly on each booster assembly feeds the center gun, and the lower sprocket feeds the outside gun.

Cal. 50 Machine Gun and Accessories

(Figure 6-149)

Function. The four cal. .50 machine guns operate automatically from recoil action. The first cartridge is injected into the gun by an automatic gun charger (1) which actuates the cocking mechanism by compressed air. The gun charger (1) also ejects dud shells. A recoil adapter (5) is mounted on the gun in the front, and a gun-slider assembly (2) in the rear. A gun heater (8) is installed on each gun to prevent freezing of the gun. A rounds-counter actuator (4) which consists of a small snap-action switch, opens and closes a circuit to the rounds counter every time a shot is fired is mounted on the two center guns. The gun accessories also include a link chute (3), feed guide (6), and a cartridge positioner (7).

Components

Gun Charger. (Figure 6-150.) The gun charger (6) cocks the gun (2), injects the first shell into the gun and fires the gun. It also clears the gun of defective ammunition in case of misfire.

Recoil Adapter. (Figure 6-150.) The recoil adapter screws on the barrel jacket of the gun and contains two mounting bolts for mounting the front of the gun to the saddle assembly. The recoil adapter is designed to absorb and lessen the shock caused by the recoil of the guns. The recoil adapter is Government-furnished equipment.

Link Chute. (Figure 6-150.) The link chute (5) is a metal fitting attached to the inboard side of the gun (2). It is attached to the pawl pin and directs the links downward into the turret well.

Gun Heater. (Figure 6-150.) Each gun is equipped with a gun heater (8) which consists of a resistance coil assembly, attached to the side of the gun. The gun heaters are used to furnish heat to the working parts of the gun.

Gun Slider. (Figure 6-150.) The guns are mounted, at the rear, by the gun sliders (9) which permits the horizontal motion of the guns caused by recoil.

Rounds-counter Actuator. (Figure 6-150.) The rounds-counter actuator (1) is located on the recoil adapter and consists of a recoil actuated snap action switch that opens and closes the ammunition recorder circuit each time the gun recoils. The rounds-counter records the shots fired and keeps the gunner informed as to the ammunition supply.

Gun-feed Guide. The feed guide (bell mouth) (7) is secured by a pawl pin to the outside of the gun. This guide prevents the ammunition belt from catching on sharp surfaces as the ammunition enters the gun (2).

Ammunition Guide. The ammunition guide is a steel plate that fits over the top of the two outside guns and guides the ammunition into the center guns. The ammunition guide prevents the cartridges from catching on rough surfaces of the outside guns.

Cartridge Positioner. (Figure 6-150.) The cartridge positioner (4) is a small metal device attached to the side of the two left-hand guns by the pawl pin. As the cartridge enters the gun (2) it is positioned by this device, which is shaped to fit the contour of the cartridge. The cartridge positioner is used on left guns only.

Gun Enclosure

(Figure 6-151). The gun enclosure is designed to follow the contour of the dome assembly and consists of three sections. The lower section is secured to the saddle ring and covers the guns when they are elevated. The second section fits over the guns and is secured to the saddle ring by quick-disconnect fasteners. The top section projects the top of the guns and is also fastened to the saddle ring.

Dome Assembly

(Figure 6-152). The dome assembly is a

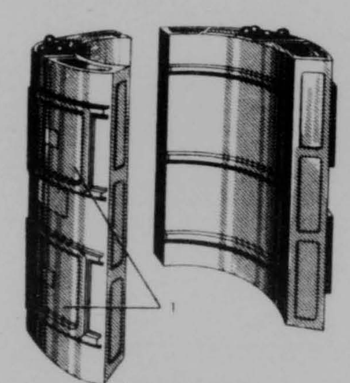
Figure 6—153. Three-Quarter View of Four-Gun Turret, Dome Removed.

streamlined aluminum cover for the turret. The dome assembly is secured to the adapter assembly by 23 equally-spaced anchor pins located on the upper flange of the adapter assembly. The dome is locked on the adapter by a wire-lock assembly (2) which is actuated by the latch assembly, located on the right-hand side of the turret. The dome assembly is designed with an access door (1) on each side of the turret. Two spring-loaded J-shaped safety locks engage the brackets on the adapter and lock the dome assembly in place.

Ammunition Frame and Chute Assembly

(Figure 6-133). The ammunition frame (7) (Figure 6-133) is attached to the saddle supports, innerring assembly, and mounts the ammunition cases (8). The ammunition cases are designed so they are concentric with the ammunition frame, and are secured to the frame by quick-disconnect fasteners. The chute assembly is a metal-assembly that directs the empty shells downward into the turret well.



1. ACCESS DOORS

Figure 6—154. Ammunition Cases.

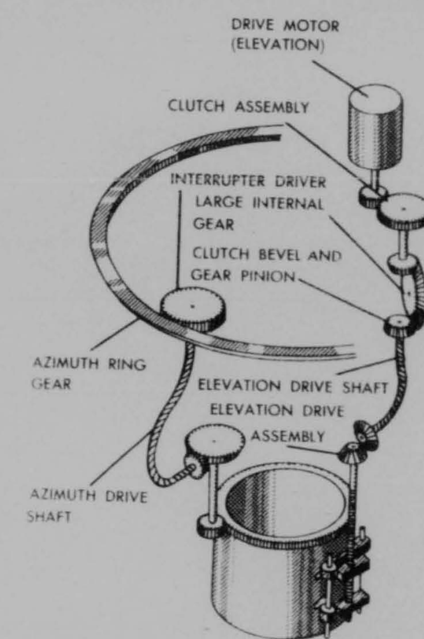


Figure 6—155. Schematic Drawing of Interrupter Drive Assembly.

Compressor and Pressure Cylinder

(Figure 6-153). The four-gun turret is equipped with a motor-driven compressor (9) and a pressure cylinder (8) which supplies the automatic gun chargers (3) with compressed air.

Ammunition Cases

(Figure 6-154). The four ammunition cases are fastened to the ammunition frame by quick-disconnect fasteners. Each case holds approximately nine-hundred rounds of ammunition plus approximately twenty-five rounds between cases and their respective guns. The early model cases are designed with two access doors, one at the bottom of the case and one at the top. Later models are designed with one door at the top. The access doors (1) allow handling of the ammunition when it is being lowered into the case.

Interrupter Driver Assemblies

(Figure 6-155.) The interrupter assembly is driven in azimuth corresponding to the azimuth rotation of the turret. The azimuth take-off gear transmits turret azimuth motion through a flexible cable, two bevel gears, and two spur gears rotating the cam drum of the interrupter assembly. The elevation interrupter drive transmits turret elevation motion through a flexible cable, two bevel gears, and to a worm pinion. The worm gear rotates as the saddle moves in elevation and drives the fire-interrupter up or down to correspond to the elevation position of the saddle.

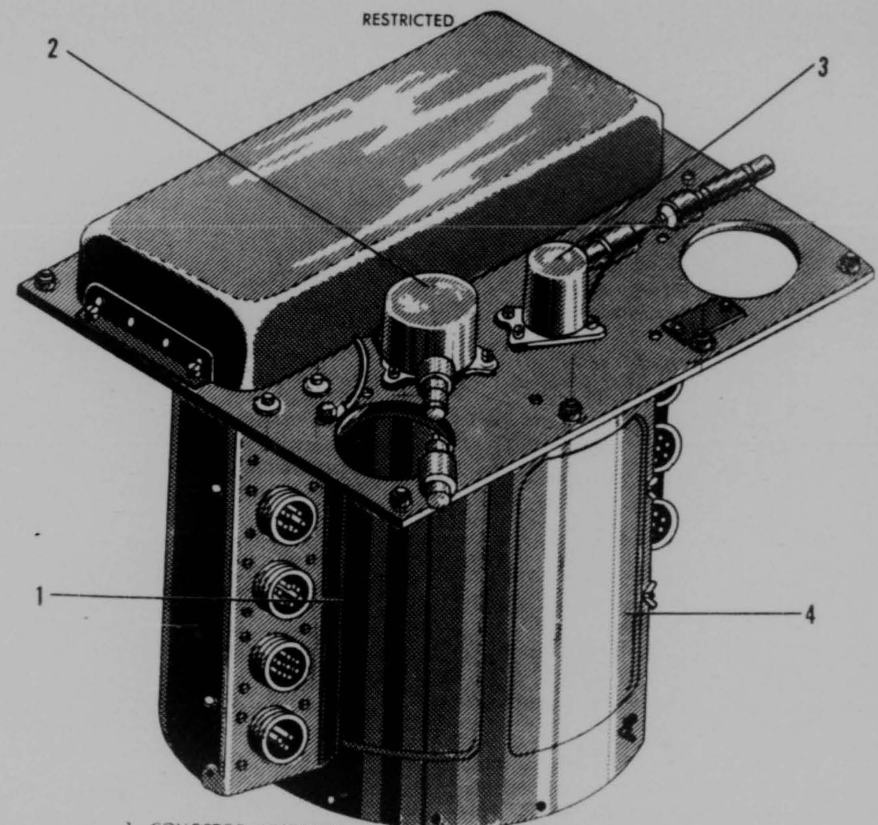
Interrupter and Collector Assembly
(Figure 6-156)

Function. The interrupter assembly prevents the guns from firing into aircraft (including propellers) by opening the firing circuit when guns are pointed at these surfaces. The collecter ring assembly provides a means of introducing power into the turret, permitting continuous rotation without twisting incoming cables.

Components

(Figures 6-157 and 6-158). The main components of the interrupter and collector assembly are the interrupter assembly, cam assembly (1) (Figure 6-157), switch-carriage (3), snap-action switches (7), collector assembly (Figure 6-158), and the brush-housing assembly (5).

Interrupter Assembly. (Figure 6-157.) The interrupter assembly consists of a cam assembly (1), a switch-carriage assembly (3), and two drives (4 and 5). When the interrupter assembly is rotated in azimuth the switch-carriage assembly rides over the cam assembly preventing the guns from firing at exposed parts of the aircraft structure.

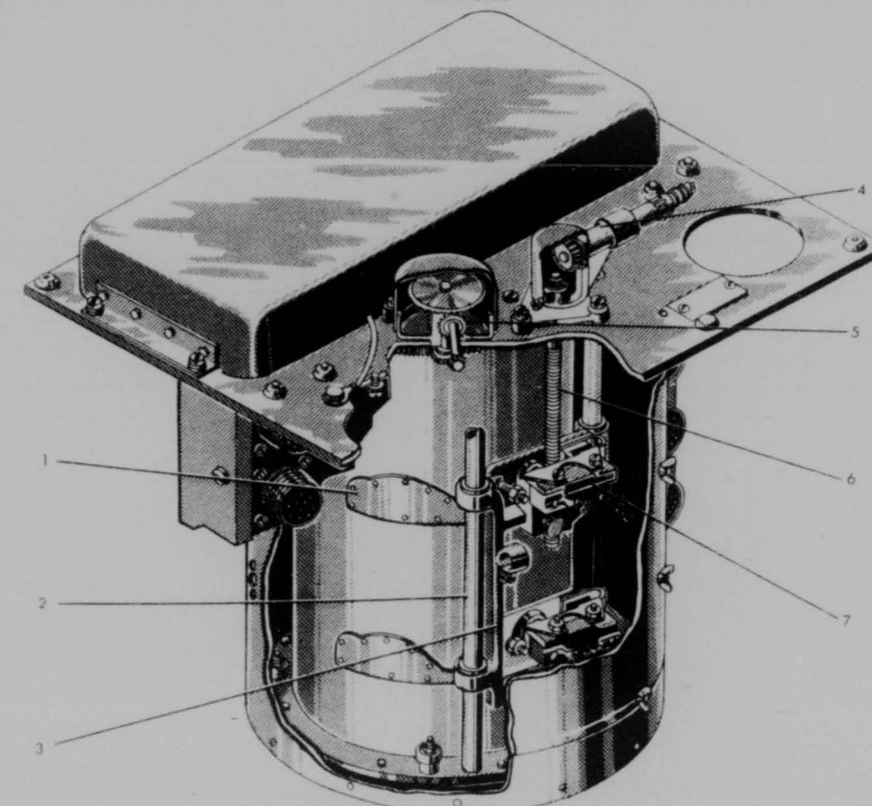


1 COLLECTOR ASSEMBLY
2 AZIMUTH DRIVE
3 ELEVATION DRIVE
4 ACCESS DOOR

Figure 6—156. Interrupter and Collector Assembly.

Cam Assembly. (Figure 6-157.) The cam assembly (1) consists of two sets of corrosion-resistant steel cam patterns. Each cam pattern represents an area such as the propeller area, for which fire must be interrupted. As the guns are turned in azimuth, the cam drum remains stationary with reference to the airplane. This is done to keep the cams in a fixed position with reference to airplane surfaces which they protect from gun fire. It is accomplished by driving the cam drum at the same speed, and in a direction opposite to the rotation of the turret. The cam drum is driven by a drive assembly connected to the azimuth ring gear.

Switch Carriage Assembly. (Figure 6-157.) The switch carriage mounts two small snap-action switches (7) that are normally closed, and are used to interrupt the fire of the guns. The switch-carriage assembly (3) is mounted on two cylindrical rods. These guide rods (2) are supported by the top and bottom plate assembly. The switch carriage is moved up and down on the guide rods by a screw shaft actuated by the elevation drive (4). When the guns are elevated or depressed, the switch carriage moves correspondingly. When the turret revolves in azimuth, the switch carriage moves correspondingly duplicating the movement of the guns.



1 CAM ASSEMBLY
2 GUIDE ROD
3 SWITCH-CARRIAGE ASSEMBLY
4 ELEVATION DRIVE
5 AZIMUTH DRIVE
6 WORM PINION GEAR
7 SNAP-ACTION SWITCHES

Figure 6—157. Interrupter Assembly.

Snap-action Switches. (Figure 6-157.) The actuators on the snap-action switches (7) are normally disengaged and their points do not touch the cam drum. When one of the actuators runs over a steel cam (1) the switch is actuated, breaking the firing circuit causing the guns to stop firing. As the guns turn in azimuth, the switch carriage rotates correspondingly. As the guns move in elevation, the switch carriage and micro switches move correspondingly. The upper cam and upper switch interrupt the fire of the two right guns. The lower cam interrupts the fire of the two left guns as required.

Collector Assembly. (Figure 6-158.) The purpose of the collector ring assembly is to provide a means of introducing power to the turret to permit full rotation of the turret without twisting the cables. This assembly includes a collector ring (4) a housing, a brush base assembly (5), and a junction box for outlet connectors. The collector ring consists of silver-plated brass rings which are separated by plastic spacers. Wires are soldered to the inside of the collector rings and are brought through the core of the collector ring assembly to a large master electric connector (9) on the bottom of the interrupter and collector as-

9. MAIN CONNECTOR
10. BRUSH HOUSING SWITCHES

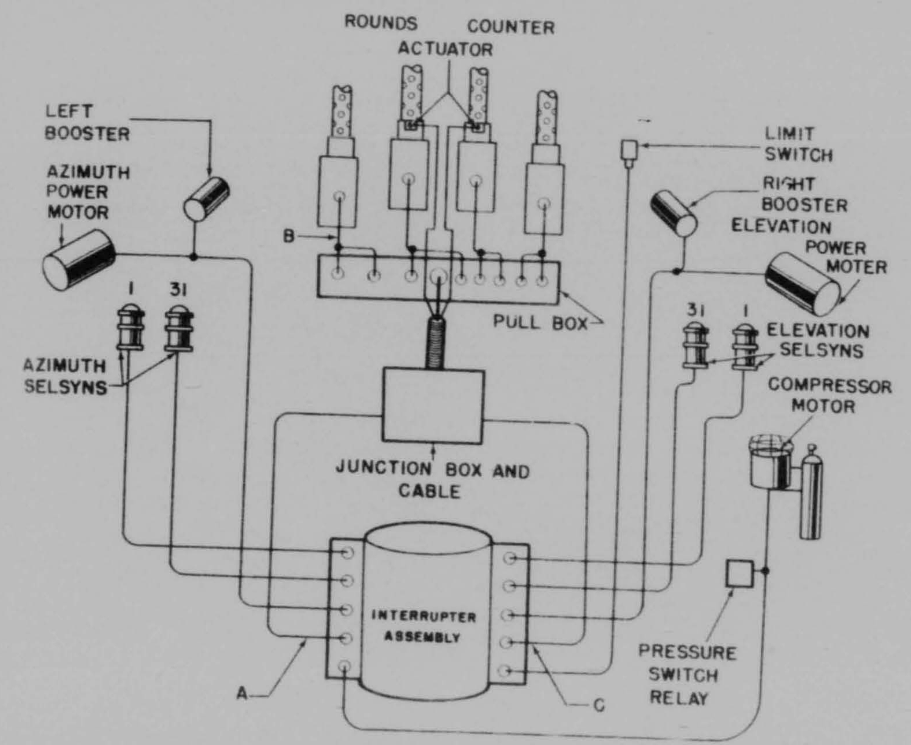
Figure 6—158. Cutaway View of Collector Assembly.

sembly (4). This connector is in turn connected to incoming wires from the control box. It is necessary to keep the position of the collector-ring assembly fixed with reference to the airplane in order to prevent the incoming leads from becoming twisted. This is accomplished by bolting the collector assembly to the cam drum (6) which remains in a fixed position relative to the airplane.

Brush Housing. (Figure 6-158.) The brush housing (10) is used to mount the carbon-silver alloy brushes (5) which ride on the collector rings (4). The top plate rotates with the turret and the housing is attached to the top plate. The brushes are attached to the housing and also rotate with the turret. Wires running from the brush terminals are brought through the top of the collector to ten connectors. Five connectors are located on each side of the interrupted and collector assembly.

Distribution Cables and Boxes

(Figure 6-159.) Power and control are introduced into the turret by the interrupter and collector assembly. All cables lead from the ten connector plugs located on the side of the interrupter assembly to the various electrical components throughout the turret.



A. Cable to left-middle rounds counters and all gun chargers

B. Cable to gun heaters and chargers

C. Cable to right-middle rounds counters and all gun heaters

Figure 6—159. Schematic Diagram Showing Distribution Cables and Boxes.

Cables are of the flexible type with drain holes for condensation.

2. TAIL TURRET

General

The tail turret is located at the rear of the airplane's fuselage. The tail turret is supplied by the Boeing Aircraft Company, except for the elevation- and azimuth-drive assemblies, gun chargers and ammunition rounds-counter actuators, which are manufactured by the General Electric Company.

Description

(Figure 6-160 and 6-161 through 6-163.)

Armament. Two cal. .50 machine guns.

Limits of Tail-turret Movement. (Figure 6-162). The tail turret moves in elevation and in azimuth. The guns can be raised to a maximum of 30 degrees above the horizontal position and can be depressed to a maximum of 30 degrees below horizontal. The limits of azimuth travel are 30 degrees on each side of the straight-aft position. The guns are so mounted that they move as a unit in azimuth and elevation.

Detailed Description of Tail Turret

(Figures 6-163 and 6-162.)

Ring Supports. The ring support (Figure 6-162) is of welded tubular construction. At the top and bottom of the ring are the bearings which support the gun cradle. The dome support is bolted to the forward side of the ring. Welded to the rear side are clips which mount Dzus fasteners for installation of the fairing hood.

Dome Support. (Figure 6-161.) The dome support is a magnesium casting which is bolted to the forward side of the supporting

ring. The elevation-drive mechanisms (Figure 6-161) (10) is mounted to the dome support (2); it drives an elevation-gear sector (4) on the saddle. Azimuth limit stops are mounted on each side of the dome support, and actuate micro switches mounted on the fuselage-frame station 1194. An azimuth-gear sector (Figure 6-162) (2) is also bolted to the dome.

Saddle. (Figures 6-161 and 6-163.) The saddle mounts the two cal. .50 Browning M2 machine guns (Figure 6-163) and ammunition case, feed-roller assemblies (Figure 6-163 [3 and 6]), and the guide chute (Figure 6-161 [6]) for empty shells and links. The saddle is mounted to the ring support (Figure 6-163 [2]) by two trunnion bolts, which allow elevation motion of the guns. The elevation gear sector is mounted to the saddle, and is driven up and down by the elevation-drive mechanism in the dome support. Limit-switch actuators and mechanical rubber limit stops (Figure 6-163) (1), limit the elevation movement of the guns. A cam actuator for operating the elevation stowing-indicators switch is mounted on the left-hand side of the saddle above the trunnion bolt. The machine guns are mounted through a yoke which is bolted to the saddle. Trunnion bolts threaded into the recoil adapter secure the guns to the yoke. The rear of the gun is secured by slider mount bushings, which are also bolted to the saddle.

Limit Stops and Switches.

Azimuth Stops and Switches. (Figure 6-162 and 6-164.) Aluminum stops with rub-

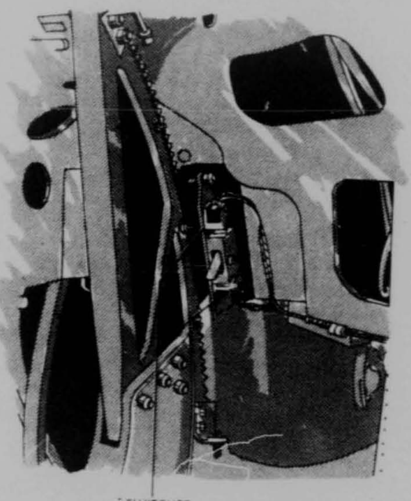

Figure 6–165. Elevation Limit Switches.

ber bumpers are mounted on the dome supports for limiting azimuth motion of the tail turret. These stops allow maximum travel of 30 degrees on each side of the center position. The azimuth limit switches are mounted on fuselage-frame station 1194 and are actuated by cams mounted on the dome.

Elevation Stop and Switch. (Figure 6-165.) The fixed-elevation limit stop is contained within the elevation drive unit and is engaged by limit stops on the left-hand side of the elevation gear-sector supports. These stops limit elevation travel to a maximum of 30 degrees above and 30 degrees below horizontal. The two elevation limit switches (for upper and lower limits) are mounted on the elevation drive assembly and are actuated by two brackets mounted on the right-hand side of the elevation gear sector.

Azimuth Drive Assembly. (Figure 6-166.)

General. The azimuth-drive assembly performs two functions: first, it supplies the mechanical power required to drive the tail turret guns in azimuth; second, it provides electrical equipment to indicate the azimuth

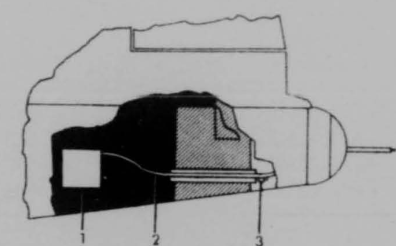
THIS PAGE IS DECLASSIFIED IAW EO 13526

position of the guns. This drive assembly moves the guns to a maximum of 30 degrees to the right and 30 degrees to the left of the straight-aft position.

Function. (Figure 6-166.) The tail-turret azimuth drive assembly includes a motor (10), two Selsyns (8 and 9), and the necessary gearing—including a friction clutch (2). The motor drives through the friction clutch to the drive pinion (7), which mates with the azimuth gear sector (6) on the gun mount. This brings about a speed reduction of approximately 800:1 between the motor and the guns. Also driven from the drive pinion shaft are the 1-speed and 31-speed Selsyn control-transformers (8 and 9). A friction clutch (2) protects the gear train from excessive shock when the guns reach their azimuth limit. A limit switch and limit stops are provided by the manufacturer of the tail turret. These limit the movement of the turret in azimuth, and cut out the power to the motor when the guns reach their limit of travel. Instead of the latch solenoid which is used on the other turrets, the tail-turret drive motor has a solenoid-operated brake. The solenoid is de-energized when the "AZ-power" switch on the control box is in the "off" position. This causes the brake to engage and hold the motor armature, thereby holding the tail turret in its azimuth position. When the "AZ-power switch is in the "on" position, the solenoid is energized, releasing the brake. The brake is also applied automatically when the sight moves beyond the azimuth limit of the gun mount. This de-energizes the solenoid, engaging the brake and holding the gun against the limit stop. When the sight is moved back within the limits of the gun movement, the brake is automatically released. The brake can also be released manually by means of the brake-release handle.

Elevation Drive Assembly. (Figure 6-167.)

General. The elevation drive assembly performs two functions: first, it supplies the mechanical power required to drive the saddle and guns in elevation; and second, it provides electrical equipment to indicate the position of the guns in elevation. The drive assembly moves the guns a maximum of 30 degrees above and 30 degrees below horizontal.

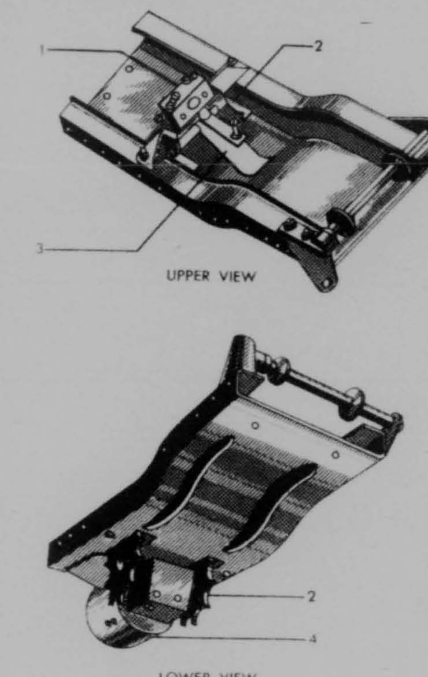


1. AMMUNITION CASE 2. AMMUNITION TRACK
3. SPROCKET-TYPE BOOSTER

Figure 6—168. Ammunition Feed to Machine Guns in Tail Turret.

Function. (Figure 6-166.) The tail-turret elevation drive assembly includes a motor (6), two Selsyns (4 and 5), a limit stop, and the necessary gearing (including a friction clutch, 8). The motor drives through the friction clutch to the drive pinion (7), which drives the elevation gear sector (3) on the saddle. This brings about a speed reduction of approximately 800:1 between the motor and the guns. Also driven from the drive-pinion shaft are the 1-speed and the 31-speed Selsyn control-transformers (4 and 5). Mounted on the elevation drive assembly is a limit stop. When the guns are elevated or depressed to their limits, the stop engages one of the two buffers mounted on the elevation gear sector—stopping the elevation travel of the guns. A friction clutch protects the gear train from excessive shocks when the guns reach their elevation or depression limit. Two limit switches are provided by the manufacturer of the tail turret. They cut off the power to the motor when the guns reach their limit of travel. The elevation motor has a solenoid-operated brake which operates similarly to that described in the preceding column on the azimuth drive assembly. The brake can be released by means of the brake release handle.

Ammunition Cases and Feed Assemblies. (Figures 6-168, 169 and 170.) Ammunition cases for the caliber .50 machine guns are



1. MICRO SWITCH 3. LEVER
2. SPROCKET 4. MOTOR

Figure 6—169. Ammunition Booster for Tail-Turret Machine Gun.

mounted on either side of the fuselage, forward of the pressure bulkhead at station 1110 (Figure 6-170). The ammunition track (Figure 6-168 [2]) is enclosed in a tube as it extends from the case through frame station 1194. A sprocket-type booster (Figure 6-168) (3) in the track pulls the ammunition belt from the case. A (Figure 6-169 [1]) is actuated by a lever, so that when the gun-feed mechanism puts tension on the ammunition belt, the booster will operate, thereby feeding additional ammunition to the gun. When sufficient ammunition is brought up to the gun, the tension of the belt is relayed, thereby shutting down the booster. A feed-roller unit mounted on three bearing rollers, guides the cal. .50 ammunition to the machine gun. As

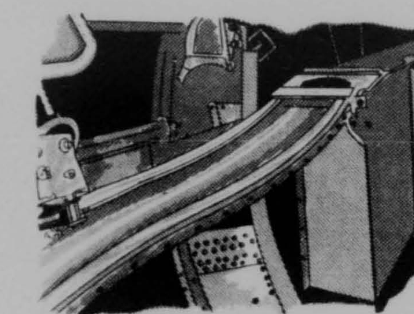


Figure 6—170. Ammunition Case and Ammunition Track Mounted on Fuselage.

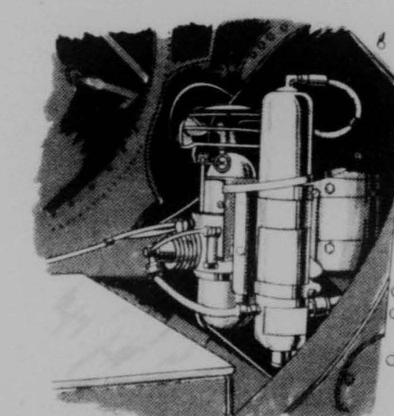

Figure 6—171. Cornelius Tail Compressor Installed.

the guns are raised or lowered in elevation, the feed-roller unit rotates, thus reducing the angle through which the ammunition belt must twist to travel to the guns from the fixed guide rollers at the end of the ammunition track.

Air Compressor System. (Figure 6-171.) The compressor system is the source of supply for the gun charger. The compressor is mounted together with its cylinder on the port side of the airplane, adjacent to the tail gun-

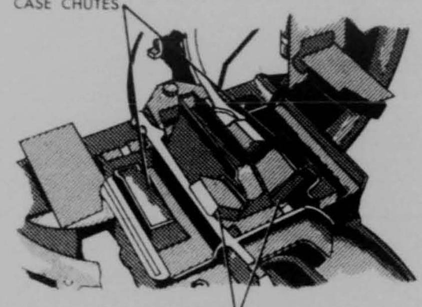

Figure 6–172. Top View of Guide Chute for Tail Turret.

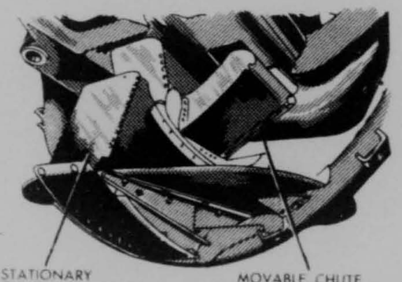

Figure 6–173. Bottom View of Guide Chute for Tail Turret.

ner's compartment. It is similar to the air compressor used on the two-gun turrets which has been described.

Guide Chute. (Figures 6-172 and 6-173.) The guide chute is used to eject the cartridge cases and links from the airplane. It consists of two sections, a stationary chute (Figure 6-173) which is bolted to the support rings, and a movable chute (2) which is composed of two cartridge case chutes (Figure 6-172) and two link chutes. The movable chute is bolted to the cartridge.

Cover. (Figure 6-169.) The cover is a dome-shaped sheet-aluminum fairing. It is Dzus-fastened to the support ring. A vertical open-

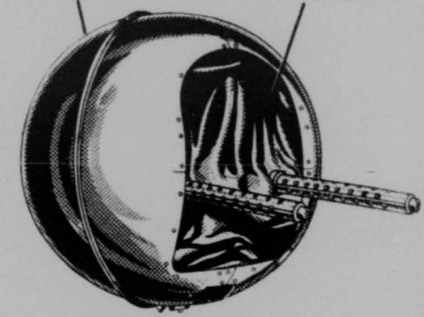

Figure 6–174. Cover Mounted on Tail Turret.

ing allows elevation movement of the cradle and gun.

Dust Cover. (Figure 6-174.) The dust cover, which is made of fabric and fastened to the fairing cover, provides a flexible covering to close off the opening of the dome. A window is provided for the line of sight of the camera.

Ammunition Rounds-counter Actuator. The actuator for the ammunition counter consists of a switch and clamp assembly, and connection cable. The actuator switch is attached with a clamp on the gun adapter so that the face of the actuator is 23/64 of an inch from the gun receiver. The two cables for the actuator switches—left and right guns, come from the junction shield mounted on the elevator drive. The actuator switch is operated by recoil each time the gun fires. When the switch closes, a coil in the counter adjacent to the gunner is energized. The figures indicating reserve ammunition decrease one every time the coil in the counter is energized. The actuators and camera may both be used at the same time without transferring the circuit with a switch on the control box.

Gun Heaters. The gun heaters are connected by two cables from the junction shield mounted on the elevation drive.

3. TURRET ACCESSORIES

Booster System Assembly
(Figure 6-175.)

Boosters are used to assist in the feeding

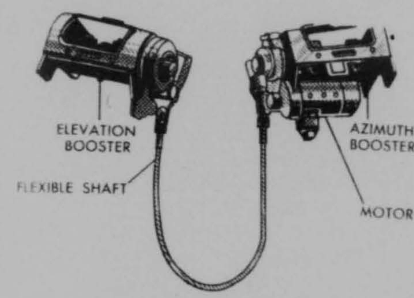

Figure 6–175. Ammunition Booster Assembly.

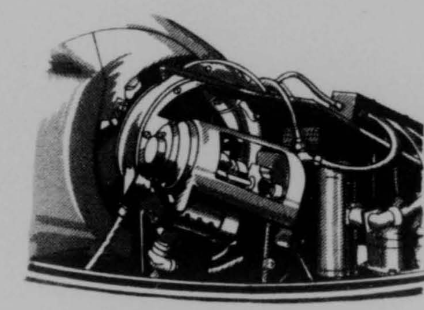

Figure 6–176. Booster Assembly Mounted on Turret.

of ammunition on both upper and lower turrets.

General. (Figures 6-176 and 6-177.) The azimuth booster when installed on the turret, is mounted on the azimuth saddle support, and the elevation booster is mounted on the elevation saddle support. A single electric motor (Figure 6-177) which is part of the azimuth booster, drives the azimuth booster, and by means of a flexible shaft connected to the azimuth booster, it drives the elevation booster. Both boosters include sprockets (17) which engage the ammunition belt in order to feed the belt to the gun.

Function. Since a Browning machine gun relies upon the recoil of the gun to pull the successive rounds of ammunition into the gun, the available pull on the ammunition belt must not be excessive or the gun will be unable to pull the succeeding round in the chamber. The boosters are designed to assist the recoil action of the gun and to insure continuous feeding of the ammunition belts. The booster runs continuously while the firing trigger is depressed. The two boosters are identical except for the motor on the azimuth unit.

Motor. The motor (Figure 6-177) (16) driving the General Electric booster assemblies is a direct-current, series-wound motor operating at 3,800 rpm. This speed is reduced by the gear train of the drive to approximately 140 rpm at the sprockets under normal load.

The sprockets (Figure 6-177) (17) which pull the ammunition belts into the guns are driven by the motor through a reduction gear training a free-wheeling unit (1). The free-wheeling assembly makes possible the rotation of the sprockets for drawing the ammunition into the guns, in the event of motor failure or a locked gear train and thus prevents any interruption of ammunition feeding. Under such conditions, the ammunition belt is fed by the action of the gun itself. The main drive shaft is provided with a brake (5) to prevent the weight of the ammunition belt from turning the booster sprockets backwards and consequently not feeding the guns.

Under normal conditions, the booster will feed the ammunition slightly faster than the gun is able to shoot. During a long burst the belt of ammunition is compressed between the sprockets and the gun and when no further compression is possible, the succeeding rounds ride up and over the sprocket's teeth. Between bursts, the motor is stopped. The row of ammunition between the sprockets and the gun remains under compression, however, thus insuring instant delivery of rounds to the gun when firing is resumed. To prevent the ammunition belt from attempting to turn with the sprockets, a stripper is provided on the bracket assembly (Figure 6-177) (18). Thus, when ammunition is pulled over the sprockets, it is stripped from the sprockets and fed into the gun without jamming ammunition around the sprockets.

4. CONTROL BOXES

General

(Figures 6-178, 6-179, 6-180 and 6-181.) There are four control boxes, one each for the upper- the nose- the blister- and the tail-sighting station positions. The control boxes are made of sheet aluminum and contain electrical devices such as switches, relays, contractors, circuit breakers, capacitors, and resistors. Each box has several AN connectors through which connections are made to other parts of the system.

Location and Function

The boxes are conveniently located so that each gunner can quickly and easily control

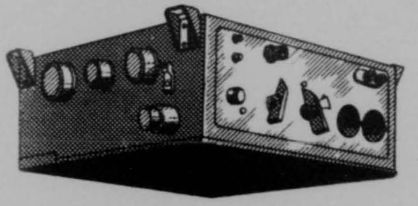

Figure 6—178. Upper Control Box.

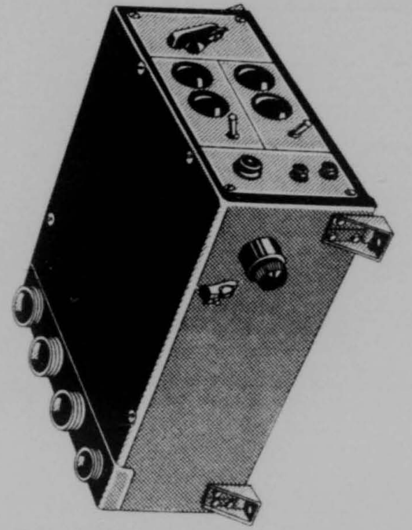

Figure 6—179. Nose Control Box.

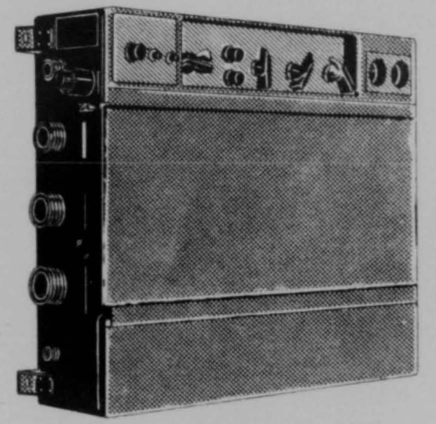

Figure 6—180. Blister Control Box.

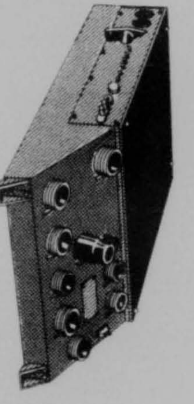

Figure 6—181. Tail Control Box.

and operate the equipment at his command or transfer the control to a gunner at a different sighting station. The nose control box is located at the right side of the nose gunner (bombardier). The upper control box is fastened to the ceiling directly aft of the upper gunner. The blister control box is located aft and between the right and left-blister gunners. The tail control box is fastened to the side of the airplane at the gunner's left.

Components

Because of the similarity in the operations to be performed, several duplicate or similar devices are used in the four control boxes. These are: circuit breakers, switches, contractors, relays, and ammunition-rounds counters. Also each control box has a terminal post for incoming 27-volt DC power and a twin-binding post for obtaining 400-cycle, 115-volt power. No junction box is used with the tail turret; therefore more relays and devices are located in the tail control box than in the other control boxes.

Circuit Breakers. (Figures 6-182 and 187.) Circuit breakers with a thermal-tripping element are used in the main circuits to provide overload and short circuit protection (K500,

K505 and K506, Figure 6-187). After they are automatically tripped, they are reset by pushing in a reset button. The circuit breakers are of two types, one larger than the other. The larger circuit breaker has ratings of 70 amperes and 120 amperes. The smaller circuit breaker has ratings of 10, 15, 20, 35 and 50 amperes.

Switches. Switches are placed on the control boxes for operating the turrets or for circuit selection.

Uniswitch. (Figures 6-183 and 6-187.) A five-position uniswitch is placed on each control box (S501, Figure 6-187). The switches simplify the operation of the turrets. The

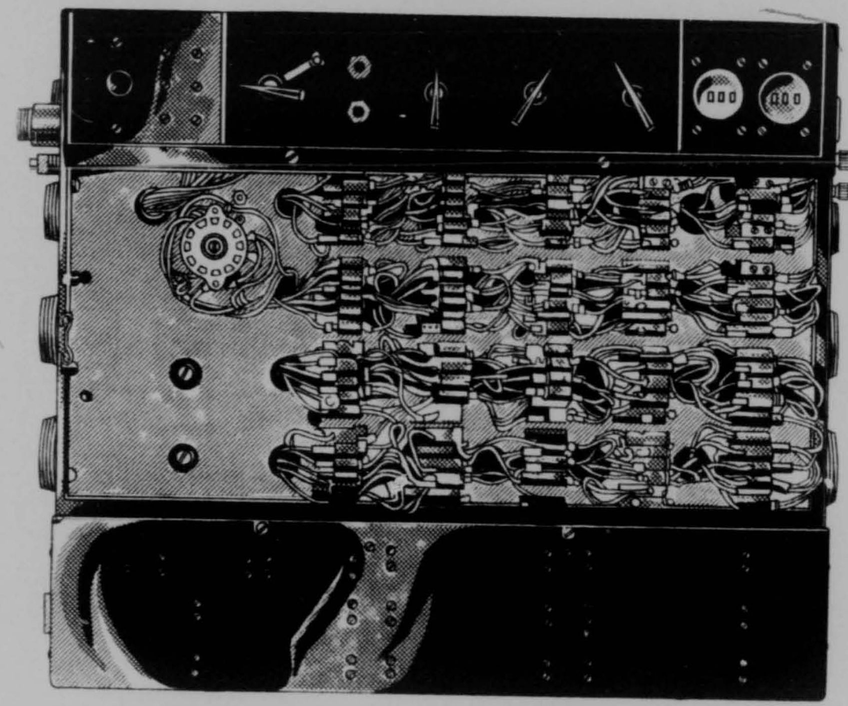

Figure 6—189. Interior View of Blister Control Box.

five positions control the five steps in the operation, which are as follows: "Off," "warm-up," "standby," "operation," and "combat" (Figure 6-183). The switch consists of switchettes so arranged that they are operated from cams. The cams rotate as the switch handle is turned from one position to another position.

Selector Switches. These switches are of the toggle type having three positions (Figure 6-184) or of the rotary type having either two or three positions (Figure 6-185).

Conversion Switches. These switches are of the two-position rotary type to be operated by a screw driver. They are set to the "restrained gyro" or "free gyro" position to correspond to the type of computer and sighting station used (S507, Figure 6-187).

Contactors. Contactors are used in the heavy-current circuits to energize and de-energize the circuits (K525, Figure 6-187). The contractors are single-pole, single-throw, double-break and are of two types, one larger than the other. The large contactor has a rating of 200 amperes and the smaller contactor has a rating of 50 amperes. Each contactor has a normally open contact which closes when its coil is energized.

Relays. Relays are used in the control boxes to energize and de-energize the various circuits to perform nine different functions.

Computer In-out Relays. In the blister control box (Figure 6-189) four-pole, double-throw relays are used to cut the computer in and out of service. In the other three control boxes, a three pole double-throw relay is used for this purpose.

Transfer Relays. The transfer relays are identical to the computer in-out relays. The

THIS PAGE IS DECLASSIFIED IAW EO 13526

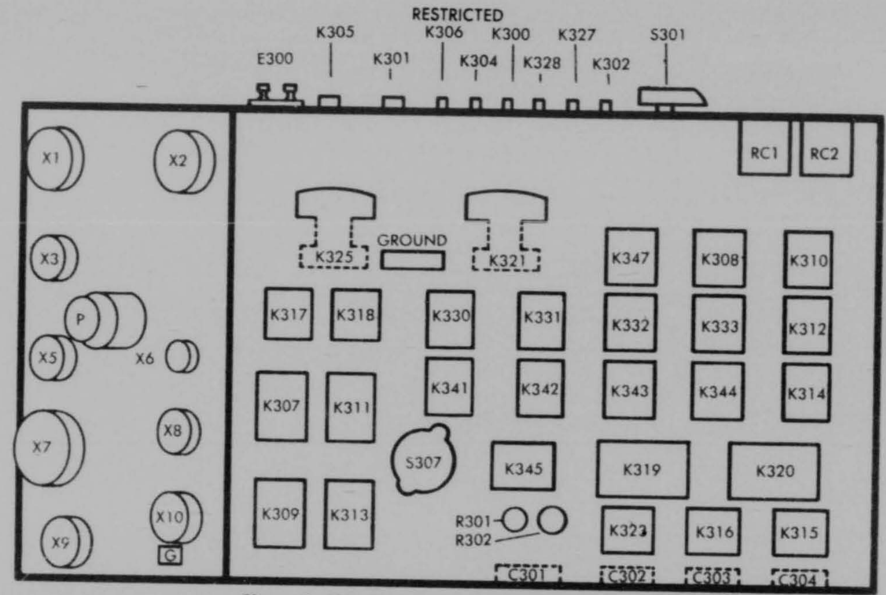

Figure 6—190. Interior View of Tail Control Box.

blister control box has four-pole double-throw relay while other control boxes have three-pole, double-throw relays (K141, Figure 6-187) for this purpose.

Field Relays. These are double-pole, double-throw relays, used in the tail control box (K307, K309, K311, and K313, Figure 6-190) for energizing the fields of the two amplidynes.

Elevation-limit Relays. These are three-pole, double-throw relays, used in the tail control box (K312 and K314, Figure 6-190) to limit the elevation motion of the tail turret.

Azimuth-limit Relays. The azimuth-limit relays are identical to the elevation-limit relays, and are used in the tail control box (K308 and K310, Figure 6-190) to limit the azimuth motion of the tail turret.

Backout Relays. These are differential-current double-coil relays located in the tail control box (K319 and K320, Figure 6-190). They are three-pole, single-throw relays. Their purpose is to provide circuit connections for moving the tail turret off of the limit switch after the azimuth or elevation limit switch has operated.

Action Relay. This is a four-pole, double-throw relay, used in the tail control box (K345, Figure 6-190).

Out of Synchronism Fire Interruption Relays. These are single-pole, double-throw differential-current relays, used in the tail control box (K317 and K318, Figure 6-190).

Time-delay Relay. This is a single-pole, double-throw relay located in the nose control box (K526, Figure 6-187). Time delay is obtained by a thermal element. The time-delay action prevents the starting of all four amplidynes at the same time.

Ammunition-rounds Counters. (Figure 6-186.) There are two ammunition-rounds counters (Figure 6-186) for each turret and they are located in the control box where the gunner has primary turret control (See RC1 and RC2, Figure 6-187). Therefore each control box has two ammunition-rounds counters except the nose control box which has four to take care of the upper-forward and lower-forward turrets.

Capacitors. Capacitors are used in the upper and the blister control boxes for the

purpose of power-factor correction and in the tail control box for stabilizing purposes. Four are used in the upper control box (C211, Figure 6-188), and four in the tail control box (C301, Figure 6-190).

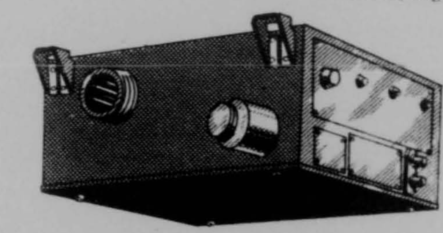

Figure 6—191. Typical Turret Junction Box.

Resistors. Two small resistors are used in the tail control box (R301 and R302, Figure 6-190). One is an azimuth grounding resistor and the other is an elevation grounding resistor.

Indicator Lights. One indicator light is placed on the upper control box, and two are placed on the blister control box (I302 and I502, Figure 6-180). Each light indicates to the gunner when a particular turret is being operated by the gunner having primary control of the turret.

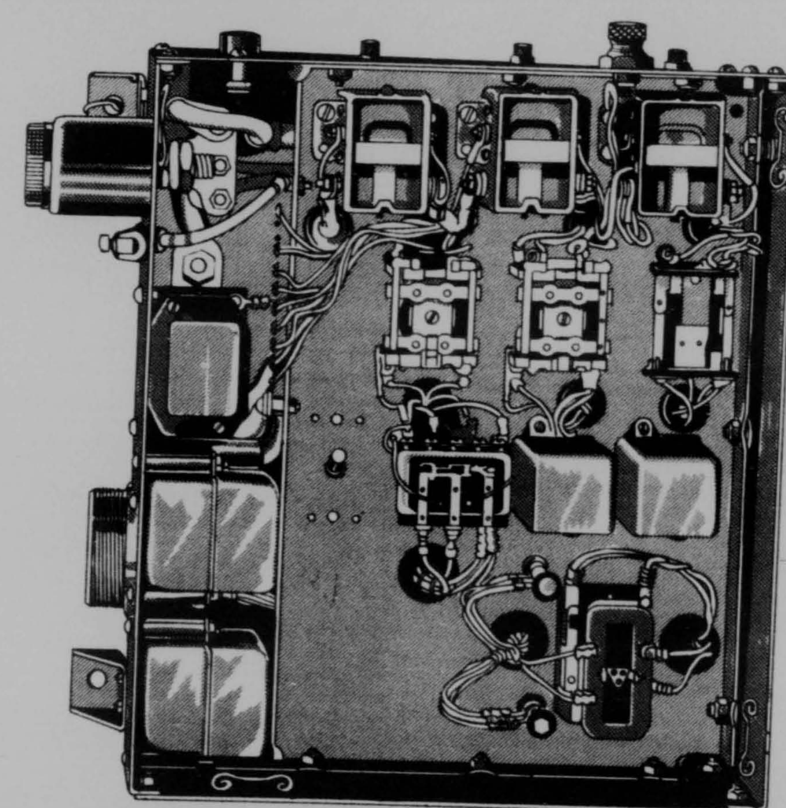

Figure 6—191A. Interior View of Typical Two-Gun Turret Junction Box.

Blister Control Box
(Figure 6-189)

This box is located aft and between the right and left-hand blister gunner.

Control Box
(Figure 6-190)

This box is fastened to the side of the airplane at the gunner's left.

5. JUNCTION BOXES
(Figure 6-191 and 6-191A)

Four junction boxes are used in the remote-control turret system, one for each of the turrets except the tail. The junction boxes house such electrical devices as capacitors, circuit breakers, relays, contactors, and resistors. All junction boxes for the two-gun turrets are identical. The junction box for the four-gun turret differs from those for the two-gun in some interior details.

Location

The junction boxes are located within the

pressurized areas of the airplane so they can be reached during flight for resetting of the circuit breakers. The upper-forward turret junction box and the lower-forward turret junction box are located to the right of the forward turrets. The upper-aft-turret junction box is mounted under the control box of the upper sighting station. The lower-aft-turret junction box is located forward of the lower-aft turret.

Components
(Figure 6-192)

Circuit Breakers. Four thermal-overload circuit breakers are located in each junction box (K1, Figure 6-192) : a 120-ampere turret-power circuit breaker (K2), a firing-power circuit breaker (K3), a 35-ampere auxiliary-power circuit breaker, and (K4), a 15-ampere turret-control circuit breaker. The firing-power circuit breaker in the two-gun turret junction box is rated 35 amperes, and the firing-power circuit breaker in the four-gun turret junction box is rated 50 amperes. The circuit-breaker reset buttons extend through the side of the junction boxes where they can be reached for resetting.

Relays. Relays are used in the junction box to energize and de-energize circuits to perform five different functions.

Field Relays. These are double-pole, double-throw relays used in the junction boxes to control power to the azimuth and elevation amplidyne control fields (K7 and 11, Figure 6-192). One set of contacts of the elevation field relay is used in connection with control of power to a backout relay.

Elevation Limit Relay. This is a three-pole, double-throw relay (K12, Figure 6-192) used in each junction box. It is connected in the firing-contactor circuit and also in the holding and stowing circuits in the two-gun turret junction box.

Elevation Backout Relay. This is a double-pole, differential-current relay (K20, Figure 6-192) used in the two-gun-turret junction boxes. It permits backout of the turret after the elevation amplidyne field relay has interrupted power from the servo-amplifier to the amplidyne control field. A three-pole, differential-current relay in the four-gun-turret junction box performs the same function. The third pole operates the motor brake.

Action Relay. This is a four-pole, single-throw relay (K45, Figure 6-192).

Out-of-synchronism Fire-interrupter Relays. These are differential-current relays (K17 and K18, Figure 6-192) used in the junction box to serve as azimuth and elevation out-of-synchronism fire interrupters. A normally closed set of contacts in each relay interrupts the firing circuit whenever the servo-amplifier outputs are sufficiently unbalanced.

Contactors. Contactors are used in the junction boxes to energize and de-energize circuits to perform four different functions.

Auxiliary-power Contactor. (K23, Figure 6-192.) This is a 50-ampere contactor which controls power to the air compressor and gun heaters.

Turret-power Contactor. (K24, Figure 6-192.) This is a 50-ampere contactor which controls power to the drive motor fields, turret latches, and certain operating relays and holding circuits.

Amplidyne Contactor. (K21, Figure 6-192.) This is a 200-ampere contactor used for starting the two turret amplidynes. Coil-shorting contacts in the unit permit temporary high coil currents to be used for pull-in of the armature.

Firing Contactor. (K15, Figure 6-192.) The firing contactor is a 50-ampere single-pole, single-throw contactor which controls power to the gun-charger firing solenoids.

Stabilizing Capacitors and Resistors. (C1, C2, C3 and C4, Figure 6-192.) Four stabilizing capacitors and two associated grounding resistors are located in each junction box. Two of the capacitors and one resistor are connected in each amplidyne output circuit.

Stowing and Holding Resistors. In the two-gun-turret junction boxes, two resistors not found in the four-gun boxes are mounted close to the limit relay. One of the resistors (Figure 6-192) is known as a stowing resistor since it is used in the turret-stowing circuit. The other is known as a holding

THIS PAGE IS DECLASSIFIED IAW EO 13526

resistor since it is used in the circuit which holds the guns in stowed position while power is on but the turret is not being operated.

Upper-lower Turret Switch. (S8, Figure 6-192.) This is a three-pole, double-throw switch which is mounted in the two-gun-turret junction box to permit shifting the circuits of the box to adapt it for use with either upper or lower turrets. This switch is concealed when the cover of the box is in place so that it will not be inadvertently thrown to the wrong position after the box is once installed. It should be safety-wired in the proper position when the box is installed.

Terminal Posts and Connectors. The junction boxes are provided for a terminal post (P, Figure 6-192) for incoming 27-volt DC power and with a twin-binding post (E1) for obtaining 400-cycle, 115-volt power. They are provided with AN connectors for connection with other circuits.

SECTION VI—SERVO AMPLIFIER

1. PURPOSE AND NOMENCLATURE

The servo amplifier is an electronic device used in the remote-control turret system. It consists of vacuum tubes, transformers, and other elements necessary in an electrical circuit for amplification and rectification of an electrical signal.

Function

In the follow-up system the servo amplifier is located between the Selsyn system which furnishes the error signal, and the amplidyne generator which generates the power for the armature of the turret drive motor. It is so located because it has 4 functions:

It must amplify the error signal so there will be sufficient power in the control field of the amplidyne to secure full amplidyne output.

It must change the AC error signal to DC for energizing the control field of the amplidyne.

It must provide a method of changing from the 31-speed to the 1-speed error signal when the sight and turret are more than three degrees out of alignment and of reverting to the 31-speed signal when the turret and sight have been brought to close alignment. As previously explained, a misalignment between the sight and turret causes an AC signal output from the Selsyn system. This output, which is an AC voltage, regulates the amount of DC flowing in each half of the control field of the amplidyne. The amplidyne output in return, causes the turret-motor armature to rotate which drives the guns into alignment with the sight. The servo amplifier is the unit to which these small AC voltages are used to control direct current large enough to excite fully either one half or the other of the amplidyne control field. The servo amplifier regulates the current in each half of the control field of the amplidyne.

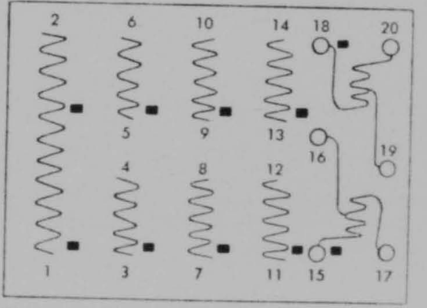

Figure 6—193. Power Supply.

It must provide a bi-directional output depending on the direction of movement of the sight.

Azimuth and Elevation Channels

The servo amplifier is really two amplifiers in one, because two motions, azimuth and elevation, must be controlled independently. It is customary to call these independent parts of the amplifier "channels" and to speak of the azimuth channel and the elevation channel. A power transformer is shared by the two channels, but there are independent secondary windings for each channel. This power transformer, referred to as T-4, is used to supply power to all tubes in the servo amplifier in both azimuth and elevation channels. (Figure 6-193). It consists of a primary winding energized by the 115 volt 400 cycle AC from the dynometer, and eight secondary windings. Four of these secondaries have 275 volts AC potential to be used for plate potential output tubes, two for azimuth and two for elevation; two secondaries of 230 volts AC potential, to supply plate potential for the one-speed tube, and plate potential for the screen grid tube (one of these secondaries for azimuth and one for elevation.) The other two secondaries of 6.3 volts AC potential are used to supply heater voltage for all tubes in the servo-amplifier. One of these 6.3 volt windings supplies heater voltage for all tubes in the azimuth channel and the other 6.3 volt winding for all tubes in the elevation channel. The servo-amplifier makes the distinction of conducting on alternate half cycles, i.e., on one-half of the AC output of the dynamotor the azimuth channel will conduct, and on the other half-cycle the elevation channel will conduct. The T-4 power transformer is so wound that when terminal 2 of the T-4 is negative, the azimuth channel will conduct because, at this time, the plates of all the azimuth tubes will have a positive potential applied. (Figure 6-194). At this same time, the plates of all the

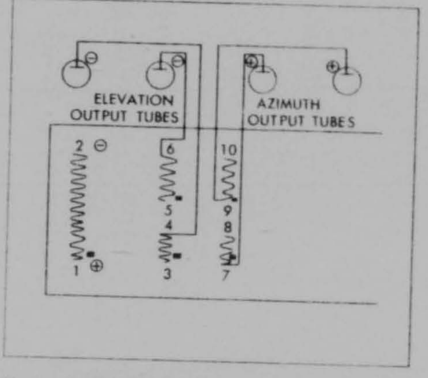

Figure 6—194. Partial Elementary Diagram, Basic Circuit, Elevation and Azimuth Output Tubes.

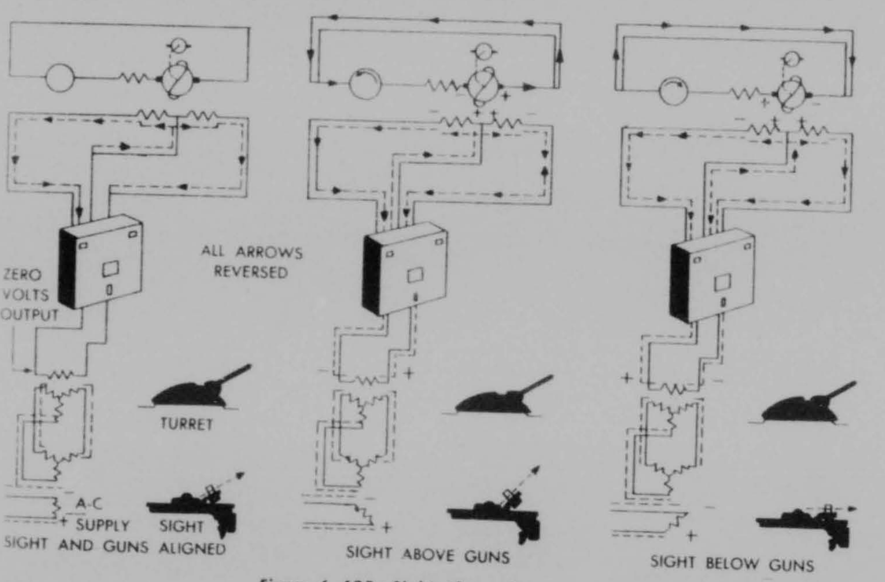

Figure 6—195. Sight Above Guns.

RESTRICTED

THIS PAGE IS DECLASSIFIED IAW EO 13526

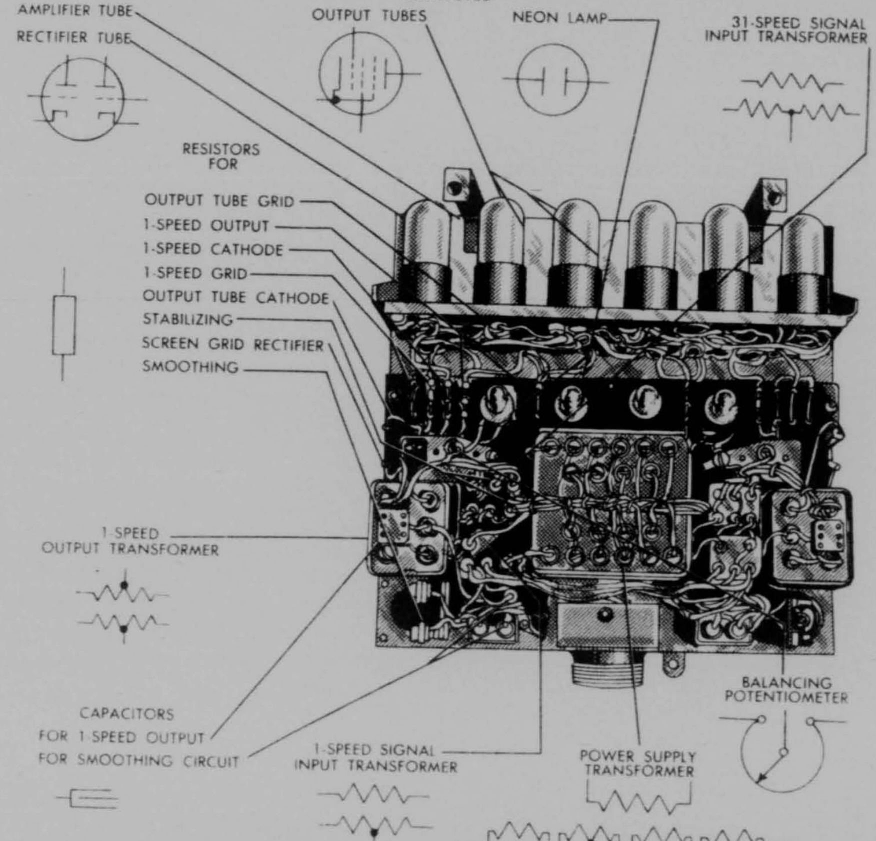

Figure 6–196. Servo-Amplifier, Type 2CV1C1, Interior View, Showing Electrical Symbols for Various Elements.

elevation tubes will have a negative potential, therefore not conducting. On the next half cycle of the dynamotor output, all these polarities are reversed, making the azimuth channel nonconducting, because of a negative potential on the plates of these tubes; but the elevation channel will conduct, due to a positive potential on the plates of its tubes. Since both channels are identical, only the elevation channel, the amplifier for which is located in the half of the case, will be described.

5. ELECTRON THEORY

Although references for this material (T.O. 11-70A-1) use the conventional theory of electron flow, (current flows from positive to negative) this information is written in accordance with the electron theory, (current flowing from negative to positive).

Operation of Electron Theory

Figure 195 shows schematically three possible conditions that might exist in the system. At the left, sight and guns are aligned, the output of both the 1- and 31-speed selsyn control transformer is zero volts and the servo amplifier allows equal currents to flow in the two halves of the amplidyne control field. This

results in no output voltage generated by the amplidyne and no motion of the elevation drive motor, which is as it should be when guns and sight are aligned.

In the center diagram of Figure 195 the sight is shown elevated. The Selsyn system sends a signal to the servo amplifier, indicated as a positive (plus sign) on the sight at a particular instant. Now more current flows in the left half of the amplidyn control field and less in the right half. The amplidyne generates a voltage of such polarity that the turret drive motor elevated the guns to align with the sight.

The diagram at the right of Figure 6-195 shows the situation when the sight is lowered below the guns. Comparing this with the center diagram it is seen that the polarity of the Selsyn signal is reversed the right half of the control field has more current and the left half has less. As a result, the polarity of the voltage generated by the amplidyne is also reversed. And the turret-drive motor now drives the guns down to align with the sight.

6. BASIC PARTS AND DETAILED DESCRIPTION

General

The physical appearance and location of each unit of the servo-amplifier are shown in Figure 6-196, together with the symbols by which the units are represented in the schematics and elementary system diagrams. The AN (Army-Navy) connector and the power supply transformer are at the lower center. The units of the elevation channel are located in the left half and similar units for the azimuth channel are in the right half.

Base

The base is a metal plate with four rubber shock mountings, one near each corner. Three straps riveted to the base serves as a support for the AN-3102-28-17P, 15-pin connector, and the anchor pins engaged by the cover lathes. All other parts are attached to the base by screws, studs or bolts. The tube types to be used in each socket are stamped on the base near the tubes.

Cover

The cover slips over the equipment to protect it. The straps on the base and the ends of the tube shelf, guide the cover into place. Sliding latches engage slot in conical pointed anchor pins attached to the straps on the base, which project through holes in the cover. Fastened to the interior of the cover are two sockets for holding a spare tube of each type used in the amplifier and a clip for a spare neon lamp. Louvres and holes permit a circulation of air to carry off the heat from the equipment. A wiring diagram is cemented to the inside of the cover.

Tube Shelf

The tube shelf contains twelve sockets for the eight 6V6-GT output tubes and the four 6SN-7-GT 1-speed amplifier and screen grid rectifier tubes. The shelf is attached to the base by screws and nuts. The eight 100,000-ohm grid-protective resistors for the output tubes are soldered between the grid tab and an unused tab of the output-tube sockets.

Capacitors

Four 0.5 microfarad, 500 volt DC output smoothing capacitors are fastened to the base of the servo with screws and nuts. They are located at the bottom, two on each side of the connector support. A .0015 microfarad, 500-volt capacitor is soldered across the primary terminals of each of the two 1-speed coupling transformers. A .0015 microfarad 500-volt screen by-pass capacitor is mounted on each of the potentiometer assemblies between the plates of the screen grid tube and its plate load resistor. This is a parallel circuit.

Transformers

The power supply transformer for both azimuth and elevation channels is mounted on the base immediately above the AN connector and is held by nuts on the studs projecting through the base. Symmetrically located on each side of the power supply transformer are the two 31-speed input transformers, the two 1-speed input transformers, and the two 1-speed output transformers. All transformers are attached to the base with studs and nuts.

The 31-speed input transformers may be identified by the two 75,000-ohm stabilizing resistors soldered to their terminals. These are not found on the 1-speed input transformers. The primaries of both types of input transformers are rated 57.5 volts 400 cycles. The two secondaries of each 31-speed input transformer are rated 28.75 volts. The secondary of each 1-speed input transformer is rated 115 volts with a midtap. The primary and secondary of each 1-speed output transformer is rated at 220 volts. Both have midtaps.

Potentiometer Assemblies

Above each transformer group is located a potentiometer assembly attached to the base by two screws with nuts, and a ground post. The 40-ohm potentiometer is mounted upon a bracket attached to the ground post at one end and riveted to an upright resistor-board assembly at the other end. An acorn-nut clamps the potentiometer shaft and covers it to prevent tampering. Adjustment of the potentiometer setting is made with a screw-driver. On each resistor-board assembly are terminals to which are soldered a 36-ohm output tube grid-bias resistor and a 5100-ohm output tube screen-grid-current-limiting resistor. Stacked on each ground post above the potentiometer bracket are three nuts and three terminals all locked by a nut on top. The several connections to ground from parts of the servo-amplifier circuits are soldered to the terminals on the ground posts.

Resistor Bracket Assemblies

At each lower corner, and using two of the DC smoothing capacitor mounting screws, are resistor bracket assemblies each mounting the two 10,000-ohm smoothing resistors. The resistors are clamped between two clips. A rivet also holds resistor base and bracket together. Terminals in the resistor base are soldered to the ends of the resistors.

Resistor Unit Assembly

Across the entire middle of the servo-amplifier is mounted the resistor unit assembly. Three posts support the resistor unit panel on the base. The panel has twenty terminals to which the ten resistors are soldered. Four sockets for the neon lamps are attached to the panel. The two outside resistors for the 1-speed amplifier tubes, at each end are 100,000-ohm grid-protective resistors. The third resistor from each end is a 510-ohm grid-bias resistor for the 1-speed amplifier. The fourth and fifth resistors from each end are 100,000-ohm current-limiting resistors for the 1-speed output.

Connection

All internal connections between the several parts of the servo-amplifier and to the AN connector are made with aircraft wire in accordance with specification AN-J-C-48. Where wires may be grouped they are served into a cable with linen twine. All wires are marked with numbers in accordance with a schedule. Number one is a ground connection. Numbers from 2 to 26 apply to the elevation channel. Numbers from 29 to 52 apply to the azimuth channel.

SECTION VII—ONE AND THIRTY-ONE SPEED CIRCUIT OPERATION

1. INTRODUCTION

A DC power circuit from the airplane generator supplies the dynamotor, the amplidyne drive motor and the field of the turret drive motor. The dynamotor generates alternating current power. 115 volt, 400 cycle AC power from the dynamotor is fed to the motor of the Selsyn generator on the sighting station and to the primary of the power-supply transformer in the servo-amplifier. The Selsyn generator sends the sight position signal over the wires of the Selsyn control transformer on the turret. The sight and guns are aligned and the AC voltage alternations are assumed to be stopped or "frozen" at the half cycle when the tube plates are positive.

The stabilizing circuit is used to overcome the tendency of the guns to overshoot the position of alignment with the sight. For example, when the action switch on the sight is depressed, and the guns slew toward alignment, their progress is so rapid that they tend to overshoot the mark. Upon returning, and unless steps are taken to prevent it, they will again overshoot. Such "hunting" for the alignment position could continue indefinitely. For this reason, a stabilizing circuit is provided.

The central station fire control system is used on several types of aircraft such as the B-26, P-61, B-29 and B-50. There are five sighting stations, four turrets and one tail mount on the B-29, and although one sighting station may control one or more turrets, the electrical connections between any given sighting station and the turret being controlled are essentially the same. The transparent dome of the sighting station, which protects the gunner from the slip-stream of the plane, does not turn when the sighting station turns. The sighting station is within the dome. The gunner sits in the seat and aims the sight, a task which he performs manually. The sight is not power driven; the guns are.

The Selsyn generator is constantly sending electric impulses, or signal voltages, to the turret. These signal voltages indicate the position of the sight, so that the turret is always informed of the position of the sight at any particular instant. The Selsyn control transformer compares the relative position of the sight and the guns. When both are pointing in the same direction, or in alignment, no further action takes place. However, if the gunner should elevate the sight, the value of the signal voltages being sent to the turret would be correspondingly altered. When the Selsyn control transformer compares the position of the sight and turret and finds that they are not in alignment, a signal is sent to the servo-amplifier by the Selsyn control transformer and brings the sight and guns in alignment, both in elevation and azimuth. Then the purpose of the central station fire control system has been achieved.

2. PRINCIPLES OF COMPUTATION

For short ranges, with a stationary gun and a stationary target, a gun can be aimed directly at the target by sighting along the gun barrel. However, as has been discussed, in aircraft practice the ideal condition is seldom met, and the direction of the gun's bore axis must be shifted with respect to the direction of a moving enemy aircraft. To better understand the principles of computation some of the work which has been previously covered will be reviewed briefly at this point. The amount that the gun must be shifted depends upon the forces acting upon the projectile after it leaves the muzzle of the gun, such as windage and gravity, and upon the velocity of the target relative to the gun. If the sight is not mounted on the gun, but is located at a distance from it, as is the case with a remote-control turret systems, the line bore must be further changed to compensate for the **"parallax"** distance.

Computing and Noncomputing Sights

There are two methods used at present for aiming the guns at the target, namely, computing and noncomputing systems. In computing systems, the computer can be switched "in" or "out" of the circuit instantly at the option of the gunner. In a noncomputing system, the line of sight is maintained parallel with the line of bore, and the gunner advances the line of sight from the target position in an amount determined by him from his own experience and judgment.

In a computing system, the line of sight is held on the target by the gunner and the relative position of the guns and the sight is determined by the computing mechanism. The use of the computer eliminates the guesswork on the part of the gunner in estimating range, ballistics, parallax, and lead prediction and leaves him free to concentrate on accurately tracking the target and keeping it aligned in the sight.

Whether a computing or noncomputing system is used, the corrections must be taken into account in order to have the projectile strike the target. In a computing system, one computer is used in conjunction with each sighting station. Each computer makes corrections for ballistics, parallax, and lead. Each of these corrections will be considered separately.

Ballistics

Ballistic correction compensates for the deviation of the projectile from the gun line. This deviation is caused by the wind and force of gravity acting upon the projectile. The total ballistic correction consists of windage, gravity, and range corrections. Windage is the term usually used to designate the effects of altitude, temperature, and airspeed on the path of the bullet. A windage force is caused by the airspeed of the airplane. This is merely the airplane's speed relative to the air. This wind force is applied to the projectile in a direction parallel and opposite to the direction of flight.

In an airplane, the wind is always from the front to the rear, never deviating more than a few degrees from the fore and aft axis of the airplane. If the projectile is fired at zero degrees elevation and straight forward or aft, the projectile is not deviated from the line of bore by the windage force. However, for any other gun position, this force will deviate the projectile from the line of bore toward the rear.

Maximum deviation occurs when the target is broadside; and for any given angle from the center line, it is greater in the two forward quadrants, since the energy of the projectile is lost at a greater rate in these quadrants because of greater resultant windage forces. The windage offsetting correction is always forward in the direction in which the airplane is moving.

The magnitude of the deviation, and hence the correction, depends upon the airspeed, air density, and range. The windage correction increases with an increase in airspeed and range and decreases with increase in altitude. For short ranges involved, the correction is nearly proportional to the range of other conditions constant.

The effect of gravity upon the projectile is to cause it to curve toward the earth. The gravity correction is greatest at more degrees elevation and decreases with the movement of guns away from the "O" position. Gravity acts upon the projectile throughout the entire time of flight, and the gravity correction varies nearly directly with the time of flight.

Range is the distance from the gun to the target. As the range is increased the time of flight of the projectile is increased, which has an effect on all corrections.

Gravity correction increases with the range and is nearly proportional to it insofar as the ranges encountered in the computer are concerned.

Windage correction also increases with range and is nearly proportional to it insofar as the ranges involved in the computer operation are concerned.

In order to calculate the ballistic correction, the computer must obtain azimuth gun position, range, and windage.

Parallax

Parallax correction is the angle between the gun and sight, measured at the target, when the gun and sight are located at different positions on the airplane. Without the parallax correction, the guns would point parallel to the line of sight and would miss the target by the distance between the gun and sight location which is parallax base length. There is no parallax correction when the gun and sight are located at the same point. Parallax position varies for different target positions or range. It is zero for straight forward or straight aft.

The factors affecting parallax correction are elevation and azimuth gun positions, range, and the parallax base length. The parallax correction increases from zero degrees to plus or minus 90 degrees elevation and is greatest at plus or minus 90 degrees. The parallax correction increases as the azimuth gun position from zero degrees to plus or minus 90 degrees and is greatest at 90 degrees and 270 degrees. The correction again decreases as the guns move toward 180 degrees azimuth. The parallax correction for a given azimuth position is changed by the movements of the gun elevation position. The parallax correction increases as the range becomes shorter and decreases as the range becomes longer. The parallax correction increases with an increase in parallax base length. In order to calculate the parallax correction, the computer must obtain azimuth gun position, elevation gun positions, range, and parallax base length.

Prediction

Lead prediction correction is an angular correction. It is the angle at the sight between the present and future position of the target. The correction is necessary to compensate for the movement of the target while the projectile is travelling from the gun to the target. It is the same correction that a hunter makes when he shoots ahead of a flying bird.

Since prediction correction is the angle determined by multiplying the angular velocity by the sight angular velocity, gun position, windage, and range. To determine the prediction correction, it is necessary to predict the future position of the target which is the location of the target at the time the projectile will reach it. The prediction of the future position assumes the path of the target to be essentially a straight line while the time taken by the projectile to travel to a point on that path is determined from known characteristics of the ammunition. The proper gun position is obtained when the target and the projectile reach the same point (future position) at the same time. With the target traveling the same direction and speed as the gunner's airplane, there is no change in the angle of sight and hence no lead prediction is necessary. Thus, only the ballistic and parallax corrections are required. However, if the gunner's plane and target are traveling in the same direction at different speeds or in opposite directions, there is a change in the sight angle, requiring a corresponding lead correction angle or "lead prediction."

In order to calculate the lead prediction correction, the computer must obtain the relative angular velocity of the target or line of sight with respect to the gunner's airplane, range of the target, air density, and ballistics as it affects the time of flight of the projectile.

3. OPERATION OF THE COMPUTER

The computing remote-control system is similar to the noncomputing system in all respects except that a computing mechanism is connected in the electrical signal circuit between the sighting station and the gun turret.

When not in use, the computer has no effect on the signals and the system continues to operate as a noncomputing system. However, when the computer is switched in, the computer automatically makes all computations for ballistics, parallax, and lead prediction and displaces the voltage distribution and polarity of the signal voltage between the sighting station and the gun turret. This displacement is of the necessary amount to aim the gun so that, when the gunner aims his sighting station directly at the target the projectile will strike the target, thus eliminating guesswork by the gunner.

Selsyn Differential Generator

Interposed in the computer, between each Selsyn generator located on the sight and Selsyn control transformer located at the turret and elevation and azimuth input unit in the computer, is a Selsyn differential generator. This is mechanically connected to the elevation total correction unit or azimuth total correction unit so that any elevation total correction or azimuth total correction made by the computer results in a rotation of the differential generator's rotor by an amount proportional to the correction. The rotation of this rotor displaces the voltage distribution of the signal by a proportional amount and so moves the gun turret, and the elevation and azimuth input unit located in the computer, by an additional amount corresponding to the correction.

Switches

Two switches control the use of the computing system. Closing the computer standby switch at the sight energizes the coils of the computer cutout relays. This closes the normally open contacts of these relays and opens the normally closed contacts. This section inserts the computer into the signal system between the Selsyn generators and Seisyn control transformers, allowing the computer to correct the Selsyn signal. Closing the computer switch at the control box supplies power to the two gyro units from the 28-volt DC bus bar. If this has been closed for fifteen seconds, allowing the gyroscopes to come to speed, the computer is ready for instantaneous operation as soon as the "standby" switch at the sight is closed.

The Input Follow-up Systems

There are four input follow-up systems in the computer, one for each signal input, namely: gun elevation, gun azimuth, range, and windage. These four inputs are fed to the computer as electrical signals which are converted into shaft rotations. These rotations act as mechanical inputs to the ballistic and parallax units and the axis converter.

Elevation and azimuth gun positions are obtained from the Selsyn system.

Range of the target is supplied by each gunner to his computer by means of a range transmitter potentiometer in his sight. This potentiometer is varied as the gunner adjusts the range knob of his sight. In the 2CHIL computers, the range input may be switched to either the sight or the radar, as he chooses.

Windage is supplied from the five windage transmitter potentiometers in the navigator's handset.

Thus, three different methods for obtaining a signal voltage are used, one through the use of the 1-speed Selsyn control transformers, another through the use of potentiometers, and the third through the use of a radar receiver. The potentiometers are not so accurate as the Selsyn controls but are simpler and more compact, and are sufficiently accurate for the purposes for which they are used. Selsyn control transformers are employed to obtain signal voltages for gun elevation and gun azimuth follow-up systems, because the gun elevation and gun azimuth input signals can be readily obtained from the Selsyn circuits between the associated sight and gun turret, the voltage at the rotor of the Selsyn differential generators in the computer indicating the gun turret positions in azimuth and elevation. Potentiometers are used to obtain signal voltages for the range and windage follow-up system.

An action switch, located on the sighting station and operated by the gunner, energizes the computer control circuits when it is closed.

The computer corrects for ballistics, parallax, and lead and allows the gunner to concentrate on accurately tracking the target and keeping the correct range adjustment. The ballistic correction compensates for the deviation of the projectile from the line of bore. Parallax correction is the angle between the gun and the sight, measured at the target, when the gun and sight are located at different positions on the airplane. Lead prediction correction is the angle at the sight between the present and future position of the target. These are accomplished by a computing mechanism connected in the electrical signal circuit, between the sighting station and the gun turret. In summation, it should be remembered that computer requires four input electrical signals: gun azimuth, gun elevation, windage, and range.

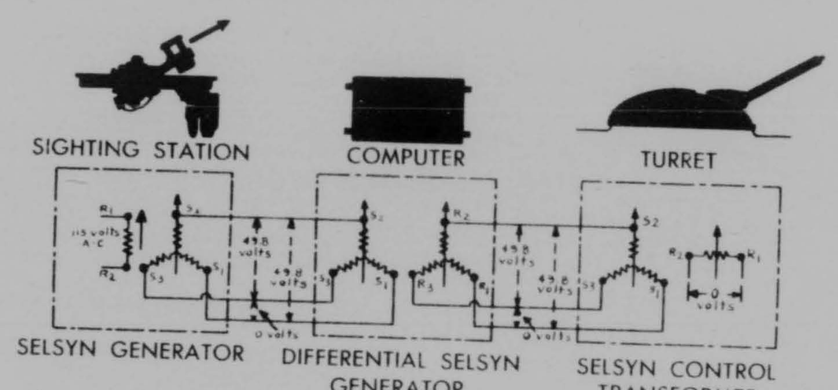

Figure 6–197. Electrical Connections of Differential Selsyn Generator into Selsyn System.

4. DIFFERENTIAL SELSYN GENERATOR USED IN COMPUTING SYSTEM

When the computer is placed in the B-29 fire control system a correction is applied to the Selsyn signal between the sighting station and turret so that the turret does not follow the sight in exact alignment but moves a slightly greater or lesser amount depending upon the corrective signal applied by the computer. For example, if the gunner is tracking an enemy aircraft through the sight, it is desirable to have the turret aim the guns slightly ahead of the target or "lead" the target, so that the target and gun fire will meet in space. The computer will automatically introduce this "lead" correction into the Selsyn system if the gunner simply follows the enemy aircraft with the sight. The correction is introduced by means of a differential Selsyn generator.

The differential Selsyn generator is similar to the standard Selsyn generator previously described except that the rotor is provided with a three-coil winding, rather than a single winding. The stator rotor is rotated by the computer by an amount determined by the correction to be applied.

Figure 6-197 shows the manner in which the differential generator is connected into the Selsyn system. The stator of the differential generator is connected to the stator of the Selsyn generator while the rotor is connected to the stator of the Selsyn control-transformer. As long as the rotor of the differential generator is in electrical alignment with its stator, as indicated in Figure 6-197, the voltages in the stator and rotor will be the same and the direction of magnetic flux the same. Thus, as indicated by the direction arrows, the position of the Selsyn generator rotor R_1, R_2, is transmitted directly to the control-transformer. This is the position of the differential generator when no correction is being introduced into the system by the computer and the turret guns are in alignment with the sighting station.

When the computer puts a correction into the Selsyn system the computer rotates the rotor of the differential Selsyn generator. In Figure 6-198 the rotor has been moved 30 degrees clockwise. This changes the voltages in the leads to the control-transformer stator so that the direction of magnetic flux in the stator is moved 30 degrees as indicated, producing an output voltage signal from the Selsyn control-transformer even though the Selsyn generator has not been moved. Hence, the correction put in by the computer pro-

THIS PAGE IS DECLASSIFIED IAW EO 13526

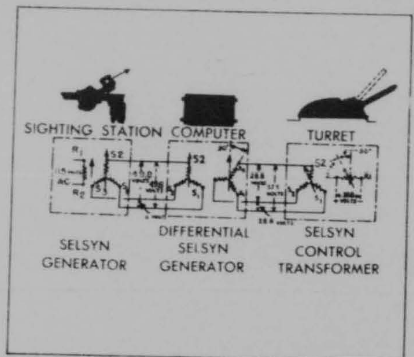

Figure 6—198. How Movement of Differential Selsyn Generator Rotor Affects Magnitude and Polarity of Voltage in Control-transformer Rotor.

duces a signal voltage to move the guns to the dotted line position.

In this way the voltages in the rotor windings of the differential generator vary in magnitude and polarity dependent upon the amount and direction in which the rotor is moved. Hence, the correction put in by the computer produces a signal voltage to move the guns to the dotted line position.

In this way the voltages in the rotor windings of the differential generator vary in magnitude and polarity dependent upon the amount and direction in which the rotor is moved. Since the three voltages in a Selsyn system represent a position, the differential Selsyn generator is a device for adding or subtracting a given angle to that position.

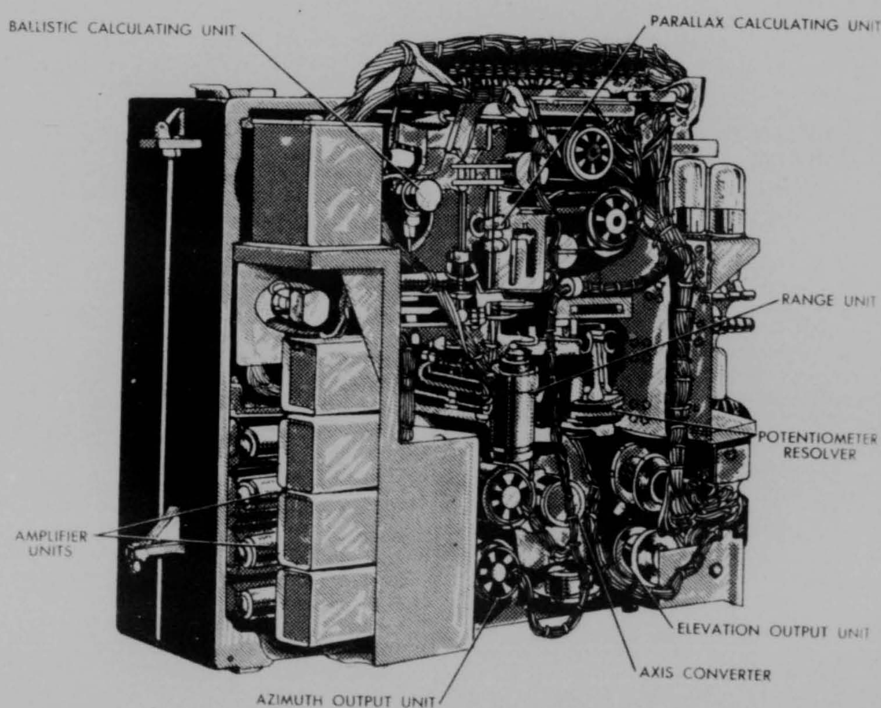

Figure 6—199. Single-parallax Computer, Model 2CH1C1 (Prototype).

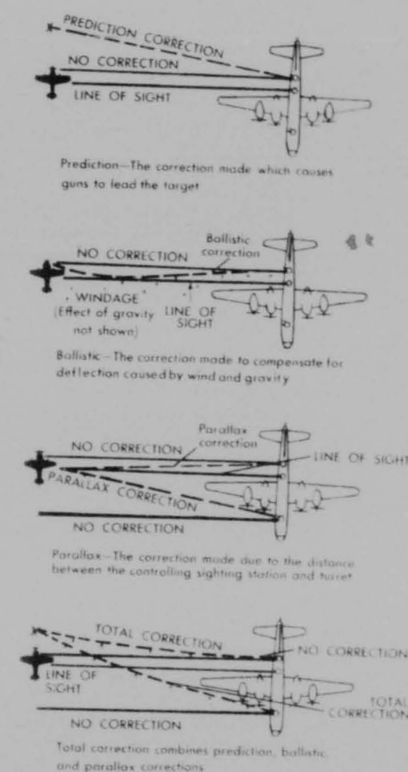

Figure 6—200. Lead, Ballistic, and Parallax Corrections.

5. COMPUTER, TYPE 2CH

General

Introduction. The type 2CH computer is designed (1) to allow a gunner to sight directly on his target, and (2) to cause the bore axes of the guns, on the turret or turrets which the gunner is controlling, to be changed from a position parallel to the line of sight to a position which will cause the projectile to hit the target.

One computer is used in conjunction with each of the five sighting stations. The five computers, however, are located remotely from the sighting stations and are connected only by electrical means. Single-parallax computers, Model 2CH1C1 (Figure 6-199) are used entirely.

Computer Corrections. (Figure 6-200). Each computer makes corrections for the following:

Ballistics. To compensate for windage and gravity forces which cause a projectile to deviate from a straight line after leaving the muzzle of the gun.

Parallax. To compensate for the distance along the longitudinal axis of the airplane between the turret and the sight which is controlling the turret.

Lead. To compensate for the distance the target travels from the time the projectile leaves the gun until it strikes the target.

How the Computer Corrections are Introduced into the System. The three corrections are added together and appear as a single total correction. This total correction is introduced into the system by means of differential Selsyn generators which are electrically connected between the Selsyn generator on the sighting station and the Selsyn control transformers on the turret. A single parallax computer has four differential Selsyn generators—1-31-speed azimuth, and 1-31 speed elevation. When the rotors of the differential Selsyn generators are rotated by the amount of the total correction—as determined by the computer—they will alter, or change, the signals from the Selsyn generators on the sighting station so that the guns on the turret will be changed (by the amount of the total correction) from a position parallel to the line of sight. This new gun position will cause the projectiles to strike the target.

Inputs Required by the Computer. In order to calculate the ballistic correction, the computer must obtain the following information:

Azimuth and elevation gun position.

True airspeed and density altitude (a function of altitude and temperature).

Range, or distance, of target from gunner's sight.

In order to calculate the parallax correction, the computer must obtain the following information:

Azimuth and elevation gun position.

Range, or distance, of target from gunner's sight.

In order to calculate the lead correction, the computer must obtain the following information:

Relative velocity of target with respect to the line of sight.

Range of target.

Density altitude (a function of temperature and barometric altitude).

Ballistics, as it affects the time of flight of the projectile.

Where the Computer Obtains its Necessary Inputs. Azimuth and elevation gun positions are obtained from the Selsyn system.

Range of the target is supplied by each gunner to his computer by means of the range potentiometer in his sight. This potentiometer is varied as the gunner adjusts his range handwheel, or grip, to keep the reticle spanning the target.

The true airspeed is obtained from the navigator's handset unit. This unit computes true airspeed from the indicated airspeed set in by the navigator. Density altitude is also obtained from the navigator's handset unit, being determined from the barometric altitude and temperature which are set in by the navigator.

Relative velocity of the target, with respect to the gunner's airplane, is furnished to the computer by two gyroscopes on the sighting station.

SECTION VIII—HARMONIZATION

1. INTRODUCTION

General

Harmonization is one of the most important and at the same time one of the most exacting of all the jobs which must be done to prepare the B-29 for a successful mission. Without proper harmonization, the best gunner in the world could never hit his target. Basically the job is the same as the harmonization of local power turrets. The line of sight and line of fire must be so adjusted that they are parallel to each other and stay that way when they move.

Problems of Harmonization

The RCT system makes harmonization a special problem. The B-29 has five turrets and five sighting stations all on different levels and at various distances from one another. The lines of sight from each turret and the RCT electrical system must be carefully adjusted so that the guns will always move accurately with the sights throughout their entire range of movement. Corrective mechanisms such as computers play no part in the harmonizing process and are disconnected during harmonization. (Computer switch in "out" position). Harmonizing, however, forms the basis for correct operation of the computer, since the corrections of the computer start off from parallelism of the line of sight and the gun bore axis. The first part of harmonization is the mechanical adjustments of the plane, sights, and turrets. The vertical axes of each turret and sight must be parallel to one another and perpendicular to the axes of the plane within the proper tolerance. The vertical axis of each turret and sight must be perpendicular to the longitudinal and transverse axes of the bomber within a tolerance of ½ degrees. The vertical axes of the turrets and sights must be parallel to one another within a tolerance of plus or minus ½ mil. Figure 6-201 and 6-201A show the proper axes relationships. The tolerance of ½ degrees between sights and turrets and axes of the ship is necessary for proper operation of the fire interrupter and contour followers.

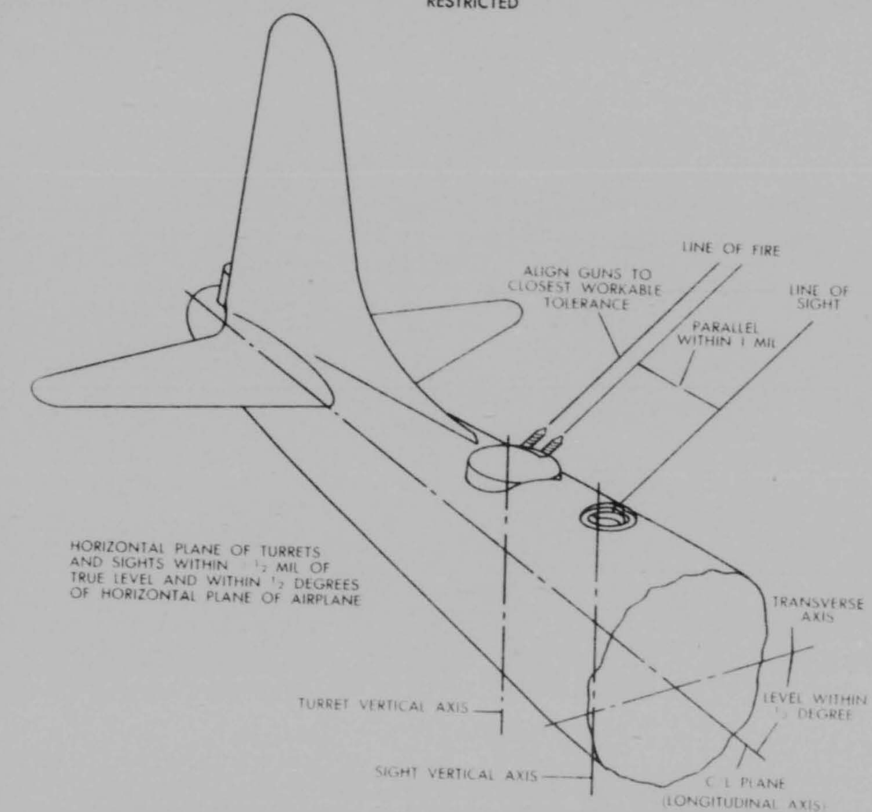

Figure 6—201. The Mechanical Tolerances.

2. LEVELING AIRCRAFT

It is necessary that the airplane be level in order to level the sights and turrets. This is done by six hydraulic jacks. Five of them are of twenty-ton capacity, and the tail jack of ten-ton capacity. Four jacks are placed under the wings at the proper jack pad positions. One is positioned at the nose, the pad being in the nose wheel well, and the tail jack is placed just ahead of the tail skid on its proper pad. When the B-29 sets at normal attitude it is approximately 2 degrees nose high. In leveling the ship the nose is lowered approximately fourteen inches. To do this it is necessary to partially retract the nose wheel. (Figure 6-202).

Placement of Jacks

Jacks are placed (on a base which will not move during the leveling) under wings and nose in preparation for lifting the ship. The nose wheel may be retracted during leveling if necessary or more convenient.

A longitudinal leveling bar and precision level is installed and the jacks adjusted until the level reads "zero." **Caution:** The level must

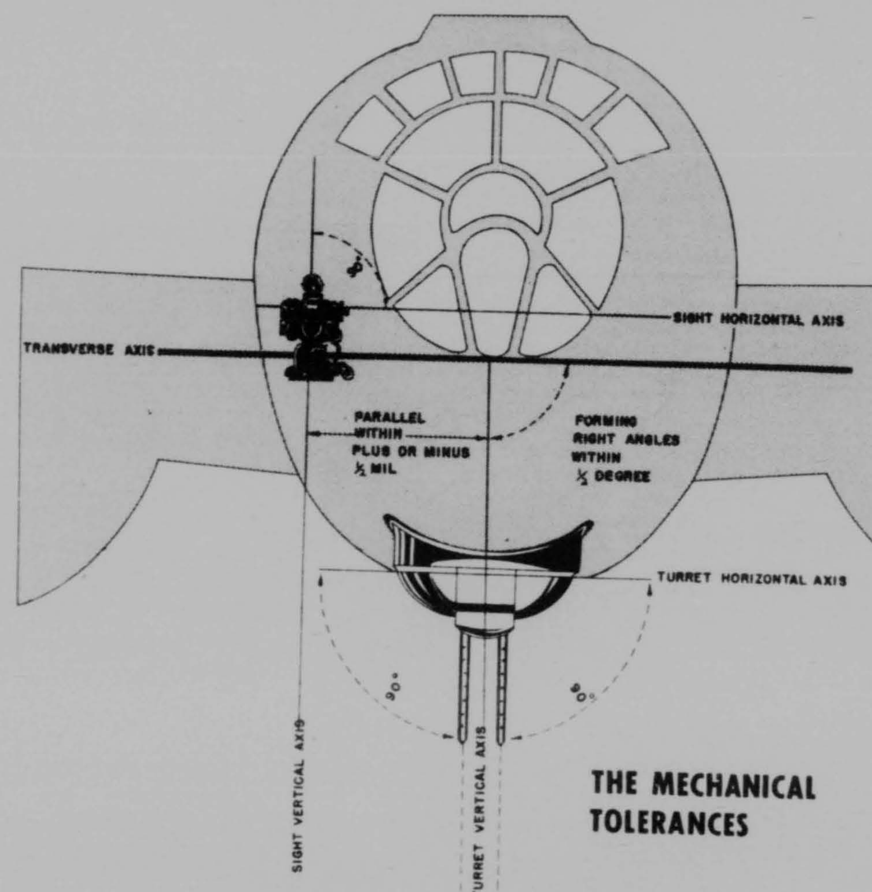

Figure 6—201A. The Mechanical Tolerances.

not be left unattended on the leveling bar. No attempt should be made to lift the airplane with the tail jack.

The transverse leveling bar and precision level are installed, and the jacks adjusted until the level reads "zero."

The longitudinal and transverse level are checked prior to, and at frequent intervals during, the leveling of turrets and sighting stations.

If it becomes necessary to level the ship with a transit, the same procedure should be followed, except that the checks for level are made with the transit. The longitudinal axis is checked for level by means of two points on the belly of the ship. The forward point is a rivet on the center line of the ship, an inch or two in front of the forward bomb-bay door opening. The aft point, which must be jacked to 6.39 inches higher than the forward point to level the airplane, is located a few inches

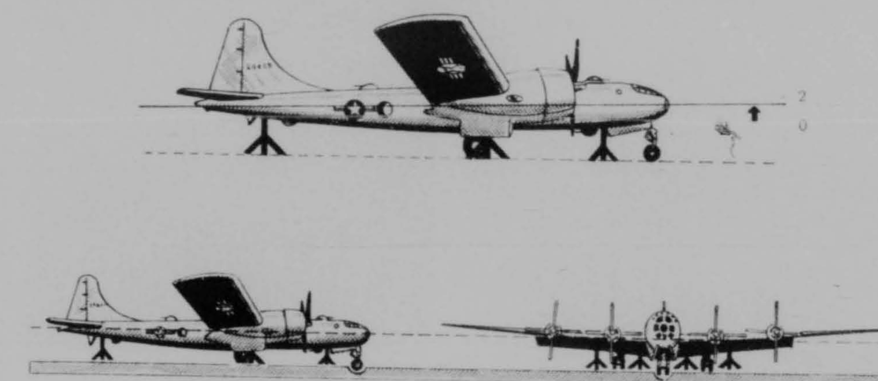

Figure 6—202. Leveling B-29.

aft of the rear bomb-bay door opening. This point can be definitely located by a small tapped hole which is on the center line of the airplane.

The transverse axis is leveled by setting the transit aft or forward of the ship with the telescope level and swinging the transit from a point underneath one inboard jack pad to a point under the inboard jack pad on the opposite side. It is necessary to measure down from the pad, on a line perpendicular to the level transit line of sight. The ship should be lifted as required to make the measurement between the transit line of sight and the jack pads exactly the same on both sides.

Gunner's Quadrant

The gunner's quadrant is used to check the level of sights and turrets. This instrument is calibrated down to fractions of mils and thus has a fine range of measurement. It is attached to the sights and turrets (as shown in Figures 6-203A, B, C, 204). To use the quadrant, the bubble is centered by the adjustable bar and adjustment knob; then a reading is taken on the calibrated arc and the Vernier adjustment knob.

Level (Align Vertical Axes of) Turret and Sighting Stations

When. The turret and sighting stations are leveled when:

Initial harmonizing is being accomplished; or

Turrets or sighting stations have been reinstalled or replaced; or

Maintenance checks indicate the desirability of releveling.

Where. The turrets and sights are leveled after the airplane is leveled as described. It has been recommended that the airplane be leveled outside the harmonizing yard when possible.

How. The planes of rotation (vertical axes) of the turrets and sighting stations must be

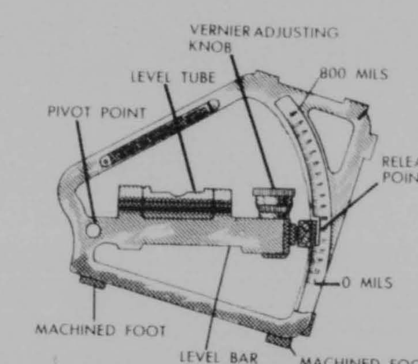

Figure 6—203. Gunner's Quadrant Levels.

Figure 6–203A. Gunner's Quadrant Levels.

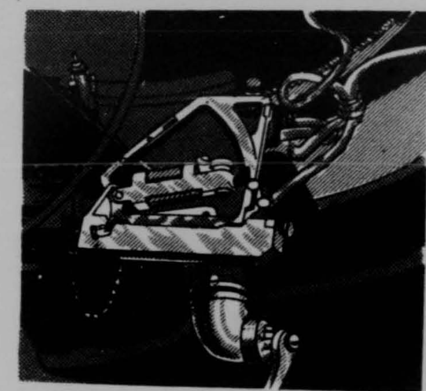

Figure 6–203C. Gunner's Quadrant Levels.

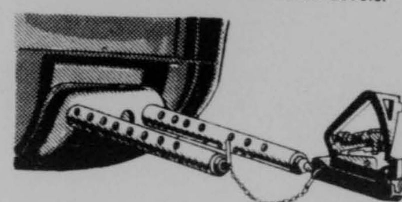

Figure 6–203B. Gunner's Quadrant Levels.

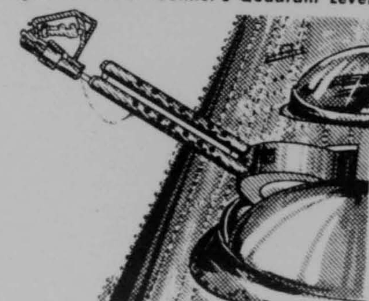

Figure 6–204. Gunner's Quadrant on Upper Turret.

parallel to each other within plus or minus 1/2 mil and must be within 1/2 degree of the level of the airplane. This is accomplished by aligning the vertical axis of the master turret (lower forward turret) with the transverse-longitudinal plane of the airplane and then aligning the vertical axes of all other sighting stations and turrets with that of the master. Also, the turrets must be installed so that the fore and aft index marks on the turret rings are parallel within 1/2 degree of the longitudinal center line of the airplane.

Longitudinal and transverse levels of the airplane should be checked.

Gunners quadrant and azimuth angle measuring sector are installed on the lower-forward turret, which is used as the master. (The angle measuring sector is used to locate points 15 degrees apart in azimuth.)

Guns are depressed to clear contour follower and lock in elevation.

The turret is rotated by 15-degree stops.

Level at each azimuth step is then read.

The tilt of turret is calculated.

Adjustment is made, as necessary, to meet tolerances specified above.

For all other turrets in turn, the level is checked, the tilt measured and adjusted as necessary to meet tolerances by shimming or the use of adjusting screws.

To the blister, tail, and upper-sighting stations, in turn, a level is attached, rotated and checked; the tilt is calculated, and shimmed as necessary to meet tolerances.

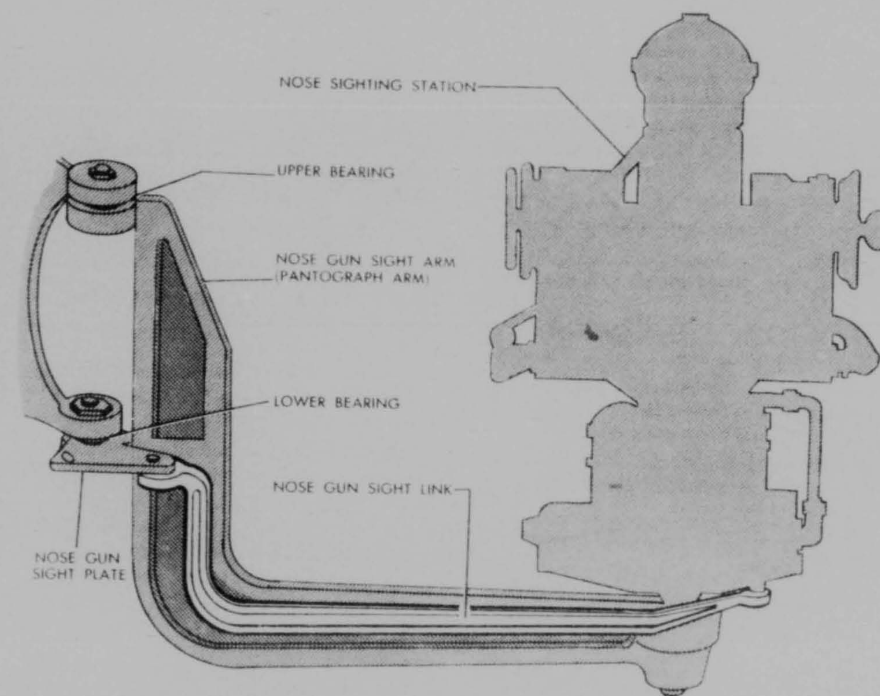

Figure 6–205. Rear View of Nose-sight Pantograph.

Since the nose-sighting station is mounted on a pantograph arm, it is not leveled by shimming under the base, as are the other sighting stations, but is leveled by adjusting the eccentric lower bushing of the main pantograph arm (Figure 6-205).

3. ALIGNMENT OF GUN AXES WITH TURRET AXES

The next step in harmonization is that of aligning the gun axes with the turret axes, i.e., making the guns in a turret parallel to each other and perpendicular to the trunnion axis (the axis around which the guns rotate when they are moved in elevation). This is done in the following manner.

When. The guns must be aligned when:

Initial harmonizing is being accomplished; or

Turret guns have been reinstalled or replaced; or

Maintenance checks indicate desirability of realigning.

Warning: Receivers of aligned guns must not be pulled unless necessary and then only one receiver is taken at a time. The cleaned receiver is then aligned with the one remaining in the turret. (It will then be unnecessary to go through the following gun alignment procedure.)

Where. The guns can be aligned with the airplane at normal or level altitude, in or out of the harmonizing yard. The airplane should be located on a level strip of ground where it will not settle.

How. The preferred method of aligning guns is described in detail below. However, the guns may be made parallel to each other but not aligned to turret axis by using only a distant target when conditions necessitate, although this method is less accurate.

If the airplane is exposed to the elements, it is suggested that it be steadied with jacks before proceeding.

The guns are swung up or down to clear contour follower and then locked in elevation.

The aligning level is placed in the right gun and the turret placed on aft azimuth index mark.

The level bubble is adjusted to level at this point and a reading made.

The inner ring is marked at the point 180 degrees from where the reading is taken (opposite "FWD" mark on outer ring).

The located point on turret inner ring is moved to the forward index mark and a reading made.

The difference of two readings is taken and divided in half.

After adding the least, or subtracting from the greater of the two readings, the resulting reading is set into the aligning level.

The turret is turned in azimuth until the bubble is level. This is the level axis.

This spot is marked on the outer ring using the regular inner ring index mark and a spot is marked on the outer ring 180 degrees away, using the spot on the inner ring located in preceding steps.

The guns are elevated or depressed in elevation until the elevation index marks match and lock. The guns should be about horizontal and broadside.

The level scales are set at 90 degrees and the rear trunnion mount of the right-hand gun adjusted in elevation until the level reads "zero."

With turret still set at level axes:

Level scales are set at zero.

Upper turret guns are elevated or lower turret guns are depressed until level reads "zero." They are then locked in elevation.

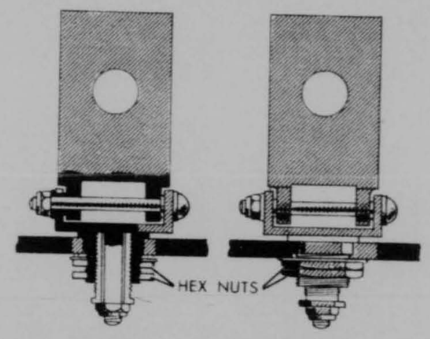

Figure 6–206. Azimuth Adjustment of Guns on Upper and Lower Turrets.

A reading of level axes is taken by rotating level 180 degrees in the bore of the gun. The level should read "zero."

Index lines are marked on saddle and saddle support trunnions to indicate this elevation position.

The level in the bore is rotated 90 degrees.

The rear trunnion mount of gun is adjusted in azimuth only until the level reads "zero."

The level is rotated 180 degrees in the bore and a check made to see that the level still reads "zero."

The right-hand gun is boresighted on a suitable parallax target (with crosshairs 7½ inches apart) or on a distant object and the left-hand gun adjusted in azimuth and elevation to make it parallel to right-hand gun.

The process is repeated for all but the tail turrets.

Cal. .50 tail guns are aligned on a suitable parallax target making adjustments at rear trunnion when necessary. An alternate method is described below.

The gun-alignment level is installed in cal. .50 gun and the turret moved in elevation until the reading is "zero." A level is inserted into the other cal. .50 gun and the gun adjusted in elevation (Figure 6-205) until the level reads "zero."

Sighting is made on a suitable boresight target and an adjustment made in azimuth (Figure 6-206) as required.

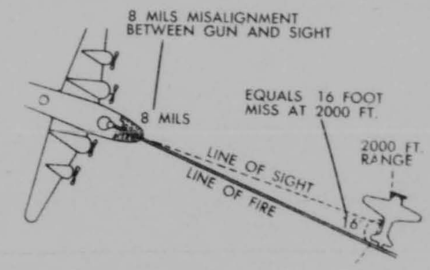

Figure 6–207. How Misalignment Affects Gun Fire.

Operational Check

When. An operational check is made:

When initial harmonizing is being accomplished.

For a maintenance check before harmonizing check.

Where. The operational check can be made at any convenient point where an energizer is available. However, if it is suspected that the system does not operate properly, the operational check should be made before the airplane is moved into the harmonizing yard. If the gunner's report indicates proper operation of the system, the plane can be moved into the harmonizing yard. The harmonizing yard is in great demand. Planes suspected of operational difficulties should be kept out of the yard.

Caution: The complete system must be given a visual check to make sure that parts of the system are all in place and properly connected, that all of the units are undamaged and that no personnel or equipment is in the way of moving parts.

Set Airplane in Harmonizing Yard

When. The airplane should be placed in the yard before proceeding with the electrical adjustments.

Where. The standard and approved method uses the middle-distant harmonizing yard. The long-range harmonizing yard is not to be used for initial harmonizing, but in emergencies may be used for replacement of individual sighting stations or turrets, or for after-flight harmonizing.

How. Procedure is as instructed in the paragraphs which follow.

Long-range Yard. The long-range yard is described briefly in this section. When locating the airplane in the harmonizing yard, each object should be distant enough or located in such a way as to reduce the parallax to the permissible tolerance when both the line of sight and the line of the gun bore are directed upon it. The sights and turrets must be aligned within a tolerance of 1 mil of each other.

For determining the distance at which a long-range target should be removed from the airplane to permit alignment within the tolerance, it should be remembered that a 1-mil error means a 1-foot error at a distance of 1,000 feet away for every foot of perpendicular or horizontal distance between the line of sight and the horizontal or vertical axes of turret (Figure 2-207). For example, a sighting station and turret combination with four-feet vertical parallax and six-feet horizontal parallax between the sighting station and the turret requires a target six thousand feet distant. (Parallax in feet [p] times 1,000 equals minimum distance of object [d], or: 1000p = d.)

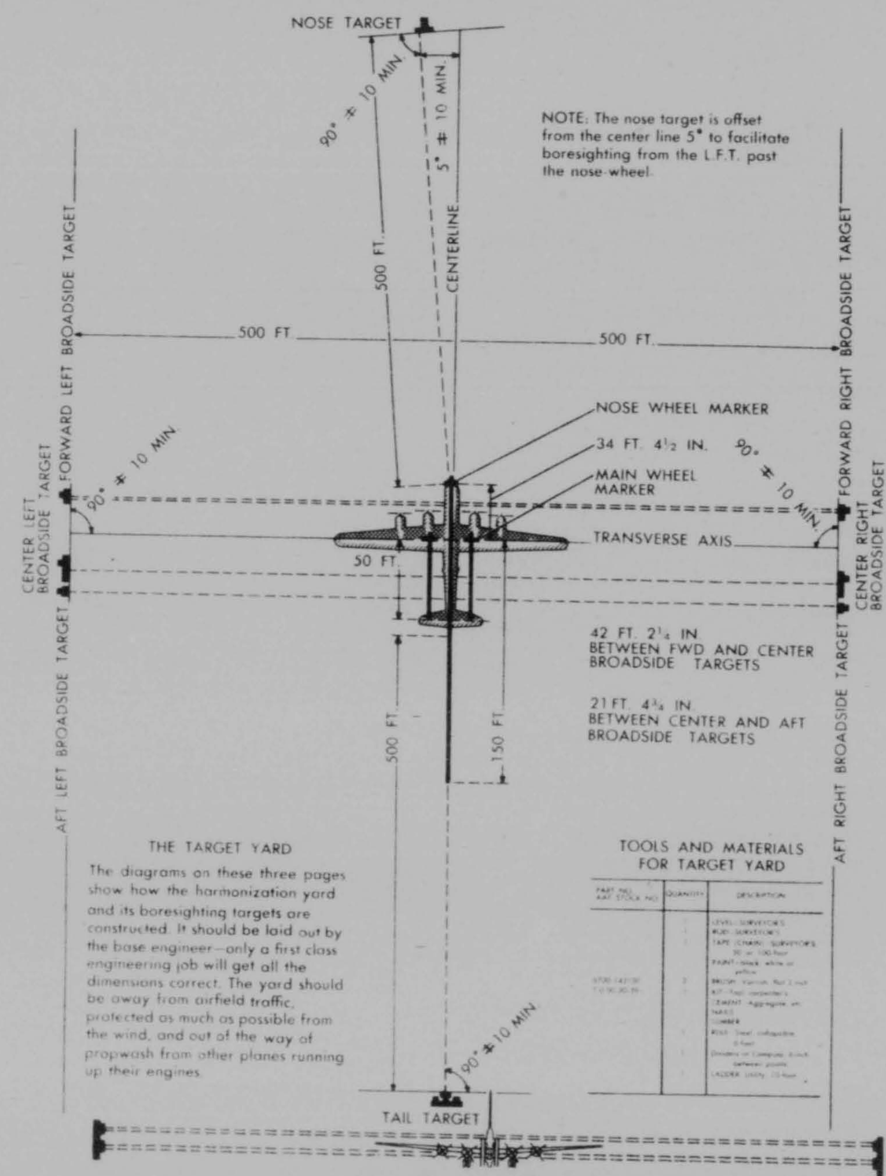
Middle-distant Yard. The middle-distant yard's construction is described in this section. Targets are normally five-hundred feet from the plane but may be moved closer if necessary. Extreme care must be used in locating the airplane when closer targets are used. The possibility of error increases and closer tolerances must be held as targets are moved closer. (At seventy or eighty feet, a one-inch misalignment of the target causes approximately a one-mil error.)

The airplane is towed into the harmonizing yard.

A yard for the normal attitude of the airplane should be used if after-flight harmonizing, or harmonizing without the airplane level is planned.

The yard for the level attitude of the plane should be used if leveling (alignment) of sights and turrets is to be done in the harmonizing yard.

THIS PAGE IS DECLASSIFIED IAW EO 13526



THE TARGET YARD

The diagrams on these three pages show how the harmonization yard and its boresighting targets are constructed. It should be laid out by the base engineer—only a first class engineering job will get all the dimensions correct. The yard should be away from airfield traffic, protected as much as possible from the wind, and out of the way of propwash from other planes running up their engines.

TOOLS AND MATERIALS FOR TARGET YARD

PART NO. AAF STOCK NO.	QUANTITY	DESCRIPTION
[illegible]	[illegible]	LEVEL—SURVEYOR'S
[illegible]	[illegible]	ROD—SURVEYOR'S
[illegible]	[illegible]	TAPE (CHAIN) SURVEYOR'S [illegible]
[illegible]	[illegible]	PAINT—black, white or yellow
[illegible]	[illegible]	BRUSH—[illegible]
[illegible]	[illegible]	KIT—Tool, carpenter's
[illegible]	[illegible]	CEMENT—[illegible]

[illegible]	[illegible]	LADDER [illegible]

Figure 6—208. The Target Yard.

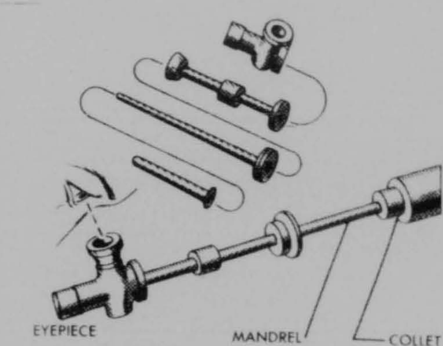

Figure 6—209. Boresight Tool.

Caution: The attitude (level or normal) of the airplane must always be correct with respect to the attitude (level or normal) of the harmonizing-yard targets.

Wheels should be located on their proper marks. The airplane should be towed into the yard with the nose wheel following the painted center line of the airplane. The wheels of the airplane should be placed within one inch of their proper location in a seventy- or eighty-foot yard, and within six inches in a five-hundred-foot yard.

Jacks are placed under the nose, wing, and tail pads.

The airplane is adjusted, with jacks if necessary, to place the longitudinal center line of the plane in the same plane as the longitudinal center line of the harmonizing targets. If the airplane is lifted very high with jacks, it is possible for wind to blow the airplane off; this may be avoided by placing the harmonizing yard in a sheltered location.

The transverse axes of the airplane are adjusted to a level position (Figure 6-208).

Note: The nose target is offset from the center line 5 degrees to facilitate bore-sighting from the L.F.T. past the nosewheel.

For a quick check to determine if the airplane's center line agrees with target's center line the blister sight is swung, stowed in elevation, from alignment on their respective targets to the blister sight marks on the forward broadside targets. The airplane is jacked slightly to obtain proper alignment. Both sights should be checked.

4. BORESIGHTING

In order to properly boresight the guns on their respective targets the J-2 boresight tool is used (Figure 6-209).

The boresight tool used in B-29 harmonization is the standard muzzle-type tool in the J-2 Boresight Kit. To use it, the collet, or sleeve, is first placed inside the gun barrel from the muzzle end. Then the mandrel, or spindle, is placed into the collet. Now, by sighting through the eyepiece, using any convenient arrangement of lenses, the observer will see exactly what would be seen if he were sighting through the barrel. The boresight tool, however, reverses the image. If the eyepiece is on either side of the gun, normal right and left will be reversed in the image. If the eyepiece is on top, the image will be upside down. The eye should be kept as close as possible to the center of the eyepiece; holding the eye off to one side or the other will introduce an error. Before using the tool, the mandrel must be checked to see that it is not bent. To check it, the tool is placed in the muzzle, on some small distant object, is boresighted. Then the tool is carefully rotated, stopping and checking at various points to make sure that the object is still exactly centered in the eyepiece.

5. THE MASTER SIGHTING STATION

All steps which have been performed up to this time have been building up to the most critical part of harmonization. These are the actual electrical adjustments necessary to establish perfect parallelism between the line of sight and the line of fire of all sight and turret combinations. It is important that these adjustments be made in the proper sequence. As a starting point the right blister sight is used, and which, for that reason is referred to as the master sighting station. Two crews may harmonize a ship at one time: one crew can work forward from the right blister sight making the necessary electrical adjustments; meanwhile the second crew

THIS PAGE IS DECLASSIFIED IAW EO 13526

works aft from the right blister sight making similar adjustments. Assuming that one crew is performing the work, the explanation will start with the combination which is harmonized first by the forward crew.

6. TYPICAL PARALLELING PROCEDURE

Following is the procedure for paralleling the lower forward turret to the right blister sight. (This procedure is essentially the same for other sighting stations and turrets.)

The entire system is given an operation check to detect any possible malfunctions.

All servos are balanced by the following method:

All sight Selsyn caps are removed.

Amplidyne contactor points are blocked open.

AC turret power and selector switches are turned on and the block action switch closed.

The servo is balanced by adjusting the potentiometer to obtain zero voltage across M&N and P&R.

All switches are turned off, the action switch is unblocked and the amplidyne contactor is unblocked.

Selsyns are zeroed on the master sighting station.

AC power switch is turned on.

Right blister sighting station is locked forward and horizontal.

Selsyns are accurately zeroed with the Roller-Smith Analyzer to within the proper tolerance (1/4) volt.

All sight Selsyn caps are replaced.

Warning: To prevent personal injury the 1-speed CT (or generator) Selsyn caps must be removed immediately after the guns have been brought into approximate alignment with the sighting station. After the 31-speed Selsyns have been adjusted, turret power SW is turned off before replacing 1-speed Selsyn caps. Selsyns should never be rotated rapidly in either direction.

The selector switches and disconnect switch are set for control of the lower forward turret from the right-blister sighting station.

The AC turret power switches on nose control box are closed and the action switch closed and blocked to align lower-forward turret with the right-blister sighting station.

Parallax-eliminating disk is inserted, in right-blister sight, on the dust-cover glass.

The right-blister sight station is aligned and locked on its broadside target using azimuth and elevation sight locking tools.

Turret power switch is turned off.

One-speed CT Selsyn caps (azimuth and elevation) are removed.

The turret power switch is turned.

The boresight tool is placed in the right-hand gun of the lower forward turret.

Note: In looking through the boresight tool, care should be taken to see that guns are brought on their correct target.

Crosshairs are positioned on the proper target by rotating the 31-speed CT Selsyns very slowly in the proper direction (both azimuth and elevation).

With turret on the target, the turret-power switch is turned off, the 1-speed CT Selsyns caps are replaced, and the 1-speed CT Selsyns (azimuth and elevation) are adjusted to zero (0) error signal to within 1/4 volt by measuring across the grounds of both 1-speed signal transformers at the servo.

The boresight tool is removed.

The turret is moved off reference in azimuth and elevation and the turret power switch is closed.

The boresight tool is installed in the RH gun and check work is performed.

The action switch is released and all switches are opened.

SECTION IX—GLOSSARY OF TERMS

Advanced (Future) Line of Sight. The line from the sight to the target at the instant of impact.

Advanced (Future) Position. The position of the target relative to the gunner's airplane at the instant of impact.

Advanced (Future) Range. The range at the instant of impact of the projectile with the target.

Air Density. The density of the air relative to standard density.

Altitude Correction. The correction which must be made in the altimeter reading to compensate for a nonstandard temperature.

Amplidyne Generator. A combination DC motor DC generator—which amplifies the less than one-watt input to its control field into more than 500 watts output.

A N Connector. A connector to provide means for quickly connecting and disconnecting a unit.

Azimuth. The angle, measured in the azimuth plane, between the nose of the ship and the elevation plane through the target or point of reference.

Azimuth Plane. The plane of the fore-and-aft axis of the airplane and the wings.

Break-down Voltage. The voltage at which ionization and conduction take place in a gas or vapor.

Collector Ring. A unit used to provide a means of introducing power to the turret and ring sight, permitting full rotation without twisting the incoming cables.

Contour Follower. A mechanism used to provide a means for raising the guns so they cannot point at the sighting station.

Dynamotor. A combination DC motor AC generator—taking in DC from the airplane generator and furnishing AC to the fire-control system.

Elevation. The angle, measured in the elevation plane, between the azimuth plane and the target or point of reference. It is 90 degrees minus the zenith distance.

Elevation Plane. Any plane through the zenith.

Fire Interrupter. A mechanism which prevents the turret guns from firing on portions of the airplane (including propellers).

Harmonization. The process of paralleling the line of sight and the gun bore axis through all points covered by them simultaneously.

Indicated Air Speed. The reading of the air-speed indicator.

Inertia Wheel. A wheel used in sights to smooth the motion of the sight in elevation through its flywheel action.

Initial Velocity. The velocity, relative to the gun, with which the projectile leaves the muzzle.

Initial Yaw. The yaw at the instant the projectile leaves the muzzle of the gun.

Ionization. Process by which ions are produced in solids, liquids, or gases.

Jump. The apparent initial change of direction of the trajectory.

Lead Angle. The angle between the present and the advanced lines of sight.

Line of Sight. The line from the sight to the target determined by the reticle or cross hairs.

Neon Lamp. Consists of two electrodes sealed within a neon gas-filled glass bulb.

Pantograph. An extending arm.

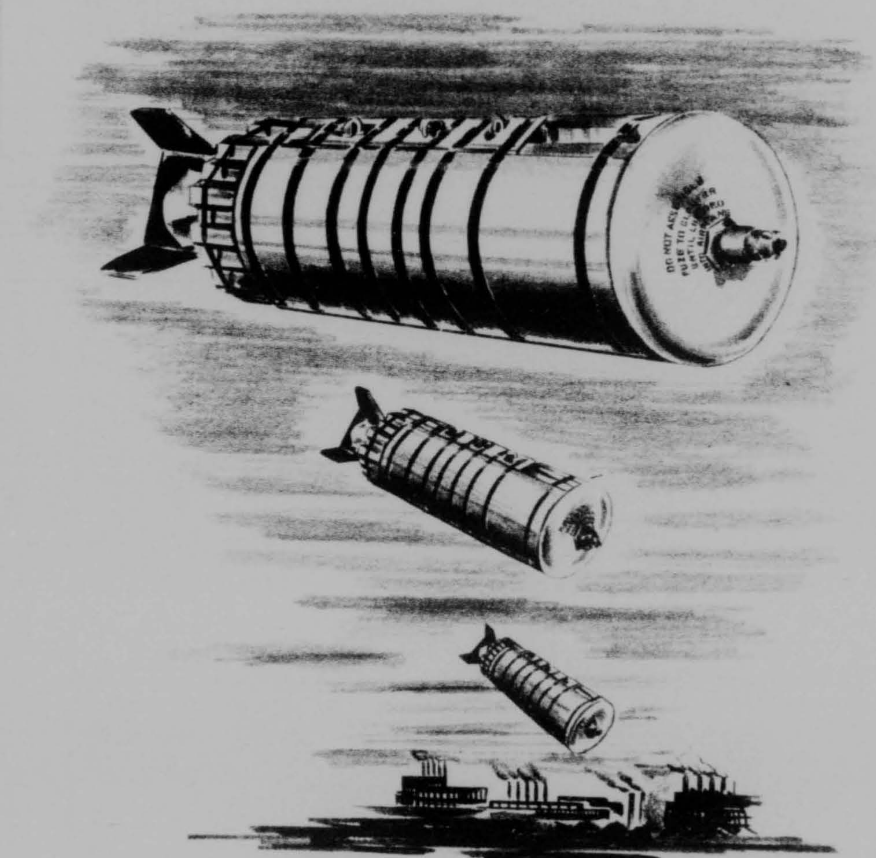
Parallax. The correction necessary to compensate for the fact that the gun and the sight are not at the same point.

Parallax Base Length. The distance between the gun and the sight.

Potentiometer. A variable voltage divider; a resistor which has a variable contact arm so that any portion of the potential applied between its ends may be selected.

Present Range. The range at the instant of firing.

CHAPTER 7— CHEMICAL WARFARE



SECTION 1 — CHEMICAL AGENTS

1. INTRODUCTION

Chemical Warfare is defined as the use of chemical substances to produce personnel casualties by inhalation of, or physical contact with, poisonous materials, to deny observation by use of screening smokes or to destroy combustible material by means of incendiary munitions. The scope of chemical warfare is very broad, however, and includes weapons, munitions and protective materiel. Weapons and munitions pertaining to this subject have been discussed in chapters 6 and 7 of Volume I. This chapter is devoted to a study of chemical agents, tactics and protective materiel.

CHEMICAL WARFARE AGENTS									
CLASS		AGENT	SYMBOL AND MARKING	ODOR	COLOR AND STATE IN FIELD	PERSISTENCY	EFFECTS ON BODY	PROTECTION	FIRST AID
CASUALTY AGENTS	BLISTER GASES	MUSTARD	H GREEN GREEN	Garlic Horse-Radish	Dark Oily Liquid Or Colorless Gas	3 To 20 Days Depending On Temperature	Irritates Eyes And Lungs. Blisters Skin.	Gas Mask, Protective Cover, And Clothing	Pinch-Blot Liquid From Skin. Rub Ointment In With Fingers. Remove: Repeat. Rub Bal In Eyes For Liquid H. Wash With Water.
		NITROGEN MUSTARDS	HN GREEN GREEN	Soapy, Fishy, To Very Little Odor	Oily Liquids Soft Solids Or Colorless Gases	1 Day To Several Weeks	Irritates Eyes And Lungs. Blisters Skin. Affects Blood And Nerves.		Wash Skin With Soap And Water. Rinse Eyes With Water 30 Sec To 2 Min.
		LEWISITE	L GREEN GREEN	Geraniums	Dark Oily Liquid Or Colorless Gas	1 To 7 Days	Irritates Eyes And Lungs. Blisters Skin. Causes Tears.		Treat Same As Mustard.
	CHOKING GAS	PHOSGENE	CG GREEN	Fresh Hay Corn Ensilage	Colorless Gas	1 To 10 Min.	Attacks Lungs. Choking And Coughing.	Gas Mask	Keep Warm. Loosen Clothing. Give Warm Non-Alcoholic Liquid To Drink.
	BLOOD AND NERVE POISONS	HYDROCYANIC ACID	AC GREEN	Almonds	Colorless Gas	1 To 10 Min.	Dizziness, Headache, Convulsion, Paralysis.		Artificial Respiration. Amyl Nitrite Capsule.
		CYANOGEN CHLORIDE	CK GREEN	Odorless	Colorless Gas	1 To 10 Min.	Dizziness, Headache, Convulsion, Paralysis.		Artificial Respiration. Amyl Nitrite Capsule.
		TABUN OR GREEN RING THREE	GA GB GD	Fruity Odor	Colorless Liquid	10 Min To 12 Hours	Pupil Of Eye Contacts, Headache, Tightness In Chest, Nausea, Diarrhea, Death.	Gas Mask Protective Clothing	Put On Mask. Wash Liquid Off Skin. Give Artificial Respiration.
HARASSING AGENTS	TEAR GASES	CHLORACETOPHENONE	CN RED	Apple Blossoms	Colorless Gas	10 Min.	Eye And Skin Irritation. Crying.	Gas Mask	Do Not Rub Or Bandage Eyes. Face Wind
		CHLORACETOPHENONE SOLUTION	CNS CNB RED	Sweetish	Liquid Or Colorless Gas	1 To 50 Min.	Eye And Skin Irritation. Crying.		Do Not Rub Or Bandage Eyes. Face Wind
	VOMITING GAS	ADAMSITE	DM RED	Coal Smoke Very Little Odor	Yellow Smoke	10 Min.	Headache, Nausea, Violent Sneezing, Temporary Mental Depression.		Remove To Fresh Air Keep Moving. Gargle Water. Wash Nasal Passage.
SMOKES	SCREENING SMOKES	WHITE PHOSPHORUS	WP SMOKE YELLOW	Burning Matches	White Smoke		Solid Particles Burn Holes In Skin.	Avoid Particles	Place Wet Rag Or Mud On Burning Area Of Skin.
		HC MIXTURE	HC SMOKE YELLOW	Sharp Acrid	Gray Smoke		Very Irritating In Long Exposure	Wear Gas Mask When Exposed For Long Periods	None.
		SULPHURTRIOXIDE CHLORSULPHONIC ACID	FS SMOKE YELLOW	Acrid	Dense White Smoke		Irritates Skin. Liquid Produces Acid Burn.	Wear Gas Mask When Exposed For Long Time	Wash With Water Immediately.
INCENDIARIES	SCATTER TYPES	JELLIED GAS (NAPALM)	NP PURPLE	Burning			Burns.		Smother Burning Area. Treat As Ordinary Burn.
		MIXTURE OF OILS, LIQUID ASPHALT, RESINS, MAGNESIUM DUST, AND OXIDES.	PT 1 PURPLE	Burning			Burns.		Smother Burning Area. Treat As Ordinary Burn.
	INTENSE TYPE	MAGNESIUM	MG PURPLE		White Smoke White Flame	8 To 10 Min.	Burns.		Smother Burning Area

Smoke in Air	Phosphoric Acid in H_2O	HC1 and H_2SO_4 in H_2O	Zinc Chloride in H_2O	Mainly Titanium Hydroxide with some HC1 and H_2O	Oil and water
Munitions suit-able for use	Explosive-type Munitions	Explosive-type Munitions or spraying devices	Burning-type Munitions	Explosive-type Munitions or spraying devices	Mechanical smoke generator
TOP Value (sq. ft.)	3500	2240	2000	*1900	Undeter-mined

* SGF1 - (Smoke Generator Fog - Warm Weather Oils)
SGF2 - (Smoke Generator Fog - Cold Weather Oils)

Figure 7–3. Principal Screening Agents.

2. CHEMICAL AGENTS

Chemical substances used for chemical warfare are called chemical agents. There are three categories of chemical agents: war gases, screening smokes and incendiaries. Only some forty chemical compounds possess the properties necessary for use as military agents. This may seem odd in view of the fact that there are over 800,000 compounds known to science today but thirty-five years of research has shown otherwise. While there are certain different requirements which war gases, screening smokes and incendiaries must meet, all must possess the following characteristics: ease of manufacture; availability of cheap, raw materials in the continental United States; stability in the presence of moisture, and in storage; non-corrosive to steel containers; and ability of withstanding an explosion when detonated. All agents presently standardized by the National Military Establishment are discussed in succeeding paragraphs. There are other agents, not discussed herein, which are under development by major world powers. From time to time it is logical that other new agents will be discovered and standardized. The Department of the Army Chemical Corps is charged with all research, development, standardization, procurement, storage, issue and maintenance of chemical warfare materiel. As such, the Chemical Corps delivers the products of the Department of the Air Force, Department of the Navy and the remainder of the Department of the Army for operational use. Each chemical agent has a symbol, assigned by the Chemical Corps, which for practical purposes identifies the agent. These symbols are very convenient since most agents have long complex names. Elsewhere in this chapter, agent symbols will be used exclusively.

3. WAR GASES

War gases are chemical agents which are used to produce personnel casualties and/or harassing effects. For convenience and to insure systematic treatment they are classified according to tactical use, physiological effect and persistency as indicated in Figure 7-1. From a tactical standpoint there are casualty, harassing, choking, tear and vomiting gases; and from a persistency standpoint there are nonpersistent and persistent gases.

Casualty Gases

Casualty gases are those capable of producing serious injury or death in field concentrations.

MUSTARD BURN 24 HOURS AFTER EXPOSURE

MUSTARD BURN TWO WEEKS AFTER EXPOSURE

Harassing Gases

Harassing gases are those which force the enemy to wear masks with a resultant and slowing or hampering of operations. Only those which produce this result with a small quantity of munition are considered primarily as harassing gases.

Blood and Nerve Poisons

These are gases which are absorbed into the body, producing their effect by interference with respiration and other body functions. Body absorption may be either through the lungs or by means of a liquid agent on exposed skin. Protection is afforded by gas masks and protective clothing.

Blister Gases

Blister gases are used for casualty effect (or threat of casualties) so that the use of ground may be restricted and operations hampered. They injure eyes and lungs and blister the skin, penetrating deeply into all exposed flesh. Protection is afforded by gas masks and protective clothing which covers the entire body.

Choking Gases

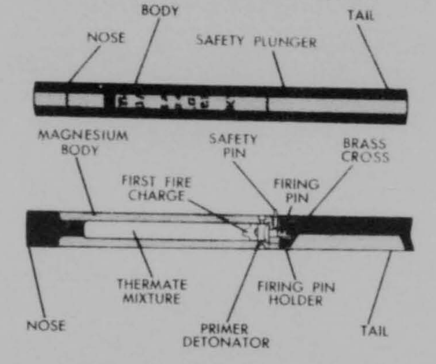
The effect of choking gases is to injure unprotected personnel in the nose, throat, and lungs. Membranes swell, lungs fill with liquid; death results from lack of oxygen. Thus these gases "choke" an individual. Protection requires only a gas mask.

Tear Gases

Tear gases are used for harassing purposes, producing copious tears and irritating the skin. Personnel casualties do not result from their use, therefore tear gases are used for training purposes and riot or mob control. Gas masks provide adequate protection.

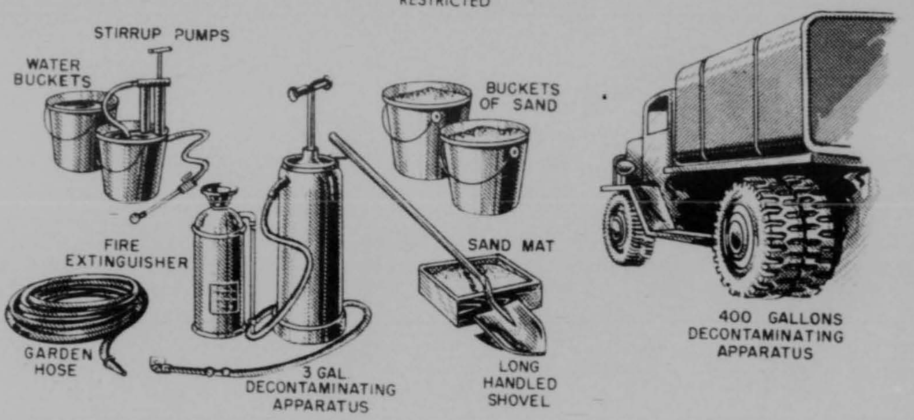
Vomiting Gases

These are used for harassing purposes in riot or mob control work. Vomiting gases act in accordance with their name and cause great discomfort temporarily. Gas masks provide protection. One feature of interest is the fact that these agents are normally solids which vaporize, when heated, to form smokes.



BOMB INCENDIARY, 4-IB, AN-M50A2

THIS PAGE IS DECLASSIFIED IAW EO 13526



PROTECTIVE EQUIPMENT FOR DEFENSE AGAINST INCENDIARIES

Nonpersistent Gases

"Persistency" means the length of time a war gas normally remains effective in the open at point of dispersion. "Effective" means that the gas is capable of producing casualty or other intended effect on unprotected personnel. Nonpersistent gases are those which are normally effective in the open for ten minutes or less at the point of dispersion.

Persistent Gases

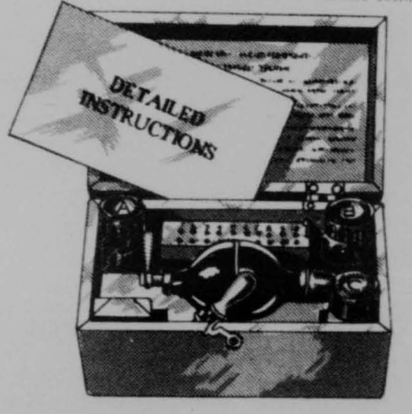
Persistent gases are those which normally are effective in the open at the point of dispersion for more than ten minutes. A further division is sometimes made into moderately persistent (ten minutes to twelve hours) and highly persistent (more than twelve hours).

Description of Gases

Brief descriptions of the more generally discussed war gases are tabulated in Figure 7-2. These data are limited to characteristics important in field identification and concern war gases available to the National Military Establishment. They are not necessarily identical with all possible enemy war gases and some are not standard United States agents.

4. SCREENING SMOKES

Screening smokes are chemical agents which, when burned, hydrolyzed, or atomized, produce a dense, white, obscuring smoke. Smoke is used to deny observation to the enemy, to reduce the effectiveness of his fire and to confuse or deceive him. Both white and colored smokes are used for signaling. These agents are not further classified since all are used as smokes and all are nonpersistent. Their physiological properties, while injurious, do not warrant detailed classification since these injurious effects are not shown by the smoke but by the agent from which the smoke is produced. A screening smoke which possessed highly toxic properties would be unsuitable since it is often used in friendly areas. The general characteristics of all satisfactory screening smokes are shown in Figure 7-3. Heavy concentrations of smoke tend



CONTENTS OF H VAPOR DETECTOR KIT M4

to nauseate personnel slightly after a prolonged exposure. For this reason and because smoke may be used to camouflage war gases, it is customary to wear gas masks in smoke clouds.

5. INCENDIARIES

Incendiaries are chemical agents which are used primarily to ignite combustible material and so destroy by fire. As such they are one of the most devastating strategic weapons available today. Protection against incendiaries is not a problem in the sense that protection against war gases and screening smokes are, rather it is a problem in defense against air attack. Therefore it will be treated as a special topic in later paragraphs.

6. DETECTION AND IDENTIFICATION

War gases may be detected without aid of special equipment by one or more of the following means; method of release, sensation, odor and appearance. Generally speaking, chemical-filled munitions have a much lower order of detonation than the same type munitions filled with HE. War gases, either in liquid or vapor form, may give a burning, biting, choking or prickly feeling in the nose, throat, lungs, or on the skin. Not all gases have characteristic odors, and the odors of the war gases that do have odors may be obscured by other smells. However, personnel whose duties call for specialized training should learn how a specific chemical agent smells to them. As an aid to positive identification of specific agents, for intelligence or other purposes, detection devices of various types have been developed and are issued to troops. These devices are discussed in later paragraphs.

SECTION II—TACTICS AND TECHNIQUES

1. DEFINITIONS

There are many unfamiliar terms applicable to the field of chemical warfare. Some of these terms have been defined previously and others will be defined in subsequent paragraphs. Certain general terms, used frequently in this chapter, which are necessary to an understanding of all remaining material are given below:

Concentration

Concentration is the amount of war gas or screening smoke present in a given volume of air. Concentration may be expressed in milligrams per cubic meter (mg m3), milligrams per liter (mg 1), or ounces per 1,000 cubic feet (oz 1,000 cu ft). Milligrams per liter and ounces per 1,000 cubic feet are almost identical numerically. Concentrations of war gases rarely exceed 1 per cent (by volume) in field areas.

Dosage

Dosage is the total concentration (C) of war gas to which a man or animal is subjected, multiplied by the length of exposure (t). Time, or t, is usually expressed in minutes (min). The CT product is usually expressed in milligram minutes per cubic meter (mg min m3). Dosages may be disabling or lethal. A lethal dosage is the amount of war gas per given volume of air, necessary to kill an average unprotected man. Exact figures for both disabling and lethal dosages depend on the kind of gas and the weather conditions.

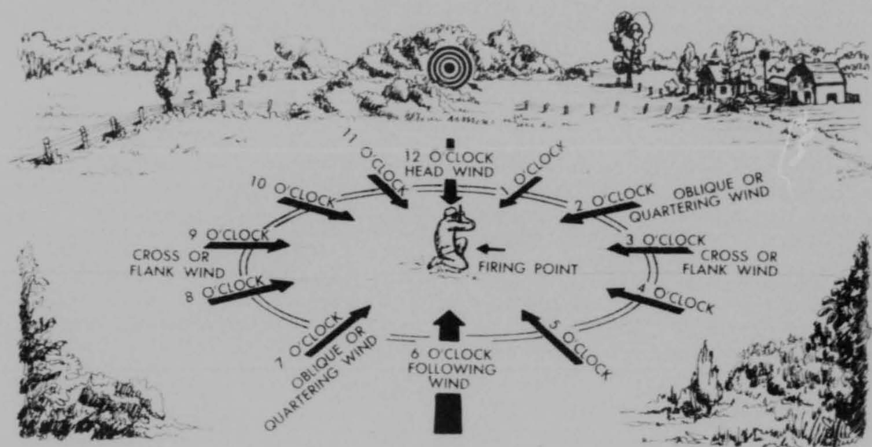
Contamination

Contamination is the state of being covered, or act of covering something with chemical agents so that it is dangerous to touch.

Decontamination

Decontamination is the process of making any object or area safe for unprotected personnel by absorbing, destroying, or making harmless the war gases clinging to, or around it. In general, only areas or materiel contaminated by persistent gases need be decontaminated, since nonpersistent gases are quickly diluted to below dangerous concentrations.

THIS PAGE IS DECLASSIFIED IAW EO 13526



Gas Casualty

A gas casualty is an individual who has been affected sufficiently by chemical agents to render him incapable ot performing his military functions or duties.

Atmospheric Stability

Atmospheric stability is a term describing air conditions. When there are many rising and falling air currents, the atmosphere is said to be unstable. When there are very few or none of these currents, the atmosphere is said to be stable. The rising and falling air currents are caused by thermal or mechanical turbulence.

Thermal Turbulence

Thermal turbulences are atmospheric conditions resulting from thermal conditions (inversion, neutral, or lapse).

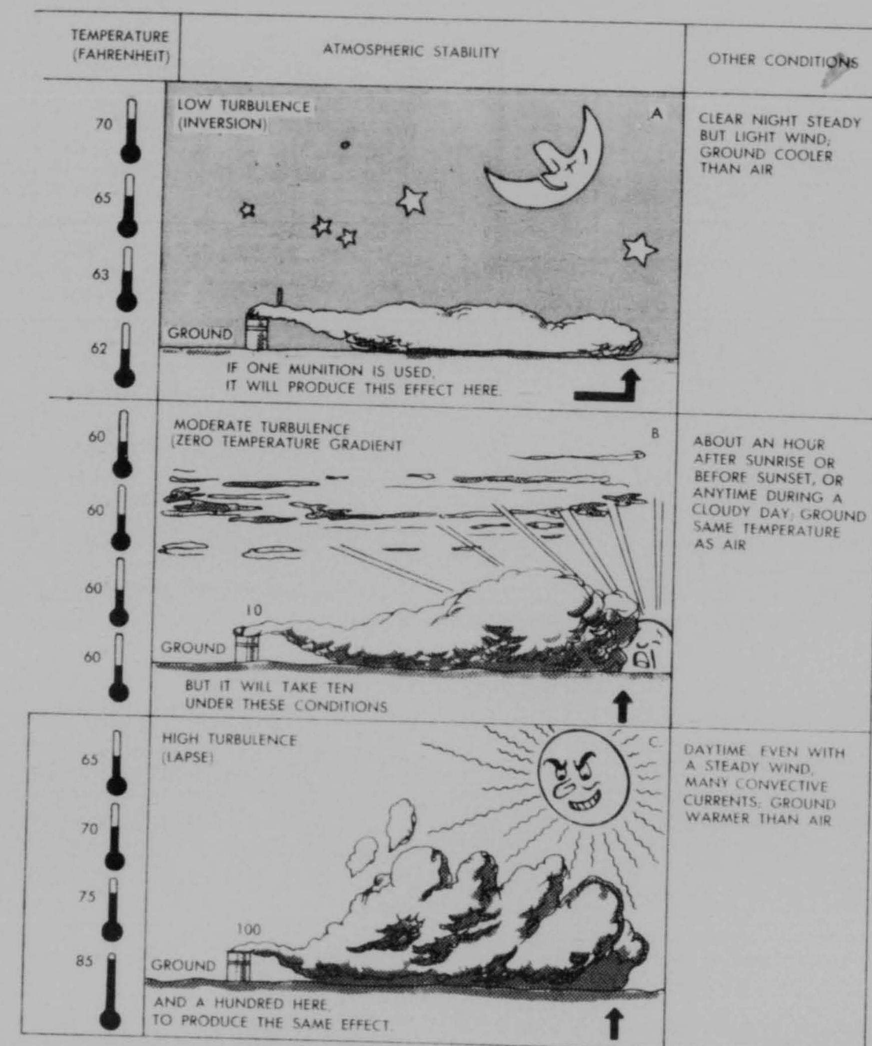
Inversion. On clear nights with a steady but light wind, a condition exists in which there is an increase in temperature with increasing height above the ground. Air currents are at a minimum, and thus there are stable atmospheric conditions near the ground. This condition favors the use of nonpersistent gas. Inversion conditions tend to be destroyed in wind speeds exceeding six to eight miles per hour over most types of terrain. Over very rough terrain, inversion conditions may be overcome by wind speeds lower than six to eight miles per hour.

Neutral. On heavily overcast days or overcast nights (and during the first hour after dawn and the hour before sunset), a condition exists in which there is very little or no change in temperature with height above the ground. There are few extensive rising or falling air currents, and thus there are moderately stable atmospheric conditions near the ground. Neutral conditions are only moderately favorable for the use of nonpersistent casualty gas.

Lapse. On clear or partially cloudy days, a condition exists in which there is a decrease in temperature with height above the ground. Air currents are at a maximum, and thus there are unstable atmospheric conditions near the ground. Lapse conditions may be modified in wind speeds over twelve miles per hour.

Mechanical Turbulence

Mechanical turbulences are atmospheric conditions resulting from terrain conditions. When air moves over a surface, many small eddies result. The rougher the surface, the more eddies exist, and the more unstable the



EFFECT OF TURBULENCE ON GAS AND SMOKE

Humidity	Immaterial		

* Refers to effect on screen. Thick low clouds might make a screen unnecessary and such a condition would then be favorable.
** Generators will be placed so a following wind will be obtained.

atmosphere becomes in the layers near the surface.

2. TACTICAL USAGE

Gases, smokes, and incendiaries should be used on targets particularly suited to each agent. They may be used alone or in conjunction with high explosives (HE). Employment of chemical agents should conform to the general principles for the use of any munitions in combat operations. Of these general principles, surprise, mass, coordination, and simplicity are most important. Although specific details of enemy tactics cannot be foreseen, reasons for using chemicals in combat can be stated. In general, war gases are used for:

Casualty Attacks

These are surprise attacks in which high concentration of war gases are built up in a short space of time (two minutes or less) on an area occupied by personnel to obtain a maximum number of casualties. Surprise is essential, since trained and well-disciplined troops minimize the results of such attacks. Usually nonpersistent agents are employed although persistent agents may be used.

Harassing Attacks

These are prolonged attacks in which a concentration of war-gas vapor is maintained in a specified area to force troops to wear gas-masks and to take other protective measures. Nonpersistent war gases may be used. However, it is more likely that persistent agents will be used because of the economy of munitions and the added inconvenience, delay, and danger due to contamination.

Neutralization Attacks

These attacks employ persistent agents to

force troops to evacuate areas or abandon materiel, to interdict strategic points by utilization of chemical barriers or to make supplies unusable. A determined enemy may elect to remain in contaminated areas or to cross chemical barriers, basing his decision upon certain calculated risks.

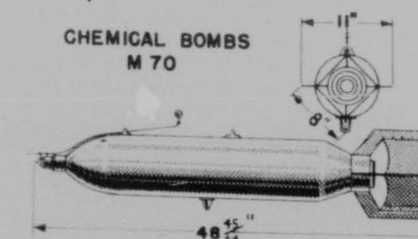
3. EMPLOYMENT OF CHEMICAL AGENTS

The characteristics and field behavior of each group of chemical agents dictate when and how the group probably will be used in field operations. It is not possible to anticipate accurately when and how an enemy will use chemical attack. A knowledge of when, and under what conditions, chemical agents can be most effectively used by the enemy, however, generally enables commanders to anticipate chemical attack.

4. NONPERSISTENT WAR GASES

Nonpersistent war gases are normally used on large groups of personnel to kill or disable. These gases generally are placed on targets very quickly and in high concentrations so that large percentages of troops are exposed to casualty-producing dosages before they have time to mask. Nonpersistent war gas is more likely to be used offensively than defensively because troops on the defensive are more likely to remain static. Weather conditions which are in general most favorable for the use of nonpersistent war gases consist of wind speeds below twelve miles per hour and inversion conditions. Wind speeds of approximately five miles per hour are most favorable. These gases are not likely to be used in heavy rains. Heavily wooded terrain is more favorable for the use of nonpersistent war gases than open areas, although some of the gas is absorbed by the foliage. Concentrations attained in woods or jungle may be three times higher than those in the open. Concentrations of nonpersistent war gas are higher in valleys and depressions than on hills and slopes. Thus, nonpersistent gases may be encountered in low places or in heavy woods.

CHEMICAL BOMBS
M 70



Use by Air Forces

Nonpersistent war gas may be dropped from the air in large bombs. This type of attack is especially dangerous because large quantities of gas can be released in very short periods of time. Air chemical attack is not limited to combat areas, and is likely to be launched against strategically important targets. In nonpersistent gas attacks laid down by air bombs the sudden expansion of a large quantity of agent to form a cloud produces a cooling of the surrounding atmosphere to form an artificial "inversion" condition. Hence, nonpersistent gas attacks by air drop are not affected by weather to the same degree as those in which ground chemical munitions are employed.

5. PERSISTENT WAR GASES

Persistent casualty gases are used against troop concentrations for casualty effect or on materiel and terrain targets to restrict use through threat of casualties. Most blister gases can be used for producing casualties through liquid contact or through exposure to vapor. Persistent casualty gases may be effectively used both offensively and defensively. There are more possibilities, however, for defensive use. Persistent casualty gas is most effectively used in hot, humid climates because the body is much more sensitive to these gases under such conditions. Persistent casualty gases may be used in wind speeds up to fifteen to twenty miles per hour, but higher wind speeds do not necessarily preclude the use of these gases. Inversion conditions are most favorable for the use of persistent casualty gases, and high vapor dosages may be expected under inversion conditions. Ground temperature is an important factor in determining how long a persistent casualty gas persists and how fast effective vapor dosages are attained (that is, the higher the ground temperature, the shorter the persistency and the faster effective dosages are attained). Heavy rains are unfavorable to persistent gas attacks. It can be very effectively used, however, during light rains or immediately after heavy rains. Contaminated vegetation is more hazardous than contaminated bare ground. Persistent casualty gases, therefore, are more likely to be used on vegetated targets. Thick woods and jungle are excellent persistent casualty gas targets, and very high vapor dosages may be attained on such targets. Thick jungle or forest canopy is a good cover from airplane spray; therefore, spray attacks are not likely to be made on heavily wooded or jungle targets, but bomb attacks set up high vapor dosages in such areas.

Use by Air Forces

Persistent casualty gases may be released from airplanes in large burster-type bombs or as sprays from spray tanks. Spray is essentially used directly against personnel. Because of its short persistency, it rarely is used on terrain targets. It should be noted that while the USAF does not consider spray tanks as the most effective method of dispersing blister gases (and does not use them for this purpose) other major world powers include spray tanks as a munition for dispersing blister gases. Burster-type bombs may be used either against personnel or on terrain. High vapor dosages are attained quickly when persistent casualty gases are laid down by burster type bombs or spray.

6. HARASSING GASES

These are used to handicap troops in carrying out missions by forcing them to wear masks or take gas-protective measures. Tear or vomiting gases, or light concentrations of nonpersistent or persistent casualty gases can be used for this purpose. Harassing attacks are usually made against troop concentrations. Tear gases may be dispersed from mortar or artillery shells, tear gas pots, grenades, bombs, or sprayed from spray tanks. Irritant smokes are usually dispersed from candles or pots.

7. SMOKES

Smoke screens and blankets are used to hinder observation and thus to hamper operations, reduce effectiveness of fire (including bombing), or reduce ability to meet an attack. In addition to its smoke effect, WP may be used for casualty effect. Smoke may be used in conjunction with casualty attacks to conceal the presence of gas. Smoke can be expected to be used under almost any weather condition. It is most likely to be employed in wind speeds under fifteen to twenty miles per hour.

Use by Air Forces

Air forces can lay smoke by using bombs or by spraying. Thus, observation points located beyond the range of ground weapons, as well as antiaircraft weapons, can be objectives of smoke missions.

8. INCENDIARIES

These are used primarily to destroy flammable materiel, but they may be used to kill, disable, or demoralize personnel, and for defoliation of camouflaged installations. The use of incendiaries in high winds tend to spread rapidly and are usually difficult to extinguish.

Use by Air Forces

Incendiary bombs of various sizes and types may be dropped on tactically or strategically important flammable installations. These bombs may be of a type which burn at extremely high temperatures and are difficult to extinguish. Highly flammable liquids in thin-cased containers may be dropped on troop concentrations and field fortifications and ignited.

9. EFFECTS OF WEATHER

Weather is an important factor in determining the field behavior of gases both from an

offensive and defensive standpoints. The following table shows the effect of various types of weather upon war gases:

Weather Elements	Favorable	Unfavorable
Winds	Weak	Strong, gusty
Temperature	Between 32° & 65°	Higher than 65° or below 32° F
Cloudiness	Overcast low, stratus type clouds	Cumulus or thunder clouds
Visibility	Poor	Good
Precipitation	None or light drizzle	Heavy rains
Season	Spring, autumn	Summer, winter

10. STRATEGIC IMPLICATIONS OF CHEMICAL WARFARE

Strategic air chemical missions are large-scale operations carried out by multiple units of heavy aircraft. These missions are usually executed in enemy rear industrial areas and are not in conjunction with actual operations on the ground. The targets are determined by higher headquarters and are assigned a regular priority. The detailed planning and execution of current air chemical operations are the joint function of the Director of Operations and Training and the chemical officer. The chemical officer advises the Director of Operations and Training so far as the chemical phase of the operation is concerned. It is the responsibility of the chemical staff officer to advise the Director of Operations and Training as to the best munitions and methods for carrying out the air chemical mission. Generally, the chemical staff officer is responsible for the following:

a) Calculating munition requirements.

b) Making certain that the munitions are available.

c) Insuring that chemical service troops are available when needed.

d) When requested, briefing pilots on any special phases of the chemical mission; for example, suggesting optimum altitude and method of release for persistent gas missions, or answering any questions regarding problems of handling and releasing chemical agents.

e) Notifying higher staffs of the mission.

f) Following up the results of the mission and reporting results to the next higher air chemical staff.

SECTION III—MUNITIONS MATERIEL

1. CHEMICAL MUNITIONS

There is a wide variety of chemical warfare munitions and allied equipment. This includes aircraft bombs; aircraft smoke tanks; such ground munitions as flame throwers, smoke generators, grenades, smoke pots and land mines; and the equipment necessary for handling such munitions. Certain chemical warfare munitions are filled just prior to use in the field. This filling, handling and loading work, formerly done by Chemical Corps units, is now a responsibility of USAF armament personnel.

2. BOMBS FOR AIRCRAFT

Chemical, smoke and incendiary bombs, presently standardized for use, are covered in chapter 7, vol. II. Significantly, however these bombs, in common with all chemical warfare munitions, are marked to conform with their tactical classification and persistency. The code used for this marking is indicated in Figure 7-1.

3. AIRCRAFT SMOKE TANKS

Aircraft smoke tanks (interchangeably called spray tanks) are devices which, when mounted on aircraft, may be used to spray liquid substances in the form of vapor clouds. At present the USAF uses these tanks only for laying smoke screens in support of ground operations, although they may be used for

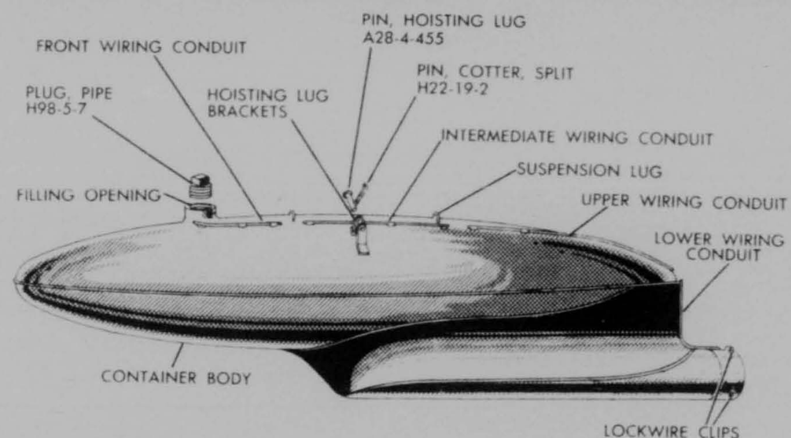


Figure 7—4. Exploded View of Container Assembly M10APST.

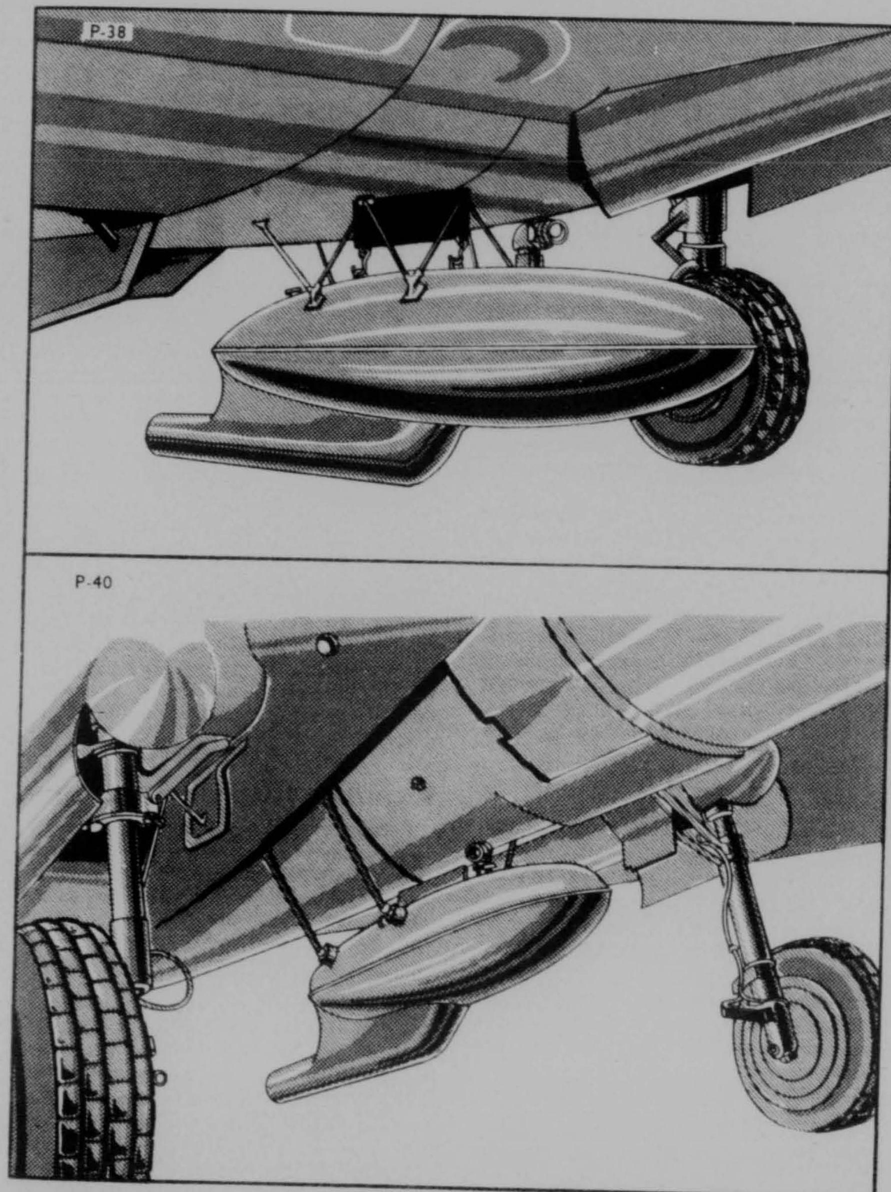
blister gases, tear gases and crop agents. Two types of smoke tanks exist; one for external mounting only and the other for external or bomb-bay mounting. These tanks operate by gravity flow, assisted by air pressure when a discharge plate is ruptured. Smoke tanks are not filled until just prior to loading aboard the aircraft. At present FS is the only smoke agent standardized for use in smoke tanks. In time of peace or training, tanks are retained on the aircraft, after discharge, and reused but in time of war externally mounted tanks are jettisoned on enemy territory after discharge.

4. M10 AIRCRAFT SMOKE TANK

This tank is designed for external mounting on fighter-type and light-bomber-type aircraft. It is a streamlined, cylindrical tank with an effective capacity of 30 gallons and a filled weight of about five hundred fifty pounds. The M10 tank consists of three main parts; a container, an air inlet assembly and a discharge line. As indicated in Figure 7-4, the container is completely sealed by means of closure plates prior to discharge. Contents of the tank are released by exploding detonators (blasting caps) fastened to the closure plates. This releases the filling, and gravity, assisted by a current of air entering through the air inlet assembly, forces it out through the discharge line. Discharge requires about six seconds during which an effective smoke curtain of about five hundred yards length can be established. This curtain will remain effective from one to four minutes depending on wind conditions. Other equipment used with these tanks include an M2 stand and an accessories set which contains a resupply of expendable closure plates, gaskets, grease and other items.

5. AN-M33A1 AIRCRAFT SMOKE TANK

The M33 smoke tank is suitable for use in bomb bays or beneath bomb-bay-type aircraft. This tank has an effective capacity of 70 gallons which, with all auxiliary equipment attached, brings its installed weight up to about 1350 pounds. A complete unit consists of the tank body, closure plate assembly, discharge line (composed of one or two sections), discharge line clamp and insulating jacket. Operation of this tank is exactly the same as for an M10 tank. Time of discharge is about eight seconds during which a smoke curtain seven hundred yards long can be established. Effective duration of curtains established with this tank vary from one to six minutes depending on wind conditions. Auxiliary equipment used with this tank is the M6 stand and an accessories set which contains a stock of expend-



M 10 TANK MOUNTED ON P-38 AND P-40

able closure plates, detonator retainers, gaskets, grease and nuts.

6. CHEMICAL CONTAINERS

Special containers are used for the storage and shipment of chemical agents. These containers range in size from one-ton containers to fifty-pound cylinders, each of which is used for specific kinds of chemical agents.

Ton Containers

These are of three designs, known as types A, D and E, and are used for storage and bulk shipment of casualty agents. A container weighs about thirteen hundred pounds empty and will hold a maximum of twenty-six hundred pounds of agent. Type D containers have large eduction tubes and are used for nonpersistent gases; while type E containers are all-purpose and may be used for any chemical agent. Special valves, valve wrenches and valve replacement mechanisms are required for use with these containers.

Drums

Light steel drums of 55-gallon and 110-gallon capacity are used for storage and shipment of harassing agents and screening smokes. Drums are equipped with one or two bungs, depending on the nature of the agent for which used.

Cylinders

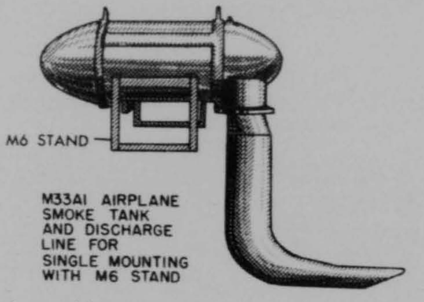
Cylinders of 50-pound, 75-pound and 150-pound capacity are used for shipping small quantities of chemical agent for training purposes.

7. CHEMICAL FILLING EQUIPMENT

Field filling operations are conducted with a variety of lines and pumps. Although each is designed for specific uses, several parts of the apparatus can be adapted for general field filling purposes. Filling equipment may be improvised from standard pipe fittings, valves, and flexible metal tubing.

Filling Line, M3

The M3 filling line is a flexible metal hose with valves, calibrated adapters and interchangeable nozzles which is designed for filling aircraft smoke tanks. These lines operate by gravity flow.



Smoke Tank Pump, M2

This apparatus is used to transfer liquid chemical agent from drums to smoke tanks by means of pumping instead of gravity flow. It embodies a special safety feature to prevent the escape of fumes during the filling operation, lines being provided both for filling and venting. Air and vapors displaced by liquid entering the smoke tanks through the filling line are forced back through the vent line to the bulk container, which is not open to the air. Thus no agent is released into the atmosphere.

8. CHEMICAL HANDLING EQUIPMENT

Certain special purpose vehicles and auxiliary equipment are provided for lifting and moving bulk containers, for moving aircraft smoke tanks and for field filling operations. The equipment includes:

Chemical Service Truck, M1

This truck is designed to carry drums or a ton container and field filling equipment. Removable compartments contain the filling equipment, protective clothing, decontamination equipment and first aid kits. An overhead rail contains a $1\frac{1}{2}$-ton hoist for moving containers. To use this hoist requires a hoist sling for drums or M2 hoisting beam for "ton" containers, both of which are included with the unit equipment.

Chemical Trailer, M1

The M1 Chemical trailer is used to transport 55-gallon drums. Two overhead rails, each equipped with a $\frac{1}{2}$ ton hoist, make it possible for one man to load or unload with ease. Due to its limited application, this trailer is obsolete but large numbers are available for use.

Chemical Handling Trailer, M2

The M2 trailer is used to transport either six filled 55-gallon drums, four filled 110-gallon drums, one filled ton container, two empty ton containers, eight filled M10 smoke tanks, or four filled M33 smoke tanks. Movable chocks are adjusted as necessary.

Swing Boom Crane Truck, M1

This unit is designed primarily for moving ton containers during field filling operations. The extension type boom can be moved right or left, up or down and the hook can be raised or lowered. Hook capacity with the boom extended is 3600 pounds.

Tank Loading Stand, M1

This stand is a tripod assembly fitted with a hoist. It is used to hoist 55-gallon drums during field filling operations.

9. FLAME THROWERS

The flame thrower is a weapon used by ground combat units for reduction of strong points and field fortifications. As such it is not used by the USAF for combat purposes. It may be used for certain auxiliary purposes such as clearing contaminated vegetation. There are two types of flame-throwers: portable and mechanized. Mechanized flame throwers are integral equipment on certain tanks and, due to nonrestriction on weight, have a very large capacity. Portable flame throwers are designed for portage by one man. Fuels used for flame throwers may be either of liquid or thickened type. This fuel is propelled to the target by highly compressed nitrogen, air or hydrogen gas.

10. FUEL MIXING AND TRANSFER EQUIPMENT

Thickened fuel consists of a specially prepared gelatinous or glue-like mixture of fuel thickener and liquid fuel. This thickened fuel is prepared prior to use in the field by means of a special kit. The presently standard unit is known as an M1 Mixing and Transfer, Thickened Fuel, Kit. Designed for preparing thickened fuel and transferring it to fire bombs, the unit contains an air compressor, air and fuel hoses, fittings, valves and air-agitation tube assemblies. Fifty-five gallon steel drums are required for mixing containers. One fire bomb requires the contents of four 55-gallon drums of thickened fuel.

11. SMOKE GENERATOR MATERIEL

In addition to aircraft smoke tanks, smoke screens may be generated by the use of mortar shell, artillery shell, smoke pots and smoke generators. Smoke pots and smoke generators may be used by USAF personnel for defense purposes. Hand smoke grenades and rifle smoke grenades are used in ground combat for blinding strong points.

Mechanical Smoke Generator, M2

The M2 Generator is a small size, lightweight device which is used, alone or in conjunction with other smoke-making devices, to produce large area smoke screens. The unit may be transported on one-quarter ton trailers, one-quarter ton trucks, boats or may be mounted on the ground. Movement of the unit while operating does not impair its efficiency. It produces smoke by forcing a mixture of fog oil (SGF) and water into a furnace assembly, where the two liquids are vaporized and then ejected in the form of a steam that condenses into thick white fog in the air. Fuel consumption is about sixty gallons per hour of fog oil. A smoke generator unit using 48 M2 generators can place an obscuring blanket of smoke over an area approximately $2\frac{1}{2}$ miles wide and from 8 to 15 miles long, depending on terrain and weather conditions.

12. CHEMICAL AGENT TRAINING EQUIPMENT

To assist in training individuals to recognize and identify chemical agents, certain kits have been developed. These units include:

Instructional Gas Identification Set

These units, called "sniff sets", consist of bottles which contain harmless concentrations of certain war gases absorbed in charcoal. By sniffing the air around the bottle's mouth it is possible to determine the odor of a specific agent. Two sets are presently standardized. The M1 set contains H, L, CG, PS, DM and CN, while the newer M2 set contains H, HD, L, PS, DA, AC, CG and CN. Either is suitable for classroom usage.

Detonation Gas Identification Set

This set is for field identification tests of war gases. Each unit contains four one-ounce tubes of H, L, PS and CG (sixteen tubes) in liquid solution and blasting caps for detonation purposes. The contents of a tube is detonated into the air and personnel then move through the gas cloud formed, noting the odor and appearance. An accessories kit is issued for use in preparing and firing the tubes.

Toxic Gas Set

The toxic gas set provides small quantities of liquid H for contamination and decontamination exercises, sensitivity tests on personnel and other training purposes.

13. FIELD LABORATORIES

The chemical laboratory unit, in functioning for the Chemical Corps devotes its efforts to surveillance of Chemical Corps materiel and to examination of enemy chemical-warfare items. In addition, it performs such functions for the other arms and other services as they may request. As a part of its work for the Air Forces, the laboratory unit analyzes materiel for indications of sabotage; tests cooling-liquids for aircraft motors, parachute silk, and cleaning mixtures; and makes investigations of corrosion inhibitors.

14. GAS CHAMBER MATERIEL

In succeeding paragraphs the military gas mask will be discussed. It is necessary to test gas masks in an atmosphere of gas to insure correctness of fit and inspire confidence. This testing is carried out in gas chambers with CN and CL. To establish concentrations of CN in a chamber, small gelatine capsules filled with CN are heated with a tallow candle on an improvised stove. Chlorine also may be released from portable cylinders.

SECTION IV—DEFENSE AGAINST CHEMICAL ATTACK

1. SCOPE

Defense against chemical attack begins with individual defensive measures and progresses to collective and tactical defensive measures. Both individual and collective protection involve the provision and use of protective equipment and installations. Tactical protection involves tactical plans and measures undertaken to lessen the probability, or security, of chemical warfare attacks.

2. ORGANIZATION

Training is a function of command. Unit commanders are responsible, therefore, for training their command in defense against chemical attack, for provision and inspection of protective equipment and for decisions as to the employment of collective protective measures in operations. To assist a commander in discharging his responsibilities, each unit has specially trained unit gas personnel. These personnel normally conduct the chemical training of their unit and are key personnel in the chemical defense plan. Within this framework, it is the individual's duty to protect himself against chemical attack. At higher command levels, staff armament officers specially qualified in chemical warfare are assigned.

3. PROTECTION

Defense against chemical attack begins with effective training. On this basis protection may be broken down into three phases: individual protection, collective protection and tactical protection. A unit commander is responsible for training his command in individual protection and for decisions as to the employment of collective and tactical protective measures. Within this framework it is the individual's duty to protect himself against chemical attack.

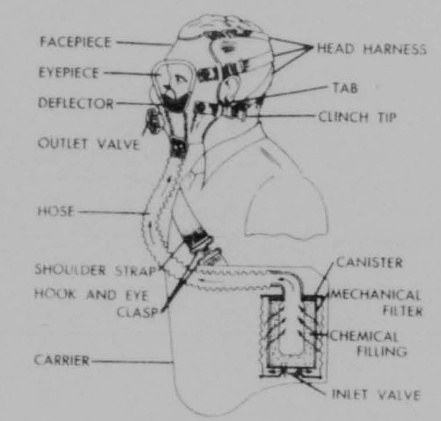
4. INDIVIDUAL PROTECTION

The first line of defense against chemical attack is individual protection. Individual protection involves the use of protective equipment such as gas masks, to remove agents from the air before they are breathed; and protective clothing, to prevent agents from coming in contact with the body. Coupled with this are first-aid measures which will be discussed later.

5. MILITARY GAS MASKS

Purpose

The military gas mask is an apparatus designed to purify the air which an individual breathes. Air is drawn into the mask when the airman inhales, and the mask is so constructed that this air must first pass through a canister containing a filtration system. This system comprises both mechanical and chemical filters, the former filtering out solid and liquid particles (smoke and dust), and the latter absorbing and neutralizing toxic and irritating gases and vapors. The air being purified by filtration is drawn to the face and after being inhaled and exhaled is expelled from the mask through an outlet valve. The facepiece fits snugly to the face so as to be gastight and is held in place by an elastic head harness. It is equipped with eyepieces of safety glass or other transparent material. It is also equipped with a deflector which deflects incoming air against the eyepieces so as to prevent condensation of moisture on the lenses, and in some types with a nosecup



M2A2 SERVICE GAS MASK

which prevents exhaled air from coming in contact with the lenses. In addition to this method of reducing dimming of the eyepieces, a soaplike substance (either in stick form or as an impregnated cloth), known as "anti-dim," is furnished with each mask (except the training mask) and which, when spread as a thin layer over the inner surfaces of the eyepieces, tends further to keep down eyepiece fogging. The facepiece is equipped with an outlet valve, through which exhaled air is expelled, and is connected to the canister by a corrugated rubber hose. The canister is a metal cylinder or oblong-shaped box containing a filter and chemicals comprising the filtration system. Ordinarily, it is equipped with an inlet valve which permits the entrance of incoming air and a nozzle for the exit of purified air. This inlet valve prevents exhaled air from passing through the canister. The nozzle of the canister usually is connected to the facepiece by the corrugated rubber hose tube through which the purified air passes to the wearer's face. The facepiece, hose and canister are contained in a canvas carrier.

Limitations

The protection afforded by the gas mask is due primarily to the canister, the other components of the gas mask merely preventing air from entering the facepiece by any other route. The filtration system of a military canister provides excellent protection against field concentrations of chemical agents. Generally, field concentrations are relatively low and do not exceed one per cent gas per volume of air. A canister does not supply or manufacture oxygen; gas masks therefore must not be used in an atmosphere containing less than sixteen per cent oxygen.

6. SPECIAL PURPOSE MASKS

Optical Gas Mask M1-1-5

The optical gas mask is designed for use with optical instruments, such as range finders, gun sights, field glasses, and periscopes, where the instruments must be held close to the eyes. It has small eyepieces made of plane glass. An adjustable bridge, called the eyepiece adjustment assembly, across the nose connects the two eyepieces so that the space between may be changed to correspond to the distance between the wearer's eye pupils, and thus permits him to focus and use binocular instruments requiring both eyes to be adjusted to the instrument eyepieces. There is a diaphragm in the mask to facilitate speech transmission. The canister is fitted to a head harness and when in use rests on the lower part of the back of the head so as to prevent interference by the hose with the operation of optical instruments. It is made only in the universal size.

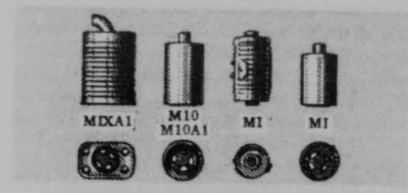
Aviators' Gas Mask

The aviators' gas mask, which is in the development stage and has not been standardized, has a fully molded rubber facepiece with eyepieces similar to those in the training mask. It contains a diaphragm to aid in speech transmission. It is so constructed that by means of a three-way valve the wearer can breathe oxygen from his oxygen tank, air that has been filtered through a canister, or unfiltered air. Thus, he can choose his air supply at will. It is made only in the universal size.

Paint Respirators

Paints, particularly the newer types of synthetics and lacquers, contain noxious constituents. Men engaged in paint spraying are subjected to the fumes of the volatile portions of these paints. Although spraying is usually done under a hood connected to an exhaust fan, some of the fumes almost always escape into the room. Since the human body can stand small amounts of these substances, only partial protection is necessary. The paint respirator covers the wearer's nose and mouth. It contains several layers of felt to stop pigment and liquid particles, and activated charcoal to catch some of the fumes. The eyes are not protected.

Protection from paint fumes should be provided in military establishments where spray-painting of vehicles and other equipment is required and no special ventilation is provided. Paint respirators to be used by the



SERVICE CANISTERS ISSUED TO THE ARMY

MVIII (substitute) a large disc-type inlet valve is in the bottom. "MVIII" is embossed on top of can.
MIXA1 a disc-type inlet valve is in the bottom. Corrugated body.
M10 or M10A1 - Smooth cylindrical body, inlet valve in bottom. The M number is embossed on top.
MI Optical - corrugated cylindrical body. Inlet valves in canister stems. Rain shield over inlet valve.
MI Training - not corrugated; straight nozzle; large inlet valve in bottom.

SPECIAL CANISTERS

1. All-purpose - red.
2. Hydrocyanic acid - yellow with white top.
3. Acid vapor - white.
4. Oil vapor - black.
5. Ammonia - green.

United States Air Force are of commercial types approved by the United States Bureau of Mines and are procured and issued by the Quartermaster Corps.

7. SPECIAL CANISTERS

Special canisters are designed for assembly with the standard service facepiece assemblies, M1, M1A1, M1A2, M2, or M2A1, or the standard diaphragm facepiece assemblies, M1, M1A1, or M11. It is also possible to use these canisters with the standard training facepiece M1, or M1A1, providing the standard 27-inch hose is employed. These canisters are to be used with carriers M111 and M111A1. The outer walls of all special canisters are made of tin plate with rounded corners and edges and are about 7 by 4½ by 3 inches. Each has an inlet valve in the bottom and each is connected to the hose by means of a canister nozzle or nozzle elbow. In order to recognize them readily, each type is painted a distinctive color as follows:

All-purpose	Red
Acid vapor	White
Hydrocyonic acid	Yellow w white top
All vapor	Black
Ammonia	Green

8. GAS CHAMBERS

Any reasonably airtight building of one or two rooms will serve for gas-chamber exercises. If such a building is not available, a pyramidal tent may be used. When using a tent for these exercises, it must be made as airtight as possible.

PHASE I

The chamber is filled with an effective concentration of tear gas (CN).

One CN capsule for each 100 cubic feet of space is used adding as needed to keep up concentration.

A heater is required to volatize capsules.

Gas-mask drill is conducted before men enter the chamber.

Ten men wearing masks enter the chamber and under the direction of an assistant, execute movements similar to those in combat.

Masks must not be tampered with while in the chamber.

When the men come out, the instructor moves the group up wind, inspects each mask for fitting, has each man remove his mask and inspects for signs of lachrymation.

Defects are noted and corrected, if possible, by adjusting the head harness, exchanging for a smaller facepiece, etc.

The masks are aired until all groups have gone through the chamber.

Personnel, upon emerging from the chamber, move up wind and face the wind before removing their masks.

PHASE II

Personnel should gain confidence in the protection afforded by the mask. This may be accomplished by the following procedure:

Men, properly masked, enter the gas chamber in which a strong concentration of CN has been generated.

After remaining in the chamber about one minute, each man in turn is told to take a position across the chamber away from the exit, remove his mask, and walk toward the exit.

An officer will be near the door to assist the men, if necessary, in leaving the chamber.

The officer should satisfy himself that each man becomes lachrymated.

Upon emerging from the chamber, the men are instructed to move up wind facing the wind, to separate and not form in groups.

Caution: Men must be instructed not to rub eyes as painful swelling may result. The men should wash their hands and face with soap and water as soon as possible.

PHASE III

Men who are properly masked enter the chamber where a high concentration of CN has been generated.

THIS PAGE IS DECLASSIFIED IAW EO 13526

They are instructed to test for gas.

They are cautioned to clear the facepieces. (In this way the men learn to detect gas and to properly clear the facepiece.)

The men then file out and face the wind as in Phase II.

PHASE IV

An assistant (junior officer or sergeant) takes his place inside the chamber.

Groups of three to six men will enter the chamber with the mask carried at the slung position.

The men hold their breath and, when at the far side, remove facepieces from the carrier and adjust them.

The assistant must emphasize the necessity of clearing the mask as the men adjust the facepieces.

The group remains in the chamber two or three minutes after adjusting the facepieces and then file out.

As the group emerges from the chamber, the officer inspects the adjustment of each mask while on the wearer before permitting removal.

Men must not touch or try to adjust masks before the inspecting officer sees them.

All adjustments to the mask should be made on the spot.

For those individuals who fail to pass the test, more preliminary drill is necessary and the test should be repeated until the desired proficiency is obtained.

9. PROTECTIVE CLOTHING

"Protective clothing" is clothing which has been impregnated with certain chemicals, and which, when worn as prescribed, affords protection against blister-gas vapor and very small droplets. It consists of two types: "permeable" protective clothing and "impermeable" protective clothing.

Permeable Protective (Impregnated) Clothing

Permeable protective (impregnated) clothing is special clothing which has been chemically treated. It affords a high degree of protection against the vapors and fine spray droplets of blister gases, since such small amounts of gases are rendered harmless when they come in contact with the clothing. This clothing does not protect against large droplets or splashes of liquid blister gases which may come in contact with the clothing when the wearer walks through heavily contaminated weeds, tall grass, or brush, or during decontamination operations of blister gases in liquid form. This clothing is issued as individual equipment.

PROPERLY ADJUSTED OUTFIT
Permeable Type

Impermeable Protective Clothing

Impermeable protective clothing is a coated fabric coverall-type suit which, when properly worn, affords complete protection to the wearer from the vapors and splashes of liquid blister agents. These liquid agents are shed by coated clothing in the same manner as rain is shed by a raincoat. During wear, body heat and moisture are held within the suit; consequently, it can only be worn for periods of approximately one-half hour by actively working men. Men working areas heavily contaminated with liquid blister agents should wear this type of clothing. Permeable protective long underwear is worn beneath the clothing. The impermeable protective clothing is issued as organizational equipment.

IMPERMEABLE TYPE CLOTHING
(Adjusted) FOR MEN

10. AUXILIARY EQUIPMENT

In addition to the gas masks and protective clothing, certain additional items of protective equipment are available. These include protective ointment and (BAL) eye ointment, eye shields, covers, and shoe impregnite.

Protective ointment is applied to exposed skin areas prior to exposure to blister gases and may be used for first aid treatment. BAL ointment is used for first aid treatment of eyes following exposure to blister gases.

Eye shields are designed to protect the eyes from liquid vesicants.

Protective covers fit over crouching individuals like an inverted sack and shield them from blister gas spray attacks. The top of the cover is transparent.

Shoe impregnite is applied to foot gear to prevent penetration of liquid blister gases.

11. PHYSIOLOGICAL EFFECTS AND FIRST AID

Blister Gases

Physiological effects of mustard gas and nitrogen-mustard gas on the eyes are:

Mustard gas (H) vapors cause no immediate symptoms; even the liquid is only mildly irritating at first. However in the first few hours the eyes become inflamed, smart, water and feel gritty, and are sensitive to light. The lids of the eyes then swell. In severe cases there is great pain, tears, and yellow discharge. In this case, permanent damage may result.

Nitrogen Mustard Gas (HN).

Nitrogen Mustard gas physiological effects are generally the same as mustard gas (H), but the damage from the more volatile forms of nitrogen mustard gas (HN) is more severe.

First Aid for the Eyes. BAL eye ointment should be applied at once, either for liquid or vapors severe enough to cause pain and spasm of the eye lids. If lids can be opened, the ointment should be squeezed directly into the eye and the lids massaged gently. If the eyes can not be opened, the ointment is applied to the closed eye and rubbed into the slits between the lids. As soon as the pain lessens and the eye can be opened, apply more of the ointment to the eye. Also rub the ointment on the eyelashes, lids, and skin around the eye.

If no BAL eye ointment is available, BAL eye solution (Item #5 in the Gas Casualty First Aid Kit) should be used. Two drops should be applied to the eyelids at once.

If no BAL eye ointment or solution is available, the eyes should be flushed with water immediately. Flushing is very helpful if done in the first minute after contamination, but valueless after two minutes. To flush, the face is held upward, opening the injured eye by pulling on the lower lid with one hand, and pouring water from a container held in the other. The patient should move his eye from side to side, and up and down. Washing should continue for one-half to two minutes. If no water is available, use urine or item #4 (eyes and nose Drops) from the Gas Casualty First Aid Kit.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Physiological Effects on the Respiratory and Digestive System. Vapors of H or HN inflame throat and wind pipe if breathed. Mouth becomes dry, throat burns, and harsh, distressing cough develops. Partial loss of voice is common. Pneumonia may develop in severe cases.

Nausea and vomiting may follow severe skin contamination, especially in hot weather, even if a mask has been worn. This is a systemic effect not due to direct injury; swallowing of contaminated food or drink may cause inflammation of stomach, pain, and vomiting.

First Aid for the Respiratory and Digestive Systems. Liquid gas should be removed from the face immediately to prevent further inhalation of vapors. Contaminated clothing also should be removed. No other first aid is effective. The victim is treated as would be a choking-gas casualty; clothes are loosened, the patient should be kept quiet and warm, given warm (non-alcoholic) drink, and evacuated by litter. If no medical treatment is available and evacuation is impossible for twenty-four hours or longer, wound tablets, from the first-aid pouch, should be administered to prevent pneumonia.

Physiological Effects on the Skin. Injury begins with the reddening of the skin, like sunburn, and may be followed by blistering (under different climatic conditions, this varies with concentration and length of exposure). Liquid always blisters unless counteracting steps are taken at once. Normally moist skin areas are most affected (like bend of elbows and knees, armpits, and crotch).

Vapor is about one-fifth as damaging as H. Liquid forms blisters more quickly, but they are less severe.

First Aid for the Skin. Liquid must be removed and skin decontaminated within three minutes to avoid blistering. Contaminated clothing is removed. The skin is then blotted with absorbent material furnished with protective ointment, or with dry cloth. Care should be taken not to contaminate additional skin while blotting. Next, protective ointment from the tube, rubbing it on the affected area for about fifteen seconds. Excess ointment is wiped off. This procedure is repeated if the skin has been heavily splashed. Soap and water can be used as a substitute, or bleach paste (equal quantities of water and dry bleach) can be used if washed off within three minutes.

Ointment or bleach should not be used if skin has already reddened or begun to blister as it only increases the burn. Instead, calamine lotion (item #2 in the Gas Casualty First Aid Kit) should be used, following instructions given in kit. Vapor burns cannot be helped by first aid, the damage is already done, and neither ointment nor soap and water helps.

Liquid burns are treated with ointment in the same manner as H liquid burns. But ointment merely dilutes and does not destroy HN. Therefore, the film of ointment should be washed off with soap and water, preferably, or with water alone. Ointment should not be used if the skin is already red; instead, soap and water should be used. Vapor burns cannot be helped by first aid, since the damage is already done.

The Physiological Effects on the Eyes of Lewisite and Other Arsenicals (Ethyldichlorasine, Methylichlorarsine, and Phenyldichlorarsine).

The eyes are specially susceptible. Vapor irritates immediately; liquid causes instant, excruciating pain and spasm of eyelids. Unless first-aid measures are taken immediately eyes swell and inflame seriously within one hour, and may be permanently injured.

ED, MD, PD, act the same as Lewisite, but generally are less severe.

First Aid for the Eyes. BAL eye ointment should be applied, at once, either for liquid or vapors severe enough to cause pain and spasm of the eyelids. If the lids can be opened, ointment should be squeezed directly into the eye and the lids massaged gently; if not, it should be applied to the closed eye and rubbed into the slits between the lids. As soon as pain lessens and the eye can be opened, more ointment should be applied. It also should be rubbed on eyelashes, lids, and the skin around the eye. If no BAL eye ointment is available, BAL eye solution (Item #5 in Gas Casualty First Aid Kit) should be used. The eye is opened and two to four drops placed in it, and one or two

drops on the eyelids. Application should be made only once.

Physiological Effects on the Respiratory and Digestive System.

The physiological effects are the same for Lewisite as for mustard gas.

ED, MD, PD., is the same as it is for mustard gas, generally, but breathing very low vapor concentration may cause coughing, sneezing, pain in the nose and throat, nausea, and vomiting and distressed feeling.

First Aid for the Respiratory and Digestive System. First Aid for Lewisite is the same as it is for mustard gas.

ED, MD, PD., are generally the same for mustard gas (H), but after exposure to low vapor concentrations (producing symptoms like those of vomiting gas), nose and throat should be rinsed with water, and the patient kept quiet). Fumes of chloroform (item #1 in Gas Casualty First Aid Kit) may be inhaled to give relief in severe case, inhalation being repeated as required.

Physiological Effects on the Skin. The physiological effects of L, ED, MD, PD, are the same as they are for H, but liquid acts faster, penetrating skin rapidly and causing stinging sensation within one or two minutes; vapors are far less dangerous than H vapors.

First Aid for the Skin. Liquid is blotted from the skin immediately. If skin hurts, gas may be assumed to be an arsenical. Protective ointments are applied as described for mustard (H) burns (although it may not completely prevent blistering if weather is hot). Soap and water should be used if no better remedy is available. An attempt should be made to prevent blisters from breaking, leaving them for medical treatment. Vapor burns cannot be helped by first aid.

M-5 Protective Ointment. All references to protective ointment noted above apply to M-4 Ointment.

M-4 ointment eventually will be replaced by M-5 ointment, now in production. M-5 ointment is used exactly as M-4 ointment with these exceptions:

On applying M-5 ointment to contaminated skin, it is rubbed for thirty seconds, instead of fifteen seconds.

It should be left on the skin.

M-5 ointment is used before exposure to blister gas, as well as after. Using the entire contents of one tube, the ointment is rubbed in a smooth, even coating on unprotected skin areas. It is applied again whenever absence of the characteristic color (gray-green) indicates that the skin is no longer protected. Protection, by application before exposure, extends only to blister-gas vapor; if droplets fall on skin, decontamination must be accomplished as directed in the above.

Choking Gases

Physiological Effects. Symptoms vary considerably, but there is usually irritation of nose and throat, coughing, difficulty in breathing and pain in the chest, especially upon deep inhalation. Other possible symptoms are tears, vomiting and blueness of lips and ear lobes. Symptoms appear immediately only if exposure has been severe. They may persist and grow worse; but often first symptoms disappear, followed by latent period in which victim feels fairly well. Here serious symptoms of lung injury may not appear for several hours.

First Aid for Choking Gas Casualties. Mask should be kept adjusted until the area is free of gas. The airman should carry on if there are no immediate symptoms. But if there are immediate symptoms, institute first aid as soon as tactically possible. The clothing should be loosened, the airman should rest, and keep warm with blankets. Artificial respiration should not be given. Nonalcoholic stimulating drinks (not tea or coffee) should be given. The patient should be evacuated to an aid station by litter as soon as possible. The greatest danger for a choking gas victim is during the first forty-eight hours after exposure.

Blood and Nerve Poisons

Hydrocyanic Acid (Hydrogencyanide) or Cyanogen Chloride.

Physiological effects are highly toxic when inhaled.

High concentrations are fatal and the symptoms progress in the following order.

Labored breathing, convulsions, coma, and death.

Low concentrations may produce headache, dizziness, and nausea. First breath may be so stimulating to respiration that it is then impossible to hold the breath.

Liquid penetrates the skin and is toxic.

First Aid for Hydrocyanic Acid (Hydrogen-cyanide) and Cyanogen Chloride.

If the victim is in a closed place, he should be masked and moved into fresh air immediately; too great a concentration may penetrate the gas mask canister.

If he has stopped breathing, artificial respiration should be given until medical aid is available. Amylnitrite (item #7 of Gas Casualty First Aid Kit) may be used meanwhile. Crush and hold close to victim's nose or thrust inside facepiece if masked. This should be repeated at three to five minute intervals, meanwhile continuing artificial respiration.

If liquid gets on the skin, it should be washed with water or a weak solution of baking soda and water. Clothes containing liquid should be removed and aired.

Physiological Effects of Arsine. Mild cases causes lassitude, headache, and uneasiness.

Increased exposure causes chills, nausea, and vomiting.

Severe exposure damages the blood, causing anemia, and the victim's urine is brown or red.

First Aid for Arsine. The mask should be adjusted and the victim removed by litter to fresh air.

He should not be allowed to walk.

He should be hospitalized immediately.

Green Ring 3 or Tabun Gas

General first aid procedures outlined for treatment of war-gas casualties are effective for treatment of casualties resulting from this new blood and nerve poison. Liquid contamination must be treated immediately. Blotting the liquid and washing the contaminated area with slightly alkaline or acid water effectively removes the liquid gas.

Physiological Effects of Vapors. Vapors, even in low concentration, causes the pupil of the eye to contract. This makes it difficult to see in dim light and causes headache. After short exposure, a sense of tightness in the chest may be noticed, which is increased by deep breathing. Vapors, when inhaled, cause nausea and diarrhea.

Liquid does not injure the skin, but penetrates the skin and poisons the body.

First Aid for Green Ring 3 or Tabun Gas. The victim's mask should be adjusted and the patient removed to a safe area, if possible. If he has stopped breathing, artificial respiration should be given. If liquid gets on the skin, it should be blotted out and the contaminated area washed immediately with soapy water or flooded with water. All contaminated clothing should be removed and care exercised by the person administering first aid not to contaminate himself or other parts of the victim's body.

If liquid enters the eye, it should be flushed with water or a solution of sodium bicarbonate in water.

Vomiting Gases

Physiological Effects: Irritation of the nose and throat, often causing coughing, sneezing, and salivation. Pain in the nose, throat and windpipe is fairly intense; gums and teeth ache. Nausea and vomiting may occur, and the victim may feel very distressed. But there is little danger, and effects usually pass within three hours. Most victims can carry on strenuous duties without harm, and often with a more rapid decrease in symptoms.

First Aid for Vomiting Gases. The mask should be adjusted as long as gas is present in the atmosphere, removing it only briefly during periods of actual vomiting. It should be removed, shaken, and the outer clothing aired if the situation permits. The skin should be washed with soap and water. If symptoms persist, the nose and throat are rinsed with water. In extreme cases, the victim should be kept quiet until distressing symptoms have passed. Fumes of chloroform (item #1 in Gas Casualty First Aid Kit) should be inhaled, repeating as required.

Tear Gases

Physiological Effects: Acute pain in the eyes, profuse tears, and spasm of eyelids. There is usually no permanent damage, and effects wear off quickly; but temporarily the victim may find it almost impossible to see.

First Aid for Tear Gases. The eyes should not be rubbed as this only increases the irritation. The mask should be kept adjusted until the atmosphere is free of gas, then removed and the victim's face turned into the wind with eyes open. Skin areas which sting or burn, or on which liquid gas has been splashed, should be washed with soapy water. If liquid has entered the eyes, they should be flushed with plenty of water, or treated with eye and nose drops (item #4 in Gas Casualty First Aid Kit). Medical treatment or evacuation is not normally necessary.

Screening Smokes

Physiological Effects of Liquid Smokes. Liquids irritate or burn the skin. Smoke itself is usually harmless except in prolonged exposure; slightly irritating to respiratory tract.

First Aid for Liquid Smokes. Liquid should be washed from the body with water (preferably soapy). If the respiratory tract is irritated by smoke, the victim should be moved to fresh air when tactically possible.

Physiological Effects of Solid Smokes. Prolonged exposure without a mask irritates the nose and throat; may cause coughing and lung irritation.

First Aid fo Solid Smoke (HC). The victim should be removed to fresh air if tactically possible.

Physiological Effects of White Phosphorus. Smoke is harmless except in prolonged exposure, but burning particles cause severe burns.

First Aid for White Phosphorus. Affected skin area is immersed in water to extinguish burning particles. Air should be excluded from particles until they can be removed; otherwise, they will reignite. Particles should be wiped or brushed from the skin with a wet cloth (medical aid may be required for this). Copper-sulfate (item #3 in Gas Casualty First Aid Kit) should be to the burned area for several minutes. This coats the particles, keeping them from the air, and permits exposure of the burn without danger of fire. Particles can then be removed more easily, preferably with forceps.

12. COLLECTIVE PROTECTION

Collective defense against chemical attack includes equipment, installations, techniques used by the unit or by smaller groups for defense of personnel, animals, and materiel, against chemicals. It includes:

Detection devices.

Alarm systems and duties of sentinels.

Gasproof shelters and fortifications.

Protection of supplies and equipment.

Decontamination of food and water.

Decontamination of equipment, terrain, and buildings.

Personnel decontamination stations.

Organizational first aid.

Defense against incendiary attack.

13. DETECTION DEVICES

Various detection devices have been designed for both the detection and identification of war gases. These devices indicate the presence of war gas by a change of color. They are useful in indicating the completeness of decontamination, in determining the presence of war gas in concentrations too low to be detected otherwise, and in estimating the hazard of operations in contaminated areas.

Liquid Vesicant Detector Paint

Detector paint is effective only for spray or droplets, not for vapor. It is olive green, turning red when in contact with blister gases. Bleach, M4 decontaminating agent, protective ointment, and certain tear gas solutions give the paint a similar red color. The paint turns brick red at temperatures over 150° F. The paint is applied to fenders and hoods of vehicles on areas visible to the driver, or to other organizational equipment, and must be renewed frequently.

Liquid Vesicant Detector Paper

Detector paper is issued in booklets of twenty-five sheets. It is heavy paper coated with detector paint, which turns red when liquid blister gas touches it. It has certain field limitations. Like detector paint, it is affected by bleach and other materials even in the absence of war gas. It does not detect vapor. Heat, steam, or oil decrease its sensitivity, and it turns red when heated to approximately 150° F. It is unreliable in determining completeness of decontamination.

Chemical-agent Detector Kit

The detector kit reveals dangerous concentrations of certain war gases by color changes in tubes through which contaminated air is drawn and to which liquid reagents are added. Complete directions for use are included with each kit. All unit gas personnel and all special gas sentinels should be thoroughly familiar with the use of the kit, and the kit should be used whenever practicable or when any doubt exists.

The sensitivity of the detector tubes makes it possible to determine whether the air contains a dangerous amount of gas. In interpreting the results obtained by sampling air or vapors, personnel must be certain that samples are taken at several points, at frequent intervals, and in accordance with wind conditions. If a large enough sample of contaminated air is taken, the detector tubes are sufficiently sensitive to detect a concentration below that which is necessary to cause casualties. Low concentrations of phosgene which are detectable by smell, however, are not detected by the kit.

14. GAS SENTINELS

All sentinels have duties in connection with defense against chemical attack. Depending upon the tactical situation, special gas sentinels may be required for installations such as gasproof shelters, for protection of materiel, and for guarding contaminated areas. These should be detailed as required. Special gas sentinels are usually posted to warn troops against dangerous gassed areas and to protect supplies at distributing points. Their duties do not differ from the usual duties of gas sentinels except that they are given special instructions regarding specific duties. Special sentinels on duty where supplies are stored should have protective clothing. Such installations may be subject to frequent spray attacks. Since such attacks develop rapidly, the sentinel must be on the alert in order to get the supply covers into position. Covers should fold and be adaptable to quick spreading in case of attack. They should always be in position when practicable. If the attack is by incendiaries, the sentinel should give the prescribed fire alarm.

15. ALARM SYSTEMS

Two different types of gas alarms are given by the sentry—one for airplane spray attack, and one for all other methods of attack.

Alarm for Spray

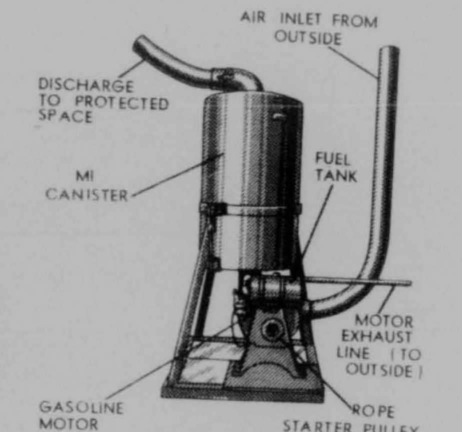
If the attack is by airplane spray, only the warning cry of "spray" is given. It should be given only when attacking aircraft are actually observed to begin a spray attack. The sentry then: Adjusts his protective cover and masks; follows SOP for defense against air attack (if firing, thrusts rifle or carbine forward through top corner of protective cover); resumes normal sentry duties.

Alarm for Other Types of Gas Attack

If the gas attack is by any other method, the sentry shouts "gas"; sounds the percussion alarm for a period of fifteen seconds, holding his breath, if necessary; adjusts his mask; resumes sounding the percussion alarm for one minute; awakens all personnel in the vicinity of his post; resumes normal sentry duties, but does not remove mask until the "all clear" order is given, or until the area is shown by test to be gas-free.

General Alarms

General alarms are sent out if large areas are involved. Such alarms are given by all normal methods of communication and embrace all areas likely to be affected. The procedure should be set forth in the unit standing operating procedure.



COLLECTIVE PROTECTOR M2

16. GASPROOF SHELTERS AND FORTIFICATIONS

Purpose

Since it is possible for an enemy attack to subject an extensive area to lethal concentrations of casualty war gas for periods ranging up to several days, some means of shelter must be provided for various types of field activities. Masks and protective clothing are sufficient protection against such concentrations, but they cannot be worn indefinitely, moreover, many essential functions cannot be performed satisfactorily while wearing such equipment. Gasproof shelters are needed, therefore, where troops can rest and eat during prolonged attacks, and where communications, command, and similar functions can be conducted without interruption. Field hospitals may also require gasproofing.

Types

If gasproof shelters are equipped with collective protectors, they are the ventilated type. If not, they are called "unventilated." Each shelter is posted with a sign giving this information, together with the capacity and length of time the shelter can be occupied. Either ventilated or unventilated shelters may be permanent, semipermanent, or improvised. Permanent and semipermanent gasproof shelters are built by the Corps of Engineers according to approved drawings. Improvised shelters, either ventilated or unventilated, are built in the field when the need arises. This section is concerned only with the field type of improvised shelter, which is usually built from structures or dugouts already in existence or easily and quickly constructed.

17. PROTECTION OF SUPPLIES AND EQUIPMENT

General

Chemical agents may damage supplies not adequately protected, both as a result of the original contamination and through acids formed by the hydrolysis of certain war gases. Moreover, supplies contaminated with blister gases are dangerous for personnel to handle or contact. Proper packaging and storing minimize the effects of chemical agents. Paulins or other covers are used over supplies stored outdoors. Paulins, used in pairs with a layer of tree branches between them, provide increased resistance to penetration of liquid agents.

Food

When possible, bulk food items are kept in closed containers (preferably moistureproof) and covered with paulins. The most vulnerable foods are placed in the least exposed positions. For protection against airplane spray, kitchen trucks are covered with paulins, and field kitchens are provided with tent flies or other overhead covers. Contaminated food is usually discarded, but instructions of the medical officer govern its disposal.

Water

Water is kept in closed containers. If Lister bags are used, they may be protected from liquid contamination by individual protective covers adapted to this purpose. The Medical Corps reports on the potability of water, and the Corps of Engineers purifies it.

Equipment

Ammunition is kept in its containers as long as possible.

Weapons are covered with protective paulins or dispersed under natural cover.

Instruments, such as those used for fire control, are kept in their containers when not being used. Both ammunition and instruments are subject to corrosion by such war gases as phosgene and such smokes as FS.

Airplanes are provided with covers (at least for cockpits, plastic windows, guns and gun compartments) when not in hangars.

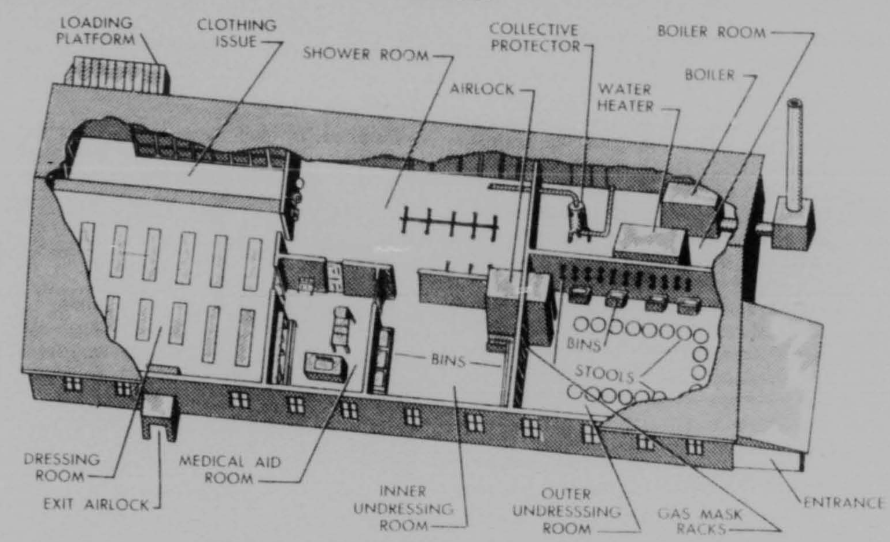
Automotive equipment is stored in woods free of underbrush, but lower portions of ravines and canyons are avoided. (Mobility of vehicles provides some degree of tactical protection.)

Flammable supplies, such as fuel, oil, and flammable munitions, are kept in containers until used.

18. DECONTAMINATION

General

Chemical agents may be destroyed or neutralized by other chemicals. No one chemical, however, is effective in all cases. Moreover, it is not practicable for an army to carry either a great variety or quantity of chemicals. Consequently, decontamination operations are necessarily limited. Whether they are practicable at all will depend upon the character of the chemical agent involved and the extent of the contamination. Other than ventilation, it is not worth while to consider destruction of agents having a low, or even moderate, persistency. Nature is the greatest decontaminator. These agents are soon dispersed by the wind. It is necessary, however, to provide for cleaning or disposing of supplies and munitions which may be affected by such agents. Persistent agents present a very different problem. Even small quantities of such



PERSONNEL DECONTAMINATION STATION

gases as mustard or Lewisite are dangerous. It will not be feasible to decontaminate large areas but there may be many cases where decontamination work is both practicable and highly desirable.

Personnel

Personnel detailed for decontamination operations should be trained for such work. They should wear gas masks and protective clothing covering the entire body. If necessary to use men who have had no training in such work, each squad at least should be under the supervision of an experienced noncommissioned officer. The supervising personnel should, in any case, have a sound knowledge of first-aid measures and should have the necessary medical equipment close at hand. The men should be inspected before commencing operations to insure that they are properly protected. Facilities away from other troops should be provided for undressing and bathing after completion of their work. Men should be taught to assist each other in removing protective clothing without touching it with the bare skin. Facilities for disposal or cleaning of contaminated clothing should be provided.

19. DECONTAMINATION AGENTS

There are a variety of materials which may be used for decontamination work. Some are more effective than others. The use of any single decontaminating agent is limited by its local availability at the time of use. Specific agents which may be used are:

Bleach

Bleach is a white powder which contains about 35 per cent available chlorine and is known commercially as chlorinated lime, bleaching powder, calcium bleach or chloride of lime. Bleach will destroy or convert H, L, ED, and HN into harmless or less toxic compounds by oxidation and chlorination. It reacts violently with liquid H, envolving much heat. Bleach is usually mixed with water or earth before being used in order both to increase its distribution and to diminish the heat of the chemical reaction with H. Although it is corrosive to most metals and injurious to most fabrics, it is the most commonly used decontaminating agent. Dry bleach may be applied directly to contaminated surfaces in situations where there is no objection to fire or vapor hazard.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Noncorrosive Decontaminating Agent (DANC)

DANC is a light cream colored powder which, when dissolved in a solvent such as acetylene tetrachloride, is used for decontamination of H, L, ED, and HN. DANC is shipped in five gallon containers. It is one of the most effective decontaminating preparations known. It is easily prepared and will destroy most persistent vesicant agents in half an hour or less. Unfortunately, it is expensive, and its use must be limited to surfaces where bleach would be too corrosive. It is not entirely noncorrosive but considerably less so than bleach. DANC, a slightly noticeable residue which, however, is corrosive if left in prolonged contact with metal. Some disadvantages are its toxicity, its tendency to soften rubber and plastics and remove paint, and the formation of hydrochloric acid when the acetylene tetrachloride comes in contact with moisture.

Caustic Soda (Lye)

Caustic soda, or lye, the chemical name for which is sodium hydroxide, is a white solid which dissolves easily in water. Preparing solutions of lye liberates considerable heat and the containers should not be handled with the bare hands. It destroys most chemical agents on contact when moisture is present, and is especially effective in destroying Lewisite. Caustic soda does not destroy mustard gas as rapidly as does bleach.

Sodium Hypochlorite

Sodium hypochlorite is a commercial solution containing approximately fourteen per cent available chlorine. It liberates chlorine upon contact with persistent agents and converts them to less toxic forms. This agent is rapid in action but more corrosive than DANC.

Washing Soda

Sodium carbonate, known as washing soda, soda ash, sal soda and laundry soda is a white powdery substance with mild alkaline properties. Its action, due to a neutralization reaction, is quite slow but it is not corrosive to materiel.

Water or Steam

Water under high pressure or steam may be used to remove dirt or grease, containing embedded chemical agents, from surfaces. Water is most effective if hot and if soap or other detergent is used.

Fuels and Solvents

Fuels may be sprayed on contaminated areas and the area then burned off. Vapors generated by this method are dangerous, however, and personnel must remain upwind. Likewise precautions must be taken to avoid uncontrolled fires. The most common solvents used in decontamination are gasoline, kerosene, motor oil and acetylene tetrachloride. Solvents are applied in such a manner as to dilute and wash away chemical agents.

Inert Materials

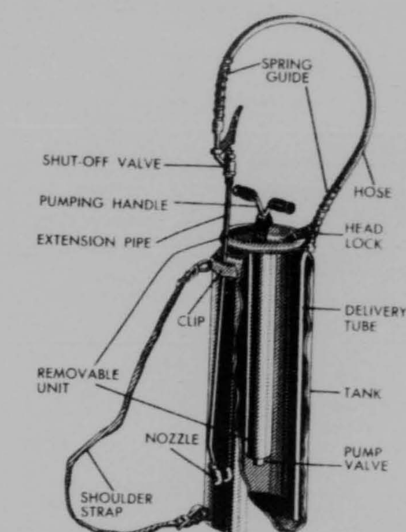
Earth, sand, ashes, soot, or sawdust may be spread over a contaminated area to give temporary protection. The covering layer should be at least three inches thick. It does not destroy the chemical agent but forms a seal preventing, for a limited time, the escape of toxic vapor. Such covering will be more effective if wet down with water.

20. DECONTAMINATION EQUIPMENT

Certain equipment is presently standardized for use in application of decontaminating agents to contaminated materiel. These include:

Decontaminating Apparatus (3-gallon)

The decontaminating apparatus (3-gallon) is a modified, commercial insecticide sprayer used for spraying contaminated equipment with DANC. The apparatus is carried empty and is filled with freshly prepared DANC immediately prior to use. It contains a pump which compresses air over liquid in the tank, thus forcing the liquid out through the dis-



DECONTAMINATING APPARATUS M1 (3 gallons)

charge line and nozzle. These apparatus are made by a number of manufacturers and will differ slightly in appearance and dimensions.

Decontaminating Apparatus (1½ Quart)

The decontaminating apparatus (1½ quart) is a standard decontaminating apparatus approximately eighteen inches long and three inches in diameter. There are two forms, the air pump type and the liquid pump type, which are similar in appearance. This apparatus is carried in all vehicles in the theater of operations for organizational decontamination. It also may be used to decontaminate small items of equipment. One filling of DANC will decontaminate up to twelve square yards of surface. The apparatus will project its filling about five feet in the form of a spray, the complete discharge requiring about ninety seconds.

Decontaminating Apparatus M3 (400 Gallon)

This apparatus is a modified commercial power-driven orchard sprayer consisting essentially of a wooden tank of 400-gallon working capacity with a rotary agitator, a piston type pump equipped with a pressure regulating unloader, or relief valve, capable of delivering approximately 35 gallons of mixture per minute at a working pressure of 400 pounds per square inch, and a power take-off unit which drives the pump and agitator by means of roller chains. The entire apparatus is mounted on a 2½ ton, six-wheel-drive, gasoline engine truck. It is assigned only to special personnel and is used for large scale operations, such as decontaminating roads, buildings, and other critical installations. It is filled with wet mix (bleach slurry), or with water and detergent (such as soap). One tank load contains sufficient agent to cover an area of approximately 1600 square yards.

Auxiliary Equipment

Other equipment which is used for decontaminating purposes includes swabs, rags, shovels, rakes and brooms. These are used for such purposes as mixing solutions, removing debris and applying solutions to very small objects or otherwise inaccessible places.

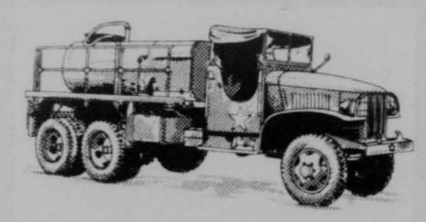
21. DECONTAMINATION PROCEDURES FOR AGENTS

Blister Gases in General

The object is to remove the threat of both liquid and vapor by destroying the gas. Intimate contact beween gas and decontaminant is necessary for rapid decontamination.

Either dry bleach alone or dry mix (two shovelfuls of bleach to three shovelfuls of dry earth) may be used to destroy blister gases. Pure bleach reacts violently with pools of liquid blister gas. Care must be used when decontaminating by this method, since heavy vapor concentrations are exuded.

Wet mix (slurry) is made in two ways: It is a fifty-fifty mixture of bleach and water by weight (for every six shovelfuls of bleach add a 14-quart bucket of water) when used for spreading by brooms or swabs; or it is mixed 40 per cent bleach and 60 per cent water by weight (twenty-six 50-pound cans of bleach



APPARATUS, DECONTAMINATING, POWER-DRIVEN, M3A2 (TRUCK MOUNT)

This apparatus consists essentially of a 400-gallon wooden tank equipped with rotary agitator, 3-cylinder piston-type pump, and relief valve. The truck supplies power to drive the pump and rotary agitator.

Weight of unit empty	11,100 pounds
Water per filling	225 gallons
Filling time from stream	10 minutes
Bleach per filling	1,300 pounds
Filling time with bleach	20 minutes
Mixing time	15 minutes
Average coverage per filling	1,300 square yards
Discharge rate per minute (slurry-1 spray gun)	11 gallons
Discharge rate per minute (slurry-2 spray guns)	20 gallons
Working pressure	400 pounds per square inch

[1,300 pounds] to 225 gallons of water) when used in the 400-gallon decontaminating apparatus. Wet mix should remain on the surface being decontaminated for from six to twenty-four hours, if possible.

Water used by itself hydrolyzes blister gases too slowly for practicable decontamination. It may be used to wash blister gases away mechanically if there is adequate drainage. Special decontaminating personnel with proper equipment may use other means, such as water, soap, and other detergents. (A solution of three pounds of soap shaving and three pounds of washing soda to one hundred gallons of water may be used.) Blister gas sinks to the bottom of pools of water, and care should be taken not to come in contact with the washings.

DANC is an effective decontaminant. It usually is employed in the decontaminating apparatus. The solvent alone (acetylene tetrachloride) may be used to wash away blister gases, but the washings remain dangerous.

Burning the area or object is a quick way of decontaminating, but tactical considerations may prohibit fires in the field.

After decontaminating measures have been completed, any item likely to be handled by personnel must be tested with detector paper or the detector kit to ascertain that decontamination is complete. (It should be remembered that paper detects only liquid agent.) In all decontamination, gas masks and protective clothing should be worn, including impermeable protective gloves, if available.

HN

Water or soap and water are the most practicable agents for field decontamination of the nitrogen mustards. Hot water is more effective than cold water, but both merely wash the gas away mechanically, and adequate drainage is required to protect personnel.

L and Other Arsenicals (MD, PD, ED)

DANC or bleach is best. Water is only partially effective. Since water may leave a vesicant solid if it is used for decontamination, the surface should be treated with a caustic solution, such as washing soda or lye.

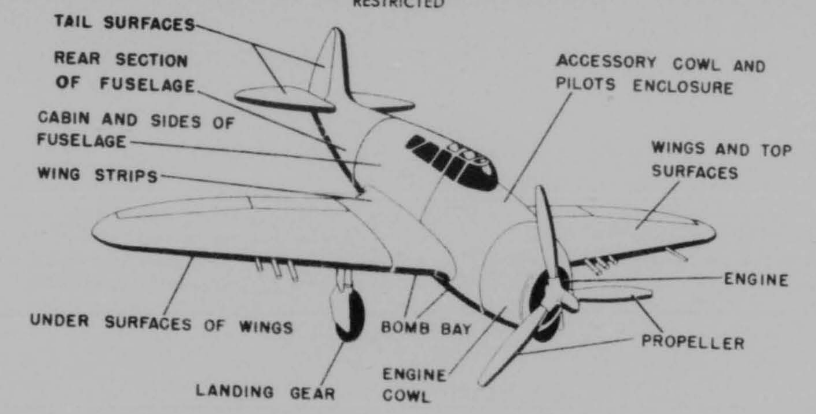
Other Gases

PS and CN, are moderately persistent. PS persists about three hours under average conditions. Aeration is usually sufficient. A hot solution of sodium carbonate (washing soda) neutralizes CN.

22. DECONTAMINATION PROCEDURES FOR MATERIEL

Rubber Articles

DANC should not be used for rubber articles, such as boots and gloves. Several days' aeration in sun and wind suffices if contamination is light. Soaking several hours in water just below the boiling point, or immersion twenty-four hours in a mixture of one part bleach to two parts water (by volume)



SEQUENCE OF AIRPLANE DECONTAMINATION

followed by rinsing and several days' aeration, is better for heavy contamination.

Ammunition

Visible contamination should be wiped with rags. DANC is applied, it is wiped with a gasoline-soaked rag, then dried. If DANC is not available, it should be scrubbed with soap and cool water. If ammunition is corroded, it must be thoroughly cleaned or destroyed. Wet mix (slurry) can be used on contaminated ammunition containers, but it must not be allowed to penetrate to the ammunition itself.

Instruments

If exposed to corrosive gases, instruments should be cleaned as soon as possible with alcohol (or gasoline, if no alcohol is available), and a thin coat of light machine oil applied. A rag dampened with DANC also may be used, followed by drying with a clean rag and application of machine oil. (DANC injures plastic or hard rubber surfaces.) Delicate instruments are decontaminated by special processes by higher echelons.

Weapons

Remove dirt, dust, grease, and oil. Do not apply wet mix, but allow surfaces to aerate after soil and dirt have been removed. DANC can be used on all metal surfaces except the bore. Hot water and soap, or repeated applications with gasoline-soaked swabs, are also effective, and protective ointment can be used for emergency decontamination of small arms as outlined. After decontamination, weapons are dried and oiled.

Airplanes

In flight, the crew of a contaminated airplane must perform sufficient decontamination to continue the mission. Masks and protective clothing should be worn. Vital interior parts, such as seats, instrument board, controls, and firing apparatus, are decontaminated immediately by blotting excess contamination with a rag, then using DANC. It must be remembered, however, that DANC roughens painted and rubber surfaces, and is harmful to plastics. Water is used to decontaminate painted surfaces free from grease and oil, but soap and water may be used more effectively. Bleach paste may be applied to rubber parts. Blister gas sprayed on wings and fuselage loses its vapor danger after flights of one to one and a half hours, but prolonged contact with the contaminated part must be avoided. Masks may be removed after this period, but tests for gas within the interior of the airplane should be made prior to removal. Hot air from the airplane engine heater may be used to decontaminate the interior of the airplane.

Only soap and water should be used on plastic surfaces since protective ointment etches these substances.

THIS PAGE IS DECLASSIFIED IAW EO 13526

If leaking munitions are the cause of contamination, they should be dropped from the airplane.

Complete decontamination of the airplane is performed by special troops after the airplane has landed.

Automotive Equipment

Light contamination from spray can be decontaminated by aeration alone. For heavier contamination, DANC is used on interior and exterior surfaces which personnel are likely to touch. For larger area decontamination, the vehicle should be washed with water and painted surfaces scrubbed with soap and water. In emergencies when the vehicle is being used, the hood and front parts only are decontaminated. Decontamination of vehicles should begin on the upwind side, upper parts first.

Terrain

Burning the area destroys gross surface contamination (except where there are pools of liquid blister gas) and destroys vegetation holding drops of liquid. Burning does not destroy liquid blister gases which have soaked into the ground; therefore, lying on ground thus treated should be avoided. When burning contaminated areas of grass or brush, great care must be exercised to determine that no friendly troops are within the danger area downwind, and if the area to be burned over is large, additional protective measures must be taken.

Dry bleach, dry mix, or wet mix are satisfactory for decontamination of terrain containing very little vegetation, but these decontaminating agents must be camouflaged either by covering with earth after spreading or by the addition of camouflage materials (dark earth) before using. The amount of bleach to be used is approximately one to two pounds per square yard. Hard road surfaces can be flushed with water under high pressure, or dry bleach can be spread from a bleach spreader. Large flat areas can also be decontaminated by using the bleach spreader to spread dry bleach. Containers of dry bleach may be detonated by use of a suitable explosive to obtain coverage of approximately one square yard of surface per one pound of bleach. Dry mix and wet mix are usually used only for localized areas because of the considerable amount of labor involved.

When decontamination is not practical or necessary, all approaches to the area should be posted with gas warnings, standard or improvised, showing the type of gas and date of contamination or discovery. Signs should be so placed as to give ample warning.

Buildings

Scrubbing with wet mix is the quickest method of decontaminating. Wet mix may be applied from the 400-gallon power-driven apparatus. It is mixed 40 per cent by weight of bleach to 60 per cent by weight of water. (Or 225 gallons of water to twenty-six 50-pound cans of bleach.) This method is especially useful for high vertical surfaces. Wet mix should remain on the surface for six to twenty-four hours before being washed away. Paste may also be used; it is scrubbed into the wood with swabs or brushes. If the surface is smooth, the outside may be washed with water and the washings neutralized with bleach. If the building is not needed, it should be burned or left to decontaminate by aeration after posting suitable warning signs.

Polished and Working Metal Parts

These are decontaminated with DANC. Bleach is extremely corrosive to metals. Kerosene or gasoline may be used to wash liquid blister gas from metal parts, but great care must be used to avoid contact with the washings, since gasoline and kerosene only dissolve and do not destroy blister gas. After decontamination, the parts are washed with soap and water and re-piled. Painted surfaces are repainted, if necessary.

23. DECONTAMINATION PROCEDURE FOR CLOTHING

Removal of Untreated Clothing

If untreated garments have been contaminated even slightly with vesicant they should be removed as soon as the tactical situation

permits. This is true whether the agent is in solid, vapor, or liquid form. A thorough soap bath should follow if at all possible. Serious burns may result if untreated garments contaminated with vesicants are worn even for a few minutes. Even if liquid does not soak through to the skin, vapor burns will result. Should there be a spot of liquid clearly visible upon the clothing, and removing the garment is not feasible, the contaminated portion should be cut from the clothing and protective ointment applied to the body area underneath. Great care should be taken in removing both untreated and protective garments and equipment to prevent contamination of additional skin areas.

Removal of Protective Clothing

A procedure for protective clothing in fixed defenses, which should be followed as closely as possible in the field, is as follows:

A special room, tent, or area is provided with a bench on which to sit. Paper should be placed on the floor at each side of the bench. All men approach the bench from the same side. Wearing their chemically treated cotton gloves, they remove their leggings and shoes. Then they turn and place their feet on the paper at the other side of the bench. Without removing their gloves they take off their hoods, masks, and coveralls. The gloves, underwear, and socks are then removed in that order. All clothing is placed in receptacles provided for this purpose. The men enter an adjacent shower room or field bathing unit and, using plenty of soap, bathe thoroughly. Avoiding the undressing area, they put on clean clothing.

Ventilation

Work upwind, if possible, from a decontamination job or area where large quantities of contaminated garments or equipment are temporarily stored. If indoors, ventilation should be sufficient to prevent accumulation of vapors in toxic concentrations.

Handling of Contaminated Clothing

Items badly contaminated or damaged should be disposed of by burning or burying. Remaining articles should be placed in covered G. I. cans or special gas-resistant sacks for transportation to the quartermaster laundry or to the decontamination site. Handlers should wear gas masks, protective clothing, and impermeable rubber gloves. If the handler is likely to be splashed with contaminated water during the decontamination process, he should wear, if possible, impermeable clothing. At the decontaminating site the containers are opened and the contents sorted into classes, such as wool, silk, cotton and linen, impermeable fabrics, leather, and rubber articles. Each requires a different type of treatment.

Soap and Water

Washing with soap and water is one of the most readily available, certain, and quickest methods of decontaminating all types of individual equipment in the field. Hot soapy water in a can or tub, with a paddle for stirring, insures a cleansing as well as decontaminating action. G. I. or laundry soap is the most satisfactory. Fresh water must be used unless salt water soap is available. Cottons and linens may be washed at much higher temperatures than woolens, which should be washed in a lukewarm soap and water solution to prevent excessive loss of the protecting chemical. Impermeable clothing cannot be laundered. When laundering, the contaminated articles (except woolens) should be stirred in the heated soapy water for at least five minutes. This should be followed by two additional washings and three rinses of five minutes each. If an odor of vesicant remains, the process should be repeated. If it still persists, the items should be discarded and buried or burned.

24. STEAMING

Uses and Duration

Steaming is a suitable decontamination procedure for clothing, fabric, and equipment contaminated with mustard gas. It is not suitable for Lewisite because of the toxic oxide which forms and which cannot be removed by solvents. Garments and textiles exposed to mustard-gas vapor or very small drops should be steamed for two hours at least. If splashed with liquid mustard gas they should be steamed for six to eight hours. Steaming is likely to result in considerable shrinkage of woolens and also produces a small amount of hydrochloric acid which deteriorates cloth. Hot water is generally superior to steaming because an abundance of water dilutes the acid to such an extent that no marked deterioration occurs.

Improvised Apparatus

A steaming unit can be made with a good-sized can, such as a large G. I. can. A false bottom, improvised of pieces of wood or other rigid material, serves to hold the clothing about a foot above the water. Six to eight inches of water are poured into the bottom of the can, the false bottom inserted, and the garments placed on the false bottom. Nails may be driven through the cover of the can and bent to provide hooks for the clothing. This allows the steam to circulate more freely through the contents of the can and insures more intimate contact between the steam and the contaminated clothing. The can should be closed and heat applied. If any odor of vesicant remains in the clothes after steaming, they should be treated again.

25. AIRING

Uses

The simplest but slowest method of decontaminating clothing is by airing it out-of-doors. Garments may be placed, widely spaced, on the ground or bushes, preferably where the sun will strike them and the air will circulate underneath. Clothes should not be placed in such a manner or location that they will attract the attention of the enemy. Airing is suitable for all types of clothing and textiles, but lack of time and unfavorable weather often will prevent its use.

Time Required

Evaporation is hastened by bright sunlight, high temperature, and a gentle breeze. In warm weather at least two days' exposure out-of-doors is necessary for fabrics contaminated by vapors, while four or five days will be sufficient for lightweight garments contaminated with droplets. In cold weather at least two or three days' exposure out-of-doors is necessary for garments contaminated with vapor, while seven to ten days will be required for lightweight garments contaminated with droplets. Heavy garments, other than those of leather and rubber, should be aired two days longer than lightweight articles. To insure complete decontamination of leather and rubber articles, methods of decontamination other than aeration should be employed.

Hot Air Indoors

If facilities permit, contaminated items of most kinds may be hung in a well-ventilated room and subjected to hot air produced by improvised equipment. This method speeds evaporation. Fumes from the room must be delivered to the open air in such a manner that personnel are not endangered. Lightly contaminated clothing may require four to six hours of this treatment if a temperature of about 140° F. is maintained. Temperature should be kept lower than the scorching temperature of the clothing. This method has the advantage of large capacity and no need for water. However, it is not always possible to obtain a suitable room and heating equipment.

26. TACTICAL PROTECTION

Tactical protection includes both active and passive chemical defensive measures taken to defeat enemy chemical warfare action. Maneuver of troops is planned so that gassed areas may be avoided or if avoidance is impossible that they are crossed at points most favorable to the security of the troops involved. Supply movement is planned so that traffic may be routed over alternate routes to avoid contaminated areas. Positions are organized so that alternate positions can be occupied in the event of a gas attack. Alternate positions are selected with a view of counteracting enemy action against the main position as well as affording security against enemy chemical agents released on the primary position. While executing the mission of attacking or defending a position, casualties may be avoided or minimized by the following measures:

Exposing the least number of personnel.

Exposing personnel for the shortest possible time.

Exposing personnel to the lowest possible concentration of war gas.

27. STANDARD OPERATING PROCEDURES

Standing operating procedures (SOP) are orders issued by an air command, air force, wing, group, or squadron, setting forth definite and uniform procedures for chemical defense of the commands. Their adoption tends to eliminate repetition of orders, minimizing danger of confusion and error in combat. SOP's for chemical defense are based on recognized methods of individual and collective protection, and are modified as means and knowledge of protection improve. The various units of a command enforce the SOP and prepare additional plans specifically required for protection of personnel. A guide to the principal items is shown in figure ———.

28. TACTICAL PLANS

General

Tactical plans apply to the local situation. They are carefully coordinated into the general scheme of attack or defense.

Estimate of the Situation

In estimating the situation and drawing up plans, commanders (assisted by chemical officers or unit gas officers) should consider:

The capabilities of enemy weapons and chemical agents.

The weather, terrain, and tactical situation.

Surprise

Generalities have been drawn to show situations which favor enemy use of one kind of chemical agent over another. Favorable weather conditions and a large number of hostile troops are usually considered essential to successful nonpersistent casualty gas attacks. Persistent casualty gas is often used to create or strengthen obstacles, against areas difficult to capture by assault (which the enemy does not intend to occupy immediately), or against marching troops or installations. Surprise, however, should always be guarded against. An enemy may use nonpersistent gas under unfavorable conditions. He may assault a position he has just contaminated with persistent casualty gas. Commanders should be constantly on the alert for signs of an enemy chemical attack, no matter how unfavorable conditions may appear.

29. DISTANT RECONNAISSANCE

Explorations of objectives which lie outside the immediate striking range of a force are conducted by aerial observers and by highly mobile ground forces. Special attention is given areas which normally would be covered in the next several days' operations. Aerial photographs and distant ground observation show location of terrain which, if contaminated, might hamper advancing troops. Enemy chemical activity, such as installations of chemical land mines, may also be revealed. Information may come through raids or by questioning prisoners and inhabitants.

Close Reconnaissance

Chemical reconnaissance becomes more detailed as opposing forces draw together, and particular attention is given to selecting halting points, camp sites, routes of approach, and battle positions favorable or unfavorable to enemy gas attack. Aerial observation and ground reconnaissance help develop information on the enemy's chemical operations, but each unit is responsible for reconnoitering its own front and flanks, routes, and alternate routes of approach. Reconnaissance of gassed areas is difficult at night; accordingly, daytime observation is advocated. But an immediate and quick reconnaissance to determine best means of passage is necessary whenever a gassed area is encountered unexpectedly, day or night. Procedures are as follows:

For areas known to be gassed, the reconnaissance party, suitably protected, examines the area to obtain the following information:

Kind of gas and concentration (heavy, light, medium).

Location and extent of contamination.

Routes for troops and vehicles upwind and downwind of the area, and advisability of masking.

Feasibility of preparing a road, or of using established paths or roads through the area. Part of the group goes upwind to define the edge of the area and explore the possibility of passage there. Other personnel make a similar reconnaissance on the downwind side. Detection devices are used periodically. Occasionally personnel may test for gas by sniffing, but as infrequently as possible. After extent of the area is determined, it is marked with gas-warning signs showing the kind of gas and date of contamination or discovery. Units approaching from the rear are notified. If necessary, sentinels are posted to give warning. Whether passage is made depends on amount of contamination, size of area, availability of routes for bypassing it, terrain and weather conditions, extent of hazard involved, and immediate tactical urgency.

For areas suspected of contamination, careful examination is made, with special attention to low-lying patches of woods, defiles, ravines, stream beds, areas covered with high grass or underbrush, and other spots favorable to contamination with persistent casualty gas.

Battle Reconnaissance

This consists principally of gathering information on the enemy's chemical activities, actual and potential. After a gas attack, battle reconnaissance includes location of gas-free areas and information on which to base recommendations for possible evacuation of contaminated areas.

30. CHEMICAL INTELLIGENCE

After information of military value is collected, it is evaluated by intelligence personnel and disseminated. Only after evaluation does such information become intelligence. Chemical intelligence (like Air Force intelligence in general) may have two main sources: Department of the Air Force (produced under the Department of the Air Force General Staff in peace and in war) and combat (produced in the field by Air Force intelligence sections after the outbreak of hostilities).

Air Force Intelligence

Department of the Air Force intelligence summaries and bulletins are issued for units in the field by higher headquarters. Summaries and bulletins contain information on general chemical warfare developments and on results of research and experimentation. They are furnished to the division chemical officer for distribution to all concerned.

Combat Intelligence

Combat intelligence is based on information gathered by reconnaissance and observation (or by other reliable means) on enemy chemical activity, and is handled through regular intelligence channels. The intelligence itself is furnished to the unit commander by the intelligence officer or his assistants by personal contact, special messages, conferences, periodic reports, or special reports. This intelligence is used by the commander in planning his organization's chemical defense.

Collecting Agencies

Collecting agencies and sources of information available to combat units depend upon the size of the units. In large units, chemical laboratory companies and military intelligence personnel may be included. (The group is the smallest unit provided with intelligence personnel.) Collecting agencies may draw information from such sources as interrogation of prisoners, examination of enemy chemical materiel, or samples of contaminated earth. In smaller units, sources of information are limited to patrols and to unit gas personnel.

Factors Important in Combat Intelligence

The following factors are guides (not limitations) to what is most important in both chemical information and intelligence:

Local weather conditions favorable or unfavorable for enemy chemical attack.

Chemical offensive preparations of the enemy, including his capabilities for using gas, character and amount of his chemical weapons

and ammunition, location and disposition of his chemical troops, and location of weapons and munitions for dispersing gas.

Terrain which is a good target for gas, especially terrain likely to be crossed or occupied by friendly troops.

State of enemy gas training, discipline, and protective equipment.

Data regarding any particular gas attack and official report form.

Data on friendly troops, including friendly use of chemical agents, state of protective equipment, and protection available for food, water, and general supplies.

31. REPORTS

Immediate Reports

These are sent by the unit gas officer, immediately after a gas attack, noting:

Time
Place
Extent of attack
Kind of gas (if known)
Type of weapon used (if known)

32. SELECTION OF ROUTES AND POSITIONS

Factors

In choosing routes and areas, whether original or alternate, the following are particularly applicable to chemical defense:

Elevation. Gas tends to drain to low ground; high ground therefore, is preferable unless contaminated. Air currents in corridors, however, may tend to carry gas up slope and up valley during the day, down slope and down valley during the night.

Concealment and Cover. Woods in leaf offer the advantage of concealment and some measure of cover against spray. Woods with good overhead cover and clear ground beneath are preferable, but concentrations are often higher in woods than in the open.

Freedom from Underbrush. If heavily contaminated, low scrub and long grass may contaminate troops badly. Further, gas vapors linger in heavy undergrowth (particularly if the ground is low), and concentrations may be high there.

Accessibility of Water. (Water supplies are important for decontamination purposes.)

Means of Entrance and Exit. (Paths or roads should be chosen which are not in themselves dangerous from a contamination viewpoint.)

Ample area for dispersion.

Good observation for sentinels.

Other tactical or supply factors. Protection from chemical attack, however, may have to be a compromise with protection from small-arms fire, and from armored or air attack.

Bypassing a Gassed Area

Whenever possible, troops should be moved upwind of a contaminated area. If the situation requires a downwind passage, it is usually safe for masked troops to pass at a distance equal to the depth of the area, but the vapor concentration and weather factors must be considered. Unless the mission demands it, personnel should avoid remaining downwind; troops held there may suffer casualties even if the vapor concentration is low and the contaminated area small. Furthermore, the effects of blister gas are cumulative. If possible, airmen should not be exposed to blister-gas vapors if their skin is red from previous exposure.

Detection of Blister Gas

Troop officers must remember that the odor of mustard gas does not necessarily indicate dangerous amounts of vapor. Harmless impurities (which have an odor similar to the original mustard gas) or reaction byproducts from decontamination may remain in the area after the danger has disappeared. The M9 chemical agent detector kit should be used and the table in the accompanying booklet consulted.

Evacuation of Positions

If a position already occupied is heavily contaminated, casualties may be unavoidable. Tactical considerations may require that such

THIS PAGE IS DECLASSIFIED IAW EO 13526

a position be held. If the mission can be accomplished by occupation of a previously chosen alternate position, the gassed area may be evacuated and the alternate position occupied. In no case should evacuation of an original position be undertaken until it is clear that the enemy is using blister gas in quantities sufficient to jeopardize the mission of occupying troops. If the position once evacuated is threatened by enemy occupation, it should be reoccupied if it is sufficiently important.

33. OPERATIONS IN GASSED AREAS

Following a suitable lapse of time after gassing, operations can be conducted safely even in areas contaminated with blister gas. Time limits vary, depending upon protective clothing, temperature, type of contaminated soil and terrain, and task to be performed. The M9 chemical agent detector kit should be used and the accompanying booklet consulted to determine approximate time limits after which task can be performed in gassed areas.

On the March

When the mission requires, troops must pass through (or even remain in) contaminated areas. In such cases, operations may be carried on with the minimum number and least severity of casualties if good gas discipline is maintained and all practicable measures of individual and collective security are carried out. In addition, certain techniques are helpful:

Hard surface roads should be used, if available.

If roads are muddy, men should be warned to avoid splashing. Wheels of vehicles, and the feet of both men and animals are cleaned after area has been crossed. Shuffle areas of dry mix should be located at either end of crossing.

Troops should be instructed to avoid visible liquid contamination, whether fresh or old, and especially to avoid contact of liquid with the bare skin.

In motor movements, personnel should be guarded against splashing from branches or from contaminated water and mud on roads.

If the area is dry and dusty, clouds of contaminated dust should be avoided.

Movement should be rapid, reducing time of exposure to vapor. (Troops tire quicker if dressed in protective clothing and masked.)

If tactically possible, contaminated vegetation should be burned along the route, avoiding exposure to concentrated vapors produced by burning.

If practicable, details, dressed in impermeable protective clothing, should be assigned to cut lanes in advance through areas of contaminated ground.

Protection During Pursuit of Enemy

This is achieved by thorough reconnaissance and observance of all other chemical defense measures. The enemy is likely to use blister gas extensively in rear-guard action; therefore, a pursuing force must guard constantly against contaminated ground.

34. LONG-PERIOD OCCUPATION OF CONTAMINATED JUNGLE AREAS

When contaminated areas are limited in extent, troops may be moved to uncontaminated areas for eating, drinking, and personal relief. When the contaminated area is extensive, no gasproof shelters are available, and troops must remain within it for long periods (twenty-four hours or longer), the following procedures are suggested:

Preliminary Reconnaissance

A search should be made for sites likely to become gas-free at the earliest time, and for sites of least liquid contamination. It may be necessary to redispose troops so that they occupy areas free from liquid contamination.

Eating and Drinking

No attempt should be made to remove masks within the first four hours after a heavy mustard gas attack. After this time, tests with the M9 chemical agent detector kit should be made at the sites discovered in the preliminary reconnaissance above.

Urinating and Defecating

A site for a latrine area is chosen in the preliminary reconnaissance, and men must be warned of the necessity for using only the latrine area designated. For urinating, the fly of the protective clothing is unbuttoned to almost its full length with the gloved hand and the fly of the drawers widely exposed. The drawers are then unbuttoned with the bare hand. The genitals should not be exposed for more than one minute. The reverse procedure is followed in rebuttoning the clothing. For defecating, the trousers should be lowered with the gloved hands, and the drawers lowered with the bare hands. The clothes should not touch the ground, and caution must be exercised to avoid touching twigs or grass with the bare skin. The genitals should not be exposed more than two minutes. The reverse procedure is followed when adjusting the clothing.

Sleeping

Sites for sleeping should be chosen during daylight so that areas with liquid contamination can be avoided. A fox hole is dug, or the surface is scraped away even though no contamination is visible. A protective cover (or poncho) is placed under the body but not over it, since blister gas vapor may be trapped. Masks should be worn, and sentinels must see that men do not pull them off while asleep.

35. PROTECTION AGAINST NONPERSISTENT CASUALTY GAS ATTACK

Tactically, the enemy may be expected to assault a given position soon after he lays down a nonpersistent casualty gas attack upon it. Troops must be prepared to repel such assaults. Such preparations should be completed as soon as possible after the gas attack is made. Any unnecessary movement should then cease until the assault is made or until the gas laid down by the enemy has disappeared. Sometimes enemy gas attacks can be forestalled by air or artillery bombardment of the enemy's positions. Even if the gas attack is not forestalled, the enemy's following assault may be stopped by immediate bombardment.

SECTION V—DEFENSE AGAINST INCENDIARY ATTACK

1. STRATEGY AND TACTICS

Incendiary bombs may cause more destruction than any other aerial munition. The incendiary bomb is considered a strategic rather than a tactical weapon, and it has been used mainly against rear area installations, yet its tactical targets include ammunition dumps, advance depots, railheads, airdromes, and supply columns. Incendiary shell, fire bombs, grenades, and flame throwers are primarily tactical.

Type of Attack

Large incendiary bombs customarily are used only on important installations (point targets), such as airdromes, railheads, docks, depots, and factories.

Small incendiary bombs are dropped in clusters against area targets. These bombs disperse in falling, the object being to start a number of separate fires which merge into a major conflagration.

Secondary Missions

Explosive incendiary bombs often are included in incendiary bomb clusters. Besides starting fires, they impede incendiary defense.

Fires started may light the way for high-explosive, precision bombing.

2. ORGANIZATION FOR DEFENSE

Responsibility

Fire defense is a command function and responsibility. The organization for defense against incendiaries is headed by the division engineer, who may be appointed fire marshal. Corps of Engineers fire appliance troops fight appliance fires in a theater of operations. The chemical officer may be designated as adviser to the fire marshal.

Existing Organization

The existing organization for protection against air attack must provide for incendiary defense.

Fire Department Cooperation

A single small incendiary may cause an appliance fire (one which cannot be brought under control by a fire-fighting squad, but must be attacked with professional fire-fighting apparatus). In a theater of operations, large appliance fires are controlled by Army Engineer fire-appliance troops. In the United States, civilian fire-fighting organizations or civilian employees of the Army must fight these larger fires.

General Plans

While no detailed plan will cover all situations, the following are important points in setting up a defense plan:

Fireguard duty is assigned in addition to regular duty. The fireguards are stationed at point targets or important installations and used as patrols in important areas during emergencies.

Additional equipment is improvised.

An inventory is kept of locations of all materials and equipment useful in fighting incendiary bombs. This record should be maintained by the officer responsible for the fire protection of the area.

Fire-fighting supplies and equipment should be kept near all vital centers.

A military area should be divided into sectors, with an officer responsible for the organization and its functioning in each sector.

An air-raid protection organization should be set up.

Training

All personnel should be trained to use available fire-fighting equipment and taught to recognize various types of incendiaries and their characteristics.

Advance Fire-Defense Planning

General. Advance planning and a complete understanding of the plan by all responsible officers are essential. Surveys should be made and a standing operating procedure should be established. Simplicity of plan is of prime importance.

Classification of Areas. As part of the advance planning, areas should be classified according to type of construction, amount of roof coverage, and tactical importance.

3. MEANS OF DEFENSE

Defense against incendiaries must be aggressively conducted.

Precautionary Measures

Inspections should be made to insure the following:

Readily flammable materials must be kept in nonflammable containers.

Waste materials should not be allowed to accumulate.

Wooden surfaces, where practicable, should be coated with white-wash, water-glass solution, or other fire-resistant material (properly camouflaged).

Materials for fighting incendiaries should be readily accessible.

A practical incendiary spotting and alarm system should be in operation.

Combustible supplies should be dispersed.

Ingenuity should be employed in improvising supplementary equipment.

Incendiary Defense Organization

A unit defense organization should be established and taught to use available equipment.

Periodic defense drills should be held. Anti-incendiary discipline of the entire unit should be stressed.

Handling of small incendiaries is a technique that the individual airman can be

METHODS OF COMBATING INCENDIARIES

THIS PAGE IS DECLASSIFIED IAW EO 13526

taught, just as he is taught the technique of individual gas protection.

A fire guard for first-line defense should be established, consisting of individual fire guards equipped with and trained to use simple fire-extinguishing equipment.

If civilian communities with organized fire-fighting services are near, liaison should be maintained in order to obtain aid for control of fires.

Equipment

General. In the field, incendiaries and the fires that they start must be controlled with equipment on hand for fighting ordinary fires and with improvised equipment. This includes water buckets and barrels, sand and sand bags, garden and fire hose, burlap bags, axes, shovels, flashlights, rope, gas mask or goggles, and gloves. Pump tanks, 3-gallon or 400-gallon decontaminating apparatus, and soda-acid or carbon dioxide extinguishers may also be available. Fire-fighting equipment must be kept in convenient, readily accessible places known to all.

Hose. Prompt flooding with a stream of water from a hose will soon extinguish or control most small incendiary bombs of any type. The high-pressure "fog" nozzle is most effective for oil incendiaries.

Fire Extinguishers. The chief disadvantage of most fire extinguishers is their small capacity. Use of the carbon-tetrachloride extinguisher is not advisable in confined spaces because of the possible generation of toxic fumes. Soda-acid and water types should not be used directly on oil since they tend to spread the fire. The fog nozzle type of extinguisher is effective.

Water Barrels and Buckets. Barrels (kept full of water) and buckets should always be available. In freezing weather, salt should be added to the water in outdoor barrels.

Sand. Even if there is no lack of other equipment, sandbags should be conveniently placed, and containers of dry sand should be available for smothering effect. Twenty-pound sandbags are best for quick and easy handling. Twenty-pound bags, 15 by 12 by 3 inches, are known as "sand mats."

Other Equipment. Pump tanks, knapsack-type pumps, or the 3-gallon decontaminating apparatus are useful when fire or garden hose is not available. Shovels may be used to scoop up bombs or their molten particles for removal to places of safety. The 400-gallon decontaminating apparatus is excellent for fighting fires.

4. METHODS OF COMBATING INCENDIARIES IN IMPORTANT STRUCTURES

General

When an incendiary falls into an important building or area, such as an oil or ammunition depot, an attempt must be made to control the fire in spite of the risk involved.

Precautionary Measures

A percentage of incendiary bombs usually contains high explosives. Unless known to the contrary, all incendiary bombs must be considered to be of explosive type and treated accordingly. Ordinary room walls, tables, chairs, and similar objects do not provide a safe shield for a hose operator fighting such bombs. A brick wall offers adequate protection only against small explosive incendiary bombs. Only one fire fighter should risk exposure in an attempt to extinguish a bomb. When cover is available, the fire fighter's body should be shielded so only the hands are exposed. Helmets should be worn. When cover is not available, fire fighters operate from a nearly prone position and from a distance as great as equipment permits.

Employment of Equipment

Shovels. Shovels can be used to scoop up incendiary bombs after the danger time for explosion has passed. Bombs can then be thrown in a place where no damage will be done.

Sand Mats. Sand mats can be used to smother bombs. Fighters should then take cover, or run twenty yards away and lie flat. This method should be used only when incendiaries are known not to contain explosives. Sandbags or mats reduce fragmentation of

explosive bombs to some degree; some fragments are confined, and those which escape are dispersed over a substantially reduced area.

Loose Sand. Loose sand may be thrown around the bomb, helping to smother fires started by it. Sometimes it may be necessary to cover the bomb with sand and scoop it or the molten particles into a shovel. The bomb or particles are placed in a bucket partially filled with sand. More sand is placed on top, and the bomb is carried to a safe place. This method must not be used for explosive incendiaries.

Water or Fire Extinguishers. Water or fire extinguishers are employed immediately against bombs falling in vital structures, regardless of whether sandbags or sand mats are used. Carbon-tetrachloride extinguishers should not be used in confined places because they may generate toxic fumes. Soda-acid and water extinguishers should not be used directly on oil since they tend to spread the fire. The fog-nozzle extinguisher, however, is effective. Water can be used against other types of incendiaries. It may be projected from a hose, pump tank, knapsack-type pump, or 3-gallon decontaminating apparatus, or small quantities can be thrown from a can or canteen cup. Water serves two purposes—it confines the spread of the fire by wetting down the surrounding area, and it controls the magnesium types of incendiaries by increasing their rate of burning (or it extinguishes them if enough is used). Throwing large quantities of water or projecting a stream on a bomb causes scattering, but also forces the flaming particles away from the fighter.

Decontaminating Apparatus. The 400-gallon decontaminating apparatus can be used in the same manner as regular fire-fighting equipment if trained operators are available.

5. INSPECTION AFTER INCENDIARY ATTACKS

General

After an incendiary attack, maintain a watch for several hours to make certain that fire does not again break out.

Phosphorus or Oil

When phosphorus or oil bombs have been used and the filling is spattered on walls and floors of buildings, the liquid must be kept wet and scraped away with a hoe, scraper, or knife. Then, as the surfaces dry, they must be watched for reignition or remaining incendiary.

Unexploded Bombs

After each incendiary attack, a careful inspection must be made for bombs which have not detonated, and for separated explosive portions which have not detonated.

When such missiles have been located, the spot should be marked with a sign, "Unexploded Bomb," the area roped off, personnel excluded, and the bomb-disposal officer notified. Under no circumstances should untrained personnel handle these unexploded bombs.

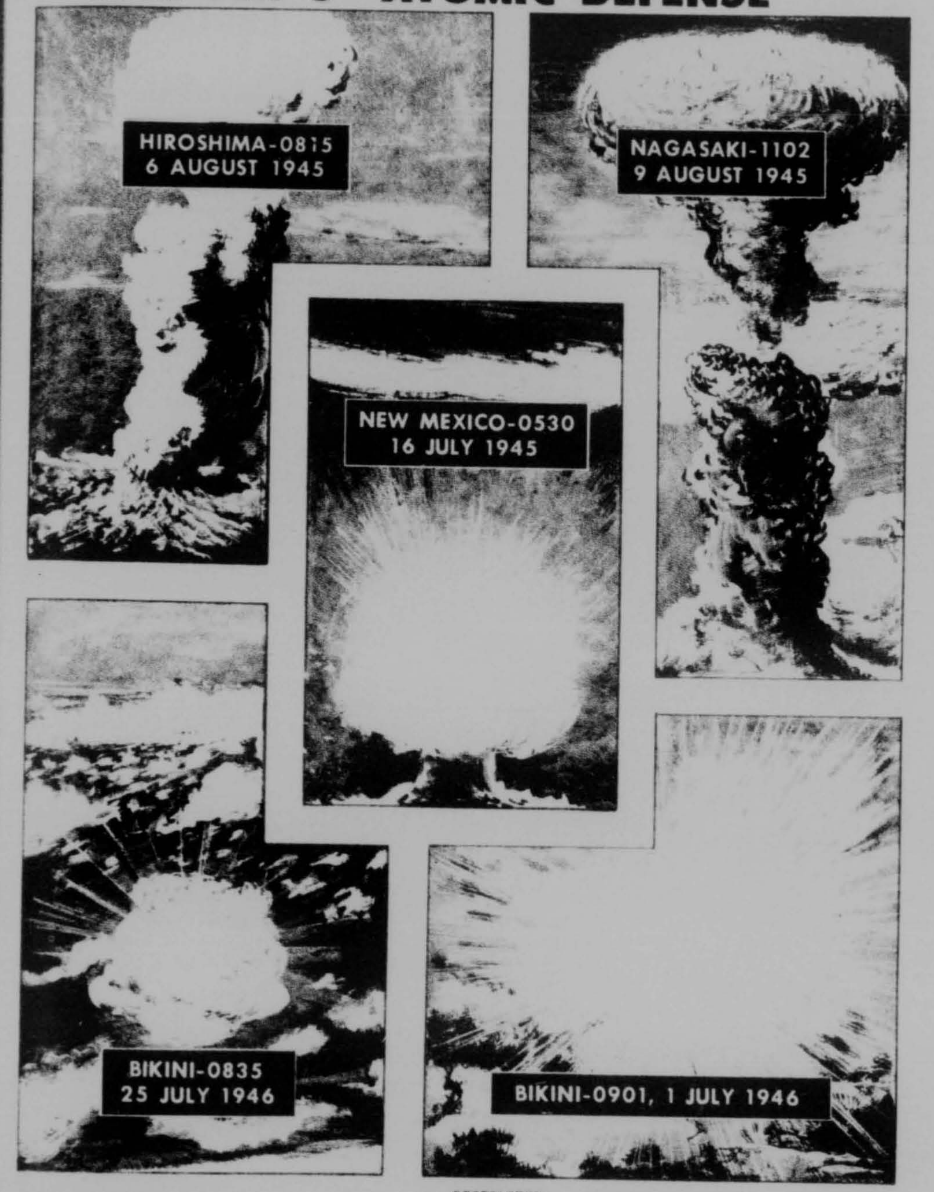
Combustible materials should be removed from the immediate vicinity to prevent their ignition in case the bomb explodes.

Bomb disposal is now a function of the Directorate of Armament. Bomb-disposal crews should be notified through channels.

Equipment

Immediately after a fire has been extinguished, all fire-fighting equipment should be inspected, restored to working condition, and returned to its usual place.

CHAPTER 8—ATOMIC DEFENSE



SECTION I—EFFECTS OF ATOMIC BOMB EXPLOSION

1. INTRODUCTION

The explosion of the first atomic bomb over Hiroshima, on August 5th, 1945, opened a new era in warfare and possibly a new era for all of mankind. Not only was this bomb a powerful new weapon, but it pointed the way to a new source of power for peaceful uses.

The casualties produced at Hiroshima have been variously estimated as being from 60,000 to 100,000. The Japanese figures are higher than those of U.S. military missions which investigated the effects of the bomb. The normal population of this city was about 240,000 but the population had been increased by an influx of the military and war workers. The Japanese estimated that there were about 300,000 persons in the city when the bomb exploded.

It is apparent now that many people died quite unnecessarily. The Japanese had only a skeleton organization for any disaster and under the impact of this blow it broke down completely. A period of five days elapsed before any significant aid reached the stricken city from the outside. Even then, the supply of drugs, blood plasma, and other necessities were not available in sufficient quantities. The medical men often made a faulty diagnosis and prescribed incorrect treatment for the casualties. It is likely that a considerable number of those who died could have been saved if there had been a well-trained and adequately supplied organization to cope with the disaster.

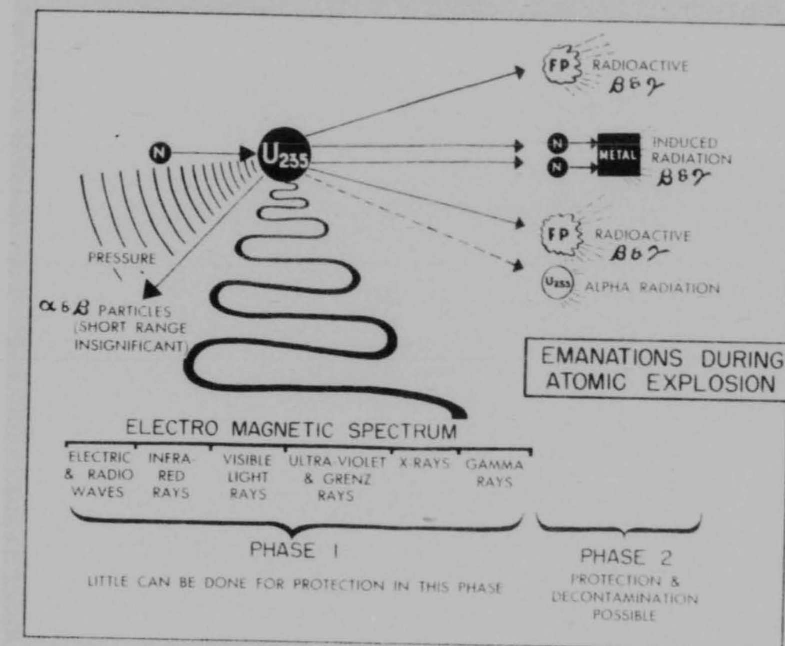
The damage done by the blast effect was enormous; the President announced that it was equivalent to that of 20,000 tons of TNT. Buildings up to a distance of two miles or more from the center of the blast were shattered and four square miles of urban area were destroyed. The destruction blocked streets, imprisoned the wounded in debris and started hundreds of fires. Here again, a well-organized disaster-control group would have been able to save many and to reduce the destruction due to fire outside the wrecked area.

It has been claimed by some that the effect of such an explosion on an American city would be much less severe due to better construction. However, the validity of this argument is questionable. The modern buildings of Hiroshima were built to withstand earthquakes and were of better construction than similar buildings in the average city. It is true that the Japanese homes were of rather flimsy construction, but it is probable that this fact actually saved lives since a casualty was often able to free himself from the wreckage of his home and thus escape the fire which broke out.

When an atomic bomb explodes great quantities of deadly radiations are released. The radiation will be discussed in some detail later in this volume. It is sufficient, for the present, to know that this radiation is deadly up to at least three quarters of a mile from an atom bomb bursting in air; that one type appears at the instant of the bomb's explosion; and that a second type may linger for a long time. Exposure to sufficient quantities of the radiation will kill as surely as bullets will kill. Exposure to high intensities of this radiation may kill quickly or the victim may linger for weeks and then die. The effects of the radiation depend upon the dosage, so that a low concentration for a long period of time may be just as fatal as a high intensity for a much shorter time.

A great amount of heat is developed at the instant of the explosion. In the first few millionths of a second, after the explosion is initiated, a great "ball of fire" develops. This is due to the fact that the gases of the air are heated to a white heat. The temperature, at the center of this mass of hot gas, is millions of degrees centigrade. Once this ball of fire is developed it begins to dissipate by two processes. It rises, rapidly; and it radiates its energy just as the sun, or any other hot body, radiates energy. The energy is radiated as visible, ultra-violet and infra-red light. The visible light can cause temporary blindness, the ultra-violet can cause injuries of the same

UNDERWATER BURST



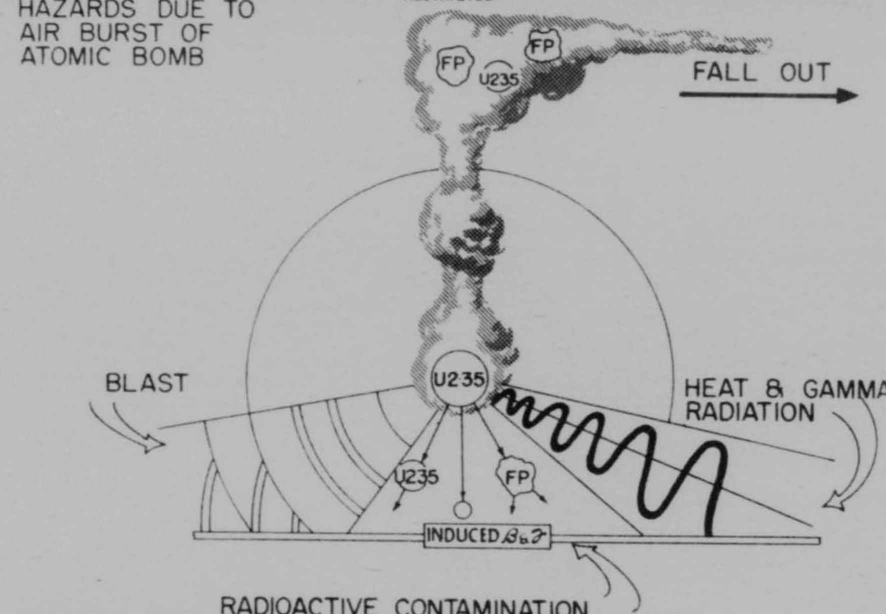
type as those of sunburn, although much more severe, and the infra-red can kill by producing flash burns. The heat causes combustion in easily inflammable materials up to a mile or more.

The bomb also, at the instant of exploding, emits quantities of gamma radiation. This radiation is the same as that from radium and produces the same harmful effects in the human body. Further, and very important, the explosion scatters certain materials over a wide area and these materials are radioactive and emit alpha, beta and gamma radiation.

Training and Organization Requirements

It seems certain that training and organization are necessary to cope with effects of an atomic blast. This training and organization is not entirely a military matter, for if the nation is to withstand an atomic attack then there must be civilian training and organization comparable in size to the military establishment. It is quite likely that the atom bomb will prove to be a strategic weapon, i.e., it will be used to destroy manufacturing plants, ship yards, ports, and morale rather than being employed primarily against troops. Civilian training is therefore indicated. The training of the military started, on a small scale, in 1947. At the present time there are three joint service schools for military personnel. One is located at the Naval Damage Control Center at Treasure Island, California, and is administered by the Navy. Another is located at the Chemical Corps School, Army Chemical Center, Maryland, and the third is located at Keesler Air Force Base, Keesler Field, Mississippi; these two are administered by the Army and Air Force respectively. The three schools have teaching staffs which are made up of officers of the Air Force, Navy and Army. All three admit officer students of all services and a very few selected civilians.

THIS PAGE IS DECLASSIFIED IAW EO 13526



SECTION II—NUCLEAR PHYSICS

1. CHEMICAL AND PHYSICAL REACTIONS

Man has manipulated chemical reactions for many years. The explosion of gunpowder is a chemical reaction. The atomic explosion is not a chemical reaction. It is a physical reaction and it is capable of releasing much more power than can be released by any chemical reaction.

In order to understand the differences between these two types of reactions it is necessary to understand some of the properties of the atom. The atom is a very simple structure. It consists of a nucleus and one or more electrons which revolve about the nucleus in stable orbits. It is in effect a miniature solar system. The nucleus is very small; it has a radius of about ten to twelve centimeters. Almost all of the mass of the atom is in the nucleus since the electrons are very light bodies. The electron moves in an orbit having a radius which is about ten thousand times greater than that of the nucleus. The simplest atom of all is that of hydrogen gas. It has only one electron in an orbit. Helium is the next most complex atom and it has two electrons in its orbits. As the atoms become heavier they have more electrons in their orbits. Thus carbon has six electrons in its orbits and uranium-235 has ninety-two electrons.

Chemical changes, or reactions, do nothing to the atoms involved except change the number of electrons in these orbits.

Physical reactions, which are the basis of the power of the atomic bomb, get their energy from changes in the nucleus. Thus, the Hiroshima bomb was equivalent, as announced by President Truman, to about twenty thousand tons of TNT, yet only a small quantity of fissionable material actually underwent physical decomposition.

Structure of the Atomic Nucleus

Since the physical reaction is the basis of

CURIUM, Cm, At. No. 96

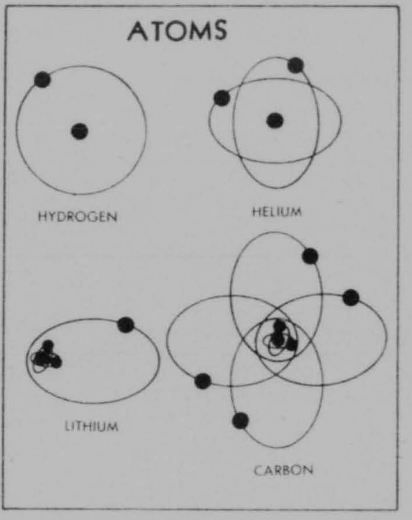
THIS PAGE IS DECLASSIFIED IAW EO 13526

the power which is under study it is necessary to examine the structure of the atomic nucleus with some care. Here also the structure is simple. The nucleus is made up of two kinds of particles packed together. They are known as neutrons and protons. The proton is the nucleus of the hydrogen atom. Its mass is very nearly one mass unit and that value is generally used except for the most precise calculations. The proton carries an electric charge equal to that of the electron but opposite in sign. That is, it carries unit positive charge. The neutron also has a mass of one mass unit, but it carries no charge. Its name comes from the word "neutral".

Discussion of Various Nuclei

It is now possible to explain how the various nuclei of the various types of atoms are built up. Hydrogen is the lightest and simplest atom. Its nucleus is made up of one proton. Helium is the next heavier and next atom in complexity. Its nucleus contains two protons and two neutrons. The mass, or weight, of the helium atom should be equal to four mass units, unless there is some loss of weight due to the energy released by formation (or packing) of the nucleous from the units involved. Lithium is the next more complex atom. Its nucleus contains three protons and four neutrons. Uranium-235 is a heavy and complex atom, but, nevertheless, its nucleus is made up from the same building blocks. The uranium-235 nucleus contains 92 protons and 143 neutrons. Its atomic mass would be 143 mass units for the neutrons plus 92 mass units for the protons, or a total of 235. That is the reason that uranium-235 is designated as it is. In effect, this name means an atom of uranium which has a mass of 235 mass units. There are other uranium atoms. One type, as an example, has a mass of 238 mass units. It is the uranium-235 which is fissionable and which can be used in an atomic bomb. We do not know how to make uranium-238 fission, or explode, therefore we cannot make a bomb of this material.

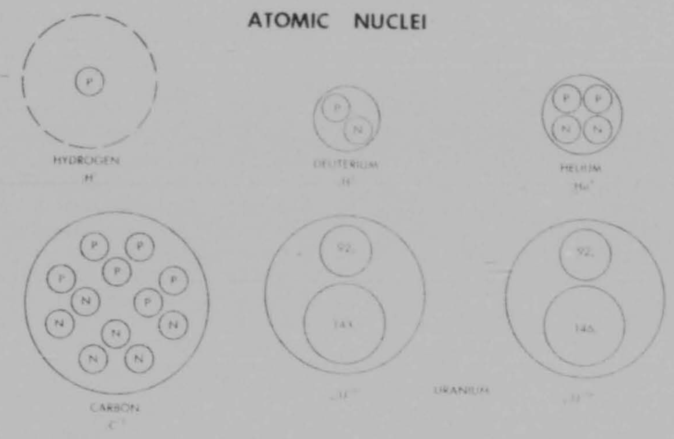
The reason for the number of electrons in the atom's orbits now becomes clear. There are as many electrons in orbits about the nucleus as there are protons in the nucleus.



Helium has two protons in the nucleus and therefore it can attract, and hold, two electrons. Uranium-235 has 92 protons in its nucleus and it can, therefore, attract and hold 92 electrons. It is observed that the uranium-235 atom is surrounded by 92 electrons.

2. ISOTOPES

The word "isotope" is much used today. Isotopes are atoms which have the same chemical properties but different weights, or masses. The chemical properties of any atom depend upon the number of electrons which surround its nucleus. Therefore, atoms with the same chemical properties must have the same number of electrons in their orbits. If they have the same number of electrons, in the orbits, they must have the same number of protons in the nucleus since there is one electron per proton. But, if their masses are different, then the nuclei must have had a different number of neutrons. Thus it is that isotopes, of the same atom, have the same number of protons in the nuclei, but different masses. This difference in mass means very little, in terms of the chemical reaction, but it is extremely important from the view of the physical reaction.



Examples of Isotopes

As an example of isotopes the metal caesium may be considered. This is a soft gray metal, much used in photo-electric cells. It has twelve known isotopes, ranging in value from 133 mass units to 145, inclusive, with no isotopes of mass 134 mass units observed. Of the twelve isotopes of caesium which are now known only one, that of mass 133 mass units, is found in nature. All the others are radioactive and are manufactured in the atomic piles or are a by product of an atomic explosion. These radioactive isotopes decay, or lose their radioactivity, by emitting radiation which is harmful to living matter. Thus, after an atomic explosion radioactive caesium would be scattered in the vicinity and as it decayed it would emit harmful radiations.

The Uranium Isotope

Uranium has seven known isotopes. Three of these occur in nature. These have masses of 234, 235 and 238 mass units. It is the 235 isotope of uranium which has been used in an atomic bomb. We do not know, at this time, how to set off a chain reaction, which leads to an atomic explosion, in the other two isotopes.

Radioactive Isotopes

It has been mentioned that the radioactive isotopes decay by the emission of energetic radiations. Certain naturally occurring radioactive isotopes have been known for many years. Radium is an example that is well-known. Radium decays by the emission of alpha and beta particles and gamma photons. The alpha particle is the nucleus of the helium atom; i. e., it is a particle which consists of two neutrons and two protons. The beta particle is nothing but a high-speed electron. The gamma photons are particles of electromagnetic radiation. That is, they have the same general character as do x-rays, or radio waves. The photon has no electrical charge. The alpha particle, since it is the nucleus of a helium atom, has a double positive charge and the beta particle has a negative charge of one unit. (Figure 8-1). The particles which are of

Alpha Particle	+2
Neutron	

Other Radioactive Substances

The decay of natural radioactive radium has been discussed. There are several known naturally occurring radioactive substances. One of these is actinium. Actinium decays by the emission of an aplha particle. This gives a new isotope, or atom, which has a mass of four units less and a nucleus which has two less unit charges. This is so because the alpha particle, which is emitted from the actinium atom's nucleus has a mass of four units and has two protons. Thus, by this process the actinium atom becomes an atom of protactinium. The electron has a very small mass and, therefore, the new atom has very nearly the same mass as did the parent but it has one more charge in the nucleus. This is so because by the act of discharging an electron the nucleus changed a neutron into a proton.

The decay process continues in this fashion. Alpha particles, or beta particles, are omitted and the parent atom changes, or decays, to become a new, or daughter, atom. At times, gamma photons are also emitted, and, significantly, all of those radiations are harmful to man. Also, it is important to note that this process continues until the initial radioactive atom decays, by a series of such steps, and becomes a stable atom. The actinium atom decays until it becomes an atom of lead (Figure 8-2).

It must be kept in mind that the material which an atomic bomb scatters is also radioactive. This material also decays by the emission of alpha and beta particles and gamma photons to become, eventually, a stable material, but, the radiations emitted in the process are harmful, they may even be deadly if they are present in sufficient quantities. Some of these decay processes go forward rapidly and one would not expect the radiation due to their decay to be present for a long period of time. However, some of them decay slowly and once an atomic bomb has been exploded, on or below the surface in an area, it must be expected that radioactivity will be present for many years. One of the radioactive isotopes of caesium has a half-life of thirty-three years. Thus, if a certain number of these atoms were scattered about in an area only one half of them would decay in the first thirty-three years. Some radioactive materials actually have half-lives of millions of years.

Source of Energy of Emitted Particles

It has been stated that the atomic explosion will scatter many radioactive atoms about and that these atoms will decay by the emission of harmful radiations. However, nothing has been said as to the source of the energy of these emitted particles. It comes from the nucleus. The nucleus loses some of its mass in the process and gains energy. This means that a new concept must be accepted. This is, "mass and energy are equivalent." This means that mass may be converted into energy. Thus, the nucleus decays and in so doing changes a small amount of its mass into energy and the energy is carried off by the radiation.

This concept of the equivalence of mass and energy is actually not new at all. It comes out of Einstein's relativity theory and was

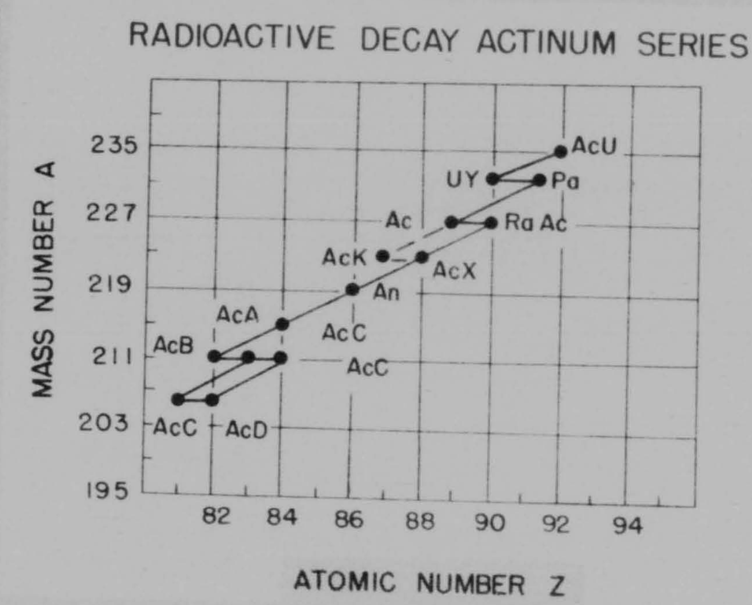

Figure 8—2. Fission, Followed by Decay of Radioactive Isotopes.

stated by him in 1905. His statement is, $E=mc^2$. This short equation merely states that if m grams of matter are converted into energy they give mc^2 ergs of energy. However c is the velocity of light and is equal to $3x10^{10}$ centimeters per second and therefore c^2 is equal to $9x10^{20}$. Thus, the conversion of a very small amount of mass releases a great deal of energy. Assume that in an atomic explosion only one gram of matter is converted into energy. Also, assume that the explosion takes place in one-millionth of a second. Then during that short time, $1x10^{17}$ horse power are developed. This is considerable power on any scale of values.

The notation commonly used to designate these isotopes should be mentioned. Consider the expression $_2He^4$. This is the designation of the helium atom, or isotope. The He stands for helium. The subscript $_2$ refers to the nuclear charge, or the number of protons in the nucleus. The superscript 4 refers to the mass which is four units in this case. Thus, the three isotopes of uranium, which occur in nature, are written as $_{92}U^{234}$, $_{92}U^{235}$ and $_{92}U^{238}$. Note that these are all uranium, that is they have similar chemical properties and the same number of protons in the nucleus, but they have different masses, and while their chemical properties and the same number of protons in the nucleus, but they have different masses, and while their chemical properties are exactly similar their physical properties are quite different. This is shown by the fact that only the U^{235} can be made to fission by chain reaction methods.

Fission

The term "fission" has been mentioned several times. This term is used to describe the process by which an atom of uranium-235 or plutonium divides into two or more parts having a total weight somewhat below that of the parent substance with the release of energy equivalent to the weight of matter which has disappeared. It is the process which is used in the bomb and which may some day yield a new source of power. The heavy uranium, or plutonium, atom undergoes fission, or splits, into two new atoms which are much lighter and which are atoms of other materials. About 200 million electron volts of energy is given up for each atom which undergoes fission. This energy comes, again, from mass. The mass of the original atom is greater than the sum of the masses of the two atoms which are left after the fission process.

The fission reaction is caused by a neutron. That is, a neutron enters the nucleus of a uranium atom and the atom blows up. This reaction does not always occur in the same way, that is, the uranium nucleus can split in a number of ways, it does not split into the same two atoms each time. Some two hundred different isotopes have been identified as being formed by this fission process, but, for the purposes of this class, all that need be remembered is that the process is started by a neutron, it yields a great amount of energy and the two atoms which are left, after the splitting, are almost always radioactive and decay to stable substances by the emission of harmful radiations. At the instant of the fission the atom also throws out two or three additional neutrons, some gamma photons and beta particles.

Therefore, since the fission reaction is produced by a neutron and since the reaction throws out neutrons, if one atom can be made to fission it might in turn set off one or more atoms and thus the process should grow. It actually grows to explosive proportions within a fraction of a millionth of a second. This is the manner in which an atomic explosion takes place. (Figure 8-3).

When the atomic bomb is detonated a great

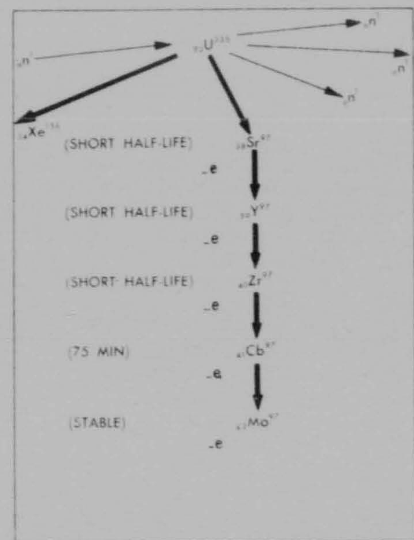

Figure 8—3. Comparison of HE and Atomic Explosions.

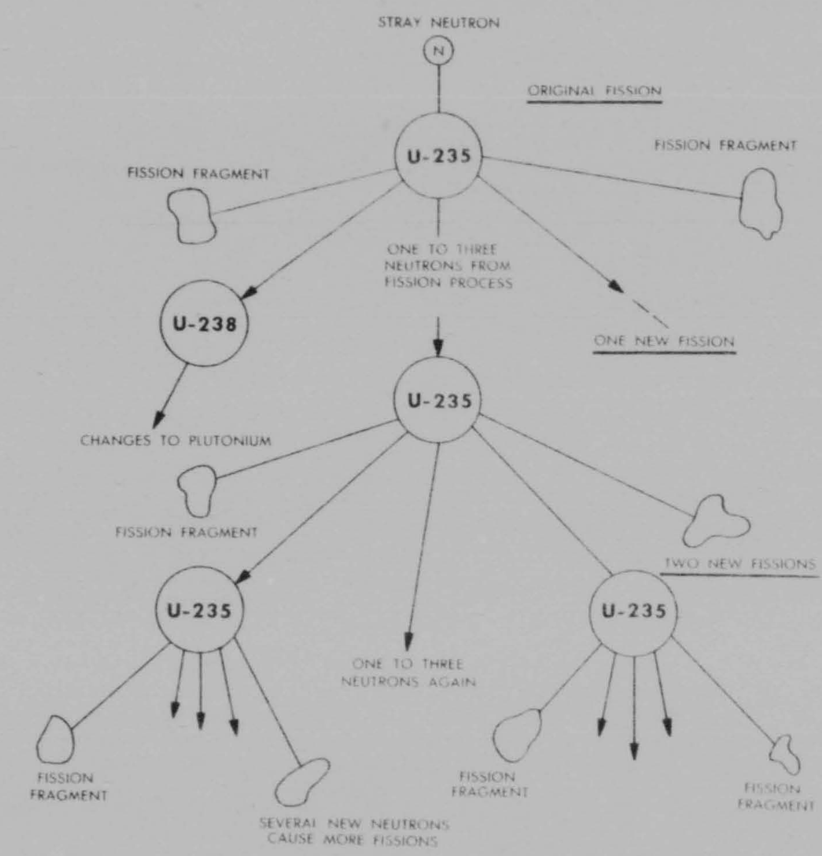
amount of energy is released within a very short period of time. This energy produces high temperatures and a great shock wave, but it does more than this. It produces intense infra-red and ultra-violet radiation; it produces a heavy flux of neutrons which can be deadly to the individual who is too close to the explosion; it produces great amounts of gamma radiation which can be deadly for individuals even though they are indoors and some distance removed from the explosion, but all of this is only a part of the story. The explosion scatters radioactive materials over wide areas. These materials decay and this decay process yields radiation which is also harmful. It is seen that the atomic bomb has many characteristics of the TNT bomb but it also has hazards far beyond anything produced by the TNT explosion.

SECTION III—ATOMIC EXPLOSION PHENOMENA



A DIAGRAM OF CHAIN REACTION IN U-235 (FAST FISSION)

Figure 8—9. The 263-Portable Beta and Gamma Geiger-Mueller Counter.

1. CHARACTERISTICS

The characteristics of the HE explosion are well known. The TNT explosion is a chemical reaction. A chain reaction, which proceeds with great velocity, is set up in the body of the explosive. This reaction converts a small volume of solid material into great quantities of heated gases. Due to the temperature and the pressure of the generated gas, a shock wave is set up in the air, for the air burst, or in the ground and the air if the explosion takes place in contact with the earth. The energy expended in this manner is quite large, per unit mass of the explosive, but it is trivial compared with the energy

THIS PAGE IS DECLASSIFIED IAW EO 13526

developed by the fission of the same amount of uranium or plutonium.

The shock wave which is set up in the air by an explosion, whether it be due to TNT or to an atomic explosion, moves outward from the center of the explosion with a velocity which is generally greater than the speed of sound. This wave is a compression wave in the air. The normal air pressure is about fifteen pounds per square inch. In the shock wave there are two conditions. There is a region in which the air pressure is greater, by several pounds per square inch, than the normal pressure. There is a second region in which the pressure is lower, by a pound or so, than the normal. These two regions constitute the shock wave. The greater the intensity of the explosion the greater the increase in the positive part of the pressure pulse and the less the pressure in the negative pulse. Also, the greater the intensity of the explosion the greater the velocity with which the shock wave moves outward from the point of the explosion. (Figure 8-4.)

Shock Waves

Assume that instruments for the measure of air pressure are set up at some distance from the point at which several pounds of TNT are to be exploded. The explosion develops the shock wave which moves outward and crosses the position of the recording instruments. The instruments will record an increase in pressure which is followed immediately by a decrease in pressure. It is this shock wave which blows out windows and often causes the collapse of structures. The positive phase of the shock wave lasts for about one-millionth of a second and this is followed by the negative pulse which lasts for about three-millionths of a second. Thus, the shock wave, for the TNT explosion, comes as a sharp blow, or pulse of pressure increase followed by a decrease in pressure. As the shock wave travels outward its intensity constantly falls off and the velocity with which it moves also decreases.

The atomic explosion also produces a shock wave which has the same general characteristics as does the TNT wave. Since the atomic explosion is more intense it would be expected

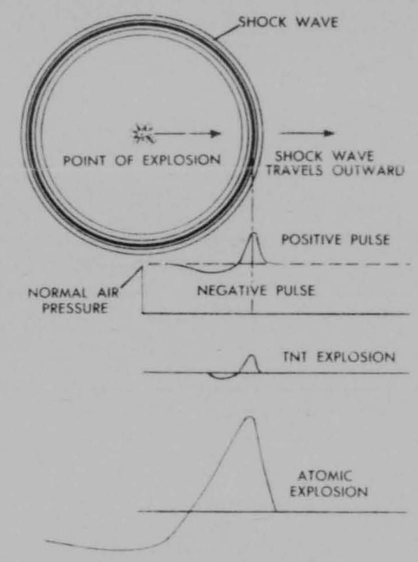


Figure 8–4. Model 247A–Dec. 1947.

that the shock wave, which accompanies it, should show a higher pressure in the positive pulse and a lower pressure in the negative pulse. Also the shock wave should travel at a higher rate of speed for the atomic explosion. This is exactly what is observed. The positive pulse may show increases in pressure which are several times the increase for the TNT explosion. The duration of the pulse may be as great as one-tenth of a second. This is 100,000 times the duration of the pulse due to a TNT explosion. It is to be noticed that if the positive pulse increases the normal air pressure, by, for example, five pounds per square inch, the shock wave can be very destructive. There are 144 square inches to the square foot and if a positive pulse of this amount impinged upon the wall of a building it would mean that each square foot of surface of the building, on the side facing the explosion, would be subjected to a force of 144 x 5—720 pounds. Further, this pressure would persist for about one-tenth of a second. Assume that a small building, eight feet high and ten feet long stands facing the point at which an atomic explosion takes place. The

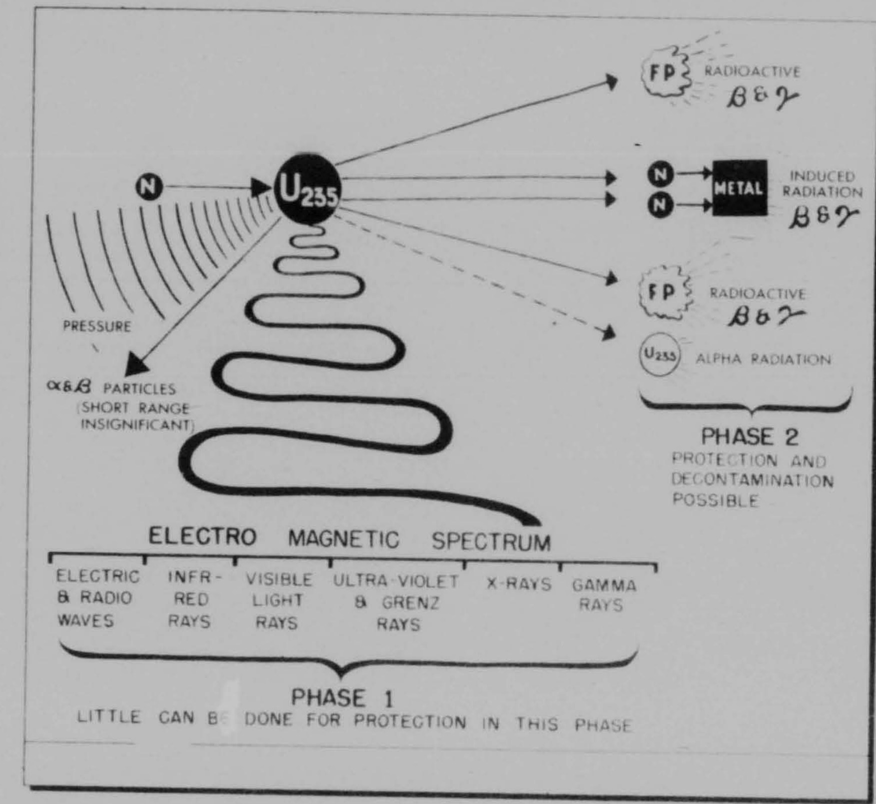

Figure 8–5. The 263–A Portable Beta and Gamma Geiger-Mueller Counter.

total force against this side of the building, due to the shock wave, would be (8 x 10) x 720 or about 29 tons. It is easy to see why most buildings will not withstand the shock wave due to an atomic explosion if they are located near the point of the blast. Thus, at Hiroshima, multistoried brick buildings were severely damaged if they were within a radius of one mile from the point of the explosion. Even modern reinforced concrete buildings were severely damaged if they were within a radius of two thousand feet from the point of the explosion.

To this point nothing new has been mentioned concerning the effects of atomic explosions. That is, the shock wave developes for this type of explosion about as it does for the TNT explosion. It is true that the shock wave is more intense; that is, the positive pulse rises to a greater value and it lasts for a much longer period of time. The shock wave of the atomic bomb is therefore much more destructive. But the mechanism by which the shock wave is developed is the same as for the TNT explosion.

Radiation Effects

As has been mentioned earlier, the atomic explosion is accompanied by radiation effects which are entirely missing from the

THIS PAGE IS DECLASSIFIED IAW EO 13526

TNT explosion. The effects of these radiations can be very serious and they will be discussed here. The radiation effects can be divided into two parts. The first group consists of those radiations which accompany the actual explosion of the bomb, the second group is comprised of those which linger, or persist, after the explosion. The radiation which accompanies the explosion can be classified as follows: (Figure 8-5.)

Electromagnetic radiation
Neutron flux
Beta particle radiation
Alpha radiation

The electromagnetic radiation can further be subdivided into ultra-violet, infra-red and gamma radiation. The ultra-violet is the same ultra-violet radiation which is found in sunlight. It has the same effect upon the skin; that is, it produces a sunburn. This burn can be severe enough to kill. Any lightweight shielding material is sufficient to protect against the ultra-violet radiation.

The infra-red radiation is heat radiation. That is, it is the infra-red portion of the sun's spectrum which transmits most of the heat. This radiation is very intense in an atomic explosion. It can set fires at considerable distances. It will produce flash burns on exposed skin tissue at considerable distances from the explosion. However, shielding will give considerable protection against it. Also, it was found at Hiroshima that individuals who were exposed to the infra-red and who were wearing light-colored clothing escaped flash burns while those who wore dark clothing received severe burns. It was also noticed that loosely fitted clothing gave more protection than did tight clothing.

The gamma radiation has the same general characteristics as does x-ray radiation. However, it is more energetic and it will penetrate greater thicknesses of shielding materials. It was estimated that, at the instant of the Able explosion at Bikini, the gamma radiation was equivalent to that of several hundred tons of radium. Since all of the world supply of radium is measured in pounds this is truly an astronomical figure. Lightweight shielding affords no protection. Gamma radiation is not completely stopped by any amount of shielding. All that the shielding does is to reduce the intensity of the radiation. Thus if the shielding is heavy enough and the source of the radiation is not too intense the individual does not receive enough radiation to cause serious effects. It was estimated that, at Hiroshima, twenty-four inches of concrete would have been sufficient to protect an individual at a distance of one mile from the explosion. For nearer points, the thickness of concrete would have to be greater. Five inches of compact clay will reduce the intensity of the gamma radiation by about one-half, but the intensity is so great that the intensity must be reduced by nearly 100 per cent if the individual is to escape injury. It is to be noticed that if five inches of clay reduces the intensity by 50 per cent, then ten inches will reduce the intensity by 75 per cent and fifteen inches will reduce the intensity by 87.5 per cent. In general the heavier materials are the more efficient in reducing the intensity of gamma radiation. Thus, less thickness of lead shielding would be required than would be the case for paper or wood. The walls of a house, of wooden construction, would afford excellent protection against the ultra-violet and infra-red radiation and almost none against the gamma radiation.

The neutron has been mentioned in an earlier lecture. It was also mentioned that the neutron causes the fission of uranium and plutonium and that neutrons are ejected from nuclei when they undergo fission. These fission neutrons are high energy neutrons and they can penetrate great thicknesses of matter. Thus, at Bikini, neutrons penetrated the steel bulkheads of ships and induced radioactivity in table salt and soap chips in the galleys. The neutron itself can cause harmful effects in the human body, but it also acts in another way. It can induce radioactivity in many substances. Thus at Bikini, and especially in the Baker test, the neutrons from the explosion caused the formation of a radioactive salt from the normal salt in the sea water. This radioactive salt then decayed, and in the process, emitted a great deal of gamma radiation. Thus, the neutron flux, which was generated at the instant of the explosion, gave rise to a lingering type of radioactivity.

Beta particles are emitted at the instant of the explosion, but they are not a serious

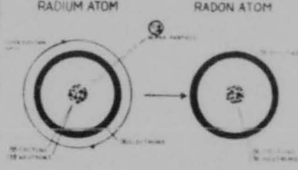

Figure 6-5.—Decay of radium to radon

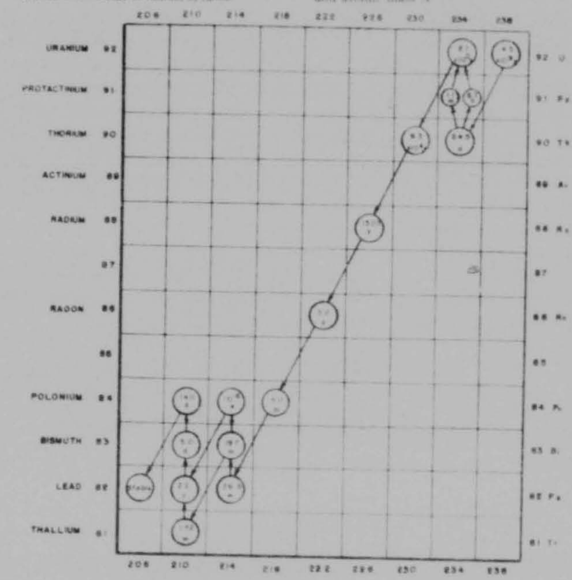
$$_{88}Ra^{226} \longrightarrow {}_{86}Rn^{222} + {}_{2}He^{4} + Q \qquad (7)$$

Just as in chemical equations, there has to be some type of a balance made on both sides of the equation. It will be noted that the superscripts representing the atomic masses add up to the same total on each side of the equation, as do the subscripts which represent the atomic numbers of the isotopes. In fact the equation for natural α-emission can be written in a more general form which applies to any element of atomic number Z and atomic mass A.



RADIOLOGICAL SAFETY

threat. The beta particle is a charged particle and will, therefore, have a short range in air. The energetic beta particles from an atomic explosion will have ranges of only about ten meters in air. Thus, while they are harmful, their range is so short that they need not be seriously considered.

Alpha particles also arise in the explosion. They are heavy compared with the beta particle, therefore their ranges are measured in centimeters. If an alpha emitter becomes lodged in the body it can be a very serious hazard, but it is not serious as long as it is external to the body.

This concludes the list of harmful radiations which arise at the instant of the explosion. They are, gamma radiation, ultra-violet and infra-red radiations, neutrons flux, beta particle radiation.

The radiation which arises at the instant of the explosion is not the only harmful radiation. There are types of radiations which persists after the explosion. This radiation arises from three sources. These are:

Unfissioned bomb material.

Fission produces of the bomb material.

Radioactivity induced in the materials of the land or sea.

Unfissioned Material

All of the material of a bomb does not undergo fission. This unfissioned material, either uranium-235 or plutonium, is reduced to a powder and scattered by the explosion. This material is an alpha particle emitter. It is not much of a hazard, due to the short range of alpha particles in air, unless it is taken into the body through the mouth or through open cuts. It then becomes a really dangerous hazard. This effect will be discussed later in this volume.

A part of the bomb material undergoes fission. It has been pointed out that, in the fission process, the atoms of uranium or plutonium break up to form lighter atoms and that these newly-formed atoms are radioactive. They decay by the emission of beta particles and gamma radiation. The beta particles are not a particularly dangerous hazard since they, like, the alpha particles, do not have a great range in air. The gamma radiation however is very dangerous. The gamma radiation from these radioactive atoms can be dangerous up to a thousand or so yards and since the fission products will also be widely scattered by the explosion the gamma radiation may be dangerous over a large area after an explosion.

The hazard due to induced radioactivity can be great in some types of explosions. This hazard is produced by the neutrons which are released at the instant of the explosion. These neutrons enter the nuclei of some atoms and cause a physical reaction which leaves a radioactive atom as a product. Not much is known about the induced radioactivity for the atomic explosion over land. However, the Bikini test showed that for underwater bursts great amounts of radioactivity are induced. This is due to the fact that the salt in the sea takes up neutrons to form a radioactive form of salt. This radioactive salt decays by emitting gamma and beta radiation and becomes magnesium. Considerable gamma radiation, due to this reaction, was present after the Baker test at Bikini.

SECTION IV—BIOLOGICAL EFFECTS OF BLAST AND RADIATIONS

1. CHARACTERISTICS

The primary and secondary radiations produced by an atomic explosion have been discussed previously. The radiations are conveniently divided into two classes. The first class consists of those radiations which arise at the instant of the explosion. They may be further broken down into two types. These are the electromagnetic and particle radiations. The complete list of these is as follows:

ELECTROMAGNETIC RADIATION
- Visible light
- Ultra-violet light
- Infra-red light
- Gamma radiation

PARTICLE RADIATION
- Alpha particles
- Beta particles
- Neutrons

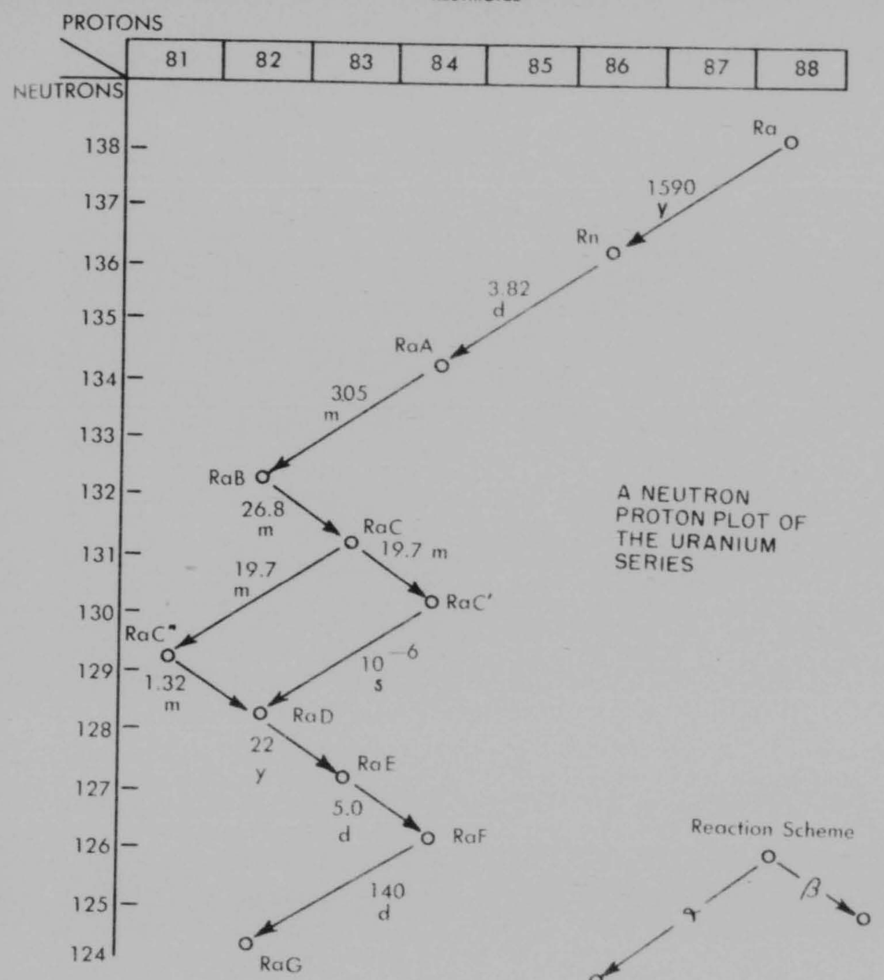
In addition to these radiations the explosion sets up a shock wave which is very destructive. This effect is generally referred to as the "blast effect." The effect of all af these radiations and of the blast effects will be briefly considered.

Primary and Secondary Casualties

The casualties produced by an explosion are often classified as being due to primary or secondary explosion effects. Thus casualties produced by the gamma radiation or directly by the shock wave would be primarily casualties while those produced by flying debris, falling buildings or fires would be secondary casualties.

Hazards

The hazards, to individuals, due to the



atomic explosion are as follows:

Visible Light. The temperature of the ball of fire which is developed at the time of the explosion is very high. Therefore, it is very bright. This brightness produces flash blindness, which, however, is temporary. No cases of permanent eye injury have been reported.

Ultra-violet. It has been mentioned that the bomb produces ultra-violet light and that this is the same type of ultra-violet that is found in sunlight. In general, the shorter the wave length of the ultra-violet light the more harmful it is to the human body. Fortunately, the most harmful portion of the sun's ultraviolet radiation is filtered out by the earth's atmosphere and does not reach the surface of the earth. This is not true for the atomic explosion. This type of radiation will, therefore, produce burns much like those produced by

rate at which it is produced but also of the rate at which it decays. In considering this case, the problem is relatively simple, since the decay rate of radium is so slow that the number of radium atoms present at any time can be considered constant. Let

N_1 = the number of ra... t

N_2 = the number of radon atoms present at time t

Then

$\lambda_1 N_1$ = the number of radon atoms formed per second by decay,

where

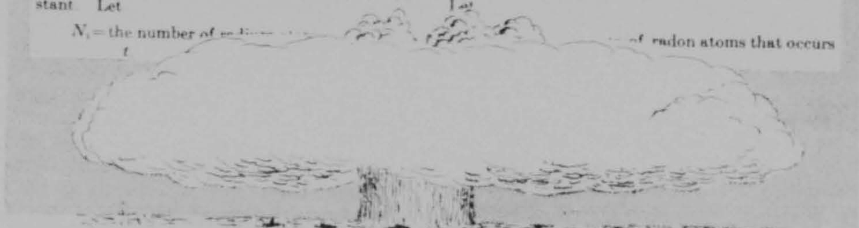
λ_1 = decay constant of radium.

Then

$\lambda_2 N_2$ = the number of radon atoms decaying per second.

Let

... of radon atoms that occurs



too long exposure to strong sunlight. It is to be noted that any light material will give adequate protection against the ultra-violet light. Thus, even the protection afforded by a suit of light colored clothing saved many of the Hiroshima citizens. The walls of the ordinary home were ample protection against the ultra-violet radiation.

Infrared: The infrared radiation carries off, by radiation, most of the heat developed by the bomb. It has been estimated that from 20 to 30 per cent of the Hiroshima casualties were due to flash burns and it must be assumed that the infrared radiation was most efficient in producing these burns. It has been estimated that the skin of many of the casualties was heated to a temperature as high as 2,000°C even though the individaual may have been as much as 2,000 feet from the blast. Clothing was set afire even though the wearer was as much as 6,000 feet from the point of detonation of the bomb. Telegraph poles were scorched up to distances of 10,000 feet.

However, the infrared, like the ultra-violet, has no penetrating power and any lightweight shielding gives protection. The reflections should be of some light color since a light color reflects most of the heat energy and does not absorb it. Thus, individuals who were dressed in light-colored clothing often escaped flash burns while others, close by, who were dresed in dark clothing received severe burns. The most protection was offered by clothing which was light in color, which fitted loosely and which consisted of several layers.

Gamma Radiation. The gamma radiation which is released at the instant of the explosion is very penetrating and is, therefore, very difficult to shield against. It is estimated that, for the Hiroshima explosion, from 15 to 20 per cent of the casualties were due to this type of radiation. The walls of the average building afford almost no protection. The clinical effects of exposure to either x-rays or gamma radiation are described by the general term of "radiation sickness." Some of the manifestations of radiation sickness are:

a) Loss of hair. Incidence of this type of injury was 75 per cent at 500 yards from the explosion. The loss appears about two weeks after the explosion. This loss does not appear to be permanent.

b) Mouth and gastro-intestinal tract. Nausea and vomiting shortly after exposure is followed by lesions of the mucous membranes of the mouth due to the radiation. A bloody diarrhea appears within a few days of the explosion.

c) Effects upon the reproductive organs. In the male, radiation produces sterility. In many cases this is temporary but it must be assumed that exposure to high intensity radiation will probably produce sterility for a long period of time. No complete report of the production of sterility in males exposed to the Hiroshima or Nagasaki blasts has been made up to this time (early 1948). To date there is no record of permanent sterility.

The female reproductive organs appear to be more easily injured than the male. It was noted that, at Hiroshima, miscarriages seemed to be more frequent after the explosion. There are no data on the frequency of premature births after the explosion.

d) Effects upon the blood forming system. Gamma radiation can easily penetrate the body and reach the bone marrow. The blood forming organs are susceptible and may be injured. This leads to leukemia or a white blood cell deficiency. This makes the individual susceptible to infection. The injury to the blood-forming organs also leads to anemia or deficiency of red blood cells. Anemia produces loss of skin color and a general weakness. Gamma radiation, by means of the injury to the blood-forming organs, also produces a tendency towards bleeding. This is due to deficiency of platelets in the blood stream. Thus, severe hemorrhages occur even though the injury may be minor. Hemorrhages may occur spontaneously.

It is to be noticed that the effects upon the blood-forming system can be serious secondary effects. The individual who has been injured by the blast, or by secondary blast effects such as flying debris, may later die due to secondary infection. The general treatment which is indicated, for radiation sickness, is: scrupulous sterile techniques, transfusions, use of penicillin, leukocytic cream and folic

THIS PAGE IS DECLASSIFIED IAW EO 13526

acid A, careful study and nursing care. It should be mentioned, in passing that the victims of the Hiroshima bombing did not receive such care and that proper care would have materially reduced the deaths due to exposure to gamma radiation.

e) Alpha Particles. The alpha particles which arise in the explosion have fairly high energies. However the alpha particle has a short range, a few centimeters, in air and does not constitute an external hazard. That is, if an alpha particle emitter enters the body it will probably reach the bone marrow. Thus the emitted alpha particles, even though their range is short, can injure the blood forming organs. The substances which emit alpha particles behave, therefore, much like radium. All of the material of the bomb does not undergo fission. The unfissioned material is pulverized by the blast and scattered over a large area. Personnel in an area contaminated with these materials must not smoke, eat or drink. Every precaution against stirring up clouds of dust must be observed.

f) Beta Particles. The range of the energetic beta particle is measured in a few meters. Therefore, the beta particles which arise in the explosion do not constitute much of a hazard. No beta particle radiation is particularly dangerous as an external hazard. However, the fission products (that is the material which undergoes fission) are beta emitters and they, like the unfissioned material, are widely scattered by the explosion and they constitute a real internal hazard. The means of protecting the individual against the internal hazards of beta particles are the same as those mentioned for protection against the internal alpha particle hazard.

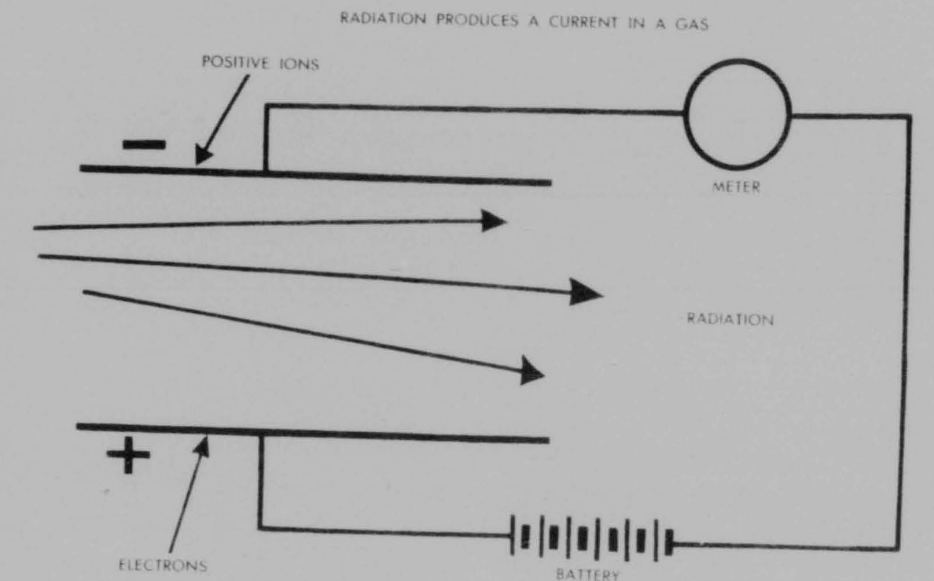
g) Neutrons. The neutron, like the beta and alpha particles, is a heavy particle. Unlike the alpha and beta particle the neutron has considerable range in air and in dense materials. It has been mentioned that the neutrons which were generated in the Able explosion at Bikini penetrated the hulls of ships in the lagoon. The effects of the neutron upon the human system are not well-known. However, it appears that fewer neutrons can produce more hazardous effects than would be the case for gamma photons. The neutron owes its power to penetrate considerable thicknesses of materials to the fact that it has no electrical charge. Thus, low energy neutrons can penetrate the body and even though they are low energy particles they can produce harmful effects. They do this by destroying the reproductive cells.

There is another way in which the neutron produces harmful effects. The neutron reacts with many substances. The products of such reactions are almost always radioactive and decay by the emission of beta particles and gamma radiation. Thus, at Bikini, the underwater burst gave large amounts of radioactive salt. This salt was produced by the reaction of the neutrons which were set free at the instant of the explosion with the normal salt of the sea water. It is not known how efficient the neutrons would be in producing radioactivity in the materials of the land when the bomb is detonated under the surface or close to the surface.

The effects described to this point are radiation effects. This does not mean that the blast effects were not important. In both the Hiroshima and Nagasaki explosions, more than half of the casualties were produced by the blast effects, primary and secondary.

The casualties due to primary blast effects were few. That is, even though the shock wave was tremendously destructive of buildings, it directly caused but few casualties. Most of the casualties, due to blast effects, were secondary in nature. Individuals were injured by falling buildings, flying debris and fires which were caused by the collapse of buildings and from heat radiations which started fires in easily combustible substances within a mile of the explosion center.

SECTION V—RADIATION DETECTION INSTRUMENT



1. DESCRIPTION AND OPERATION

Radiation is measured in various units, only one of which will be mentioned here. This unit is the roentgen. It is defined in terms of certain physical constants and the exact definition will not be given. All that need be known here is that the medico-legal standard, in this country, prescribes that more than one-tenth roentgen per day constitutes a radiation hazard. There is no time element in this definition. That is, the one-tenth roentgen may be received in one hour or twenty-four hours. It is assumed that there is no hazard as long as no more than one-tenth roentgen of radiation is received by the individual within any twenty-four hour period.

Principles of Operation

Radiation detecting instruments, at the present time, are based upon two principles. The first is the fact that harmful radiation will ionize gases. The second type of detecting device is based upon the fact that gamma, alpha and beta radiations will all cause a blackening of a film. The first type of instrument will be discussed in some detail and the second type, since the underlying principle is rather widely known, only briefly.

A neutral gas shows no electrical charge. That is, the gas in a room is made up of countless numbers of molecules of oxygen, nitrogen and some other molecules. Almost all of these molecules are usually neutral. However, in the presence of radiation the molecules become charged and if an electric field is applied to a body of the gas, a current will flow. Such currents are known as ionization currents and are weak.

Radiation ionizes a gas by tearing away one or more of the orbital electrons from the gas atoms, or molecules. This leaves a free electron and a positively charged molecule.

THIS PAGE IS DECLASSIFIED IAW EO 13526

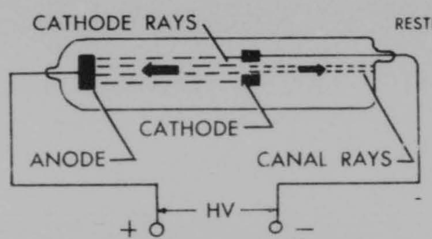


Figure 8–6. Canal Rays Passing Through a Hole in the Cathode of a Cathode Ray Tube.

The charged molecule is generally referred to as an ion. In the presence of an electric field the ions move to the negatively-charged pole and the electrons to the pole with the positive charge. Thus, the presence of radiation can be detected by the very weak current which flows through the battery which supplies the potential to the charged poles, or plates. These currents are so weak that elaborate electronic amplifying devices must be used. However, in this brief discussion the amplifiers will be ignored and it will be assumed that meters of infinite sensitivity are available. (Figure 8-6).

Types of Instruments

There are two commonly used portable types of detecting instruments which depend upon the ionization of a gas by the radiation. These are the ionization chamber instrument and the Geiger-Mueller (or G-M) type instruments. The ionization chamber instrument is commonly referred to as the 247-type radiation detector while the G-M detector is referred to as the 263-type instrument.

The ionization chamber consists of a chamber about three inches long and two inches in diameter which is fitted with a probe which extends down the center of the chamber. The probe is insulated from the chamber and carries a positive potential of 100 volts or so. When radiation enters the chamber, ions are formed and move to the probe and the chamber wall. This causes a current to flow in the external, or battery circuit, and the amount of current is a measure of the intensity of the ionization. (Figure 8-7).

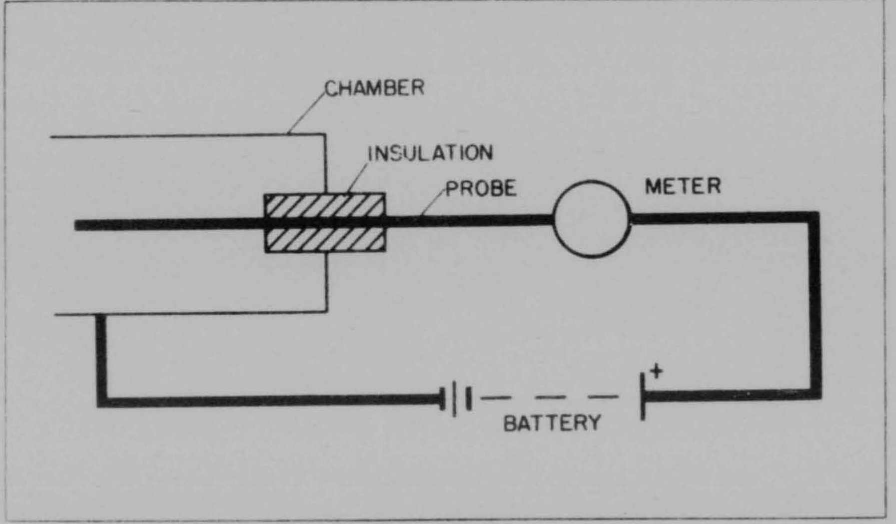

Figure 8–7. Ionization Chamber.

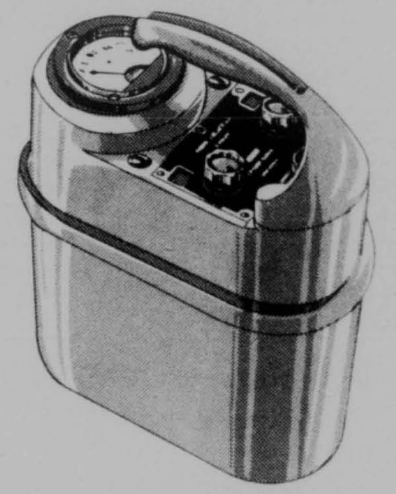

Figure 8–8. The 247 Meter.

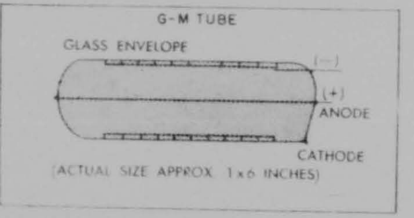
The ionization chamber, of the type used in field work, is rugged and will measure high intensities of radiation. However, it has certain disadvantages. The 247 meter is heavy but it will not measure low intensities of radiation; that is, it has low sensitivity. Other meters are light but still have the same low sensitivity. (Figure 8-8).

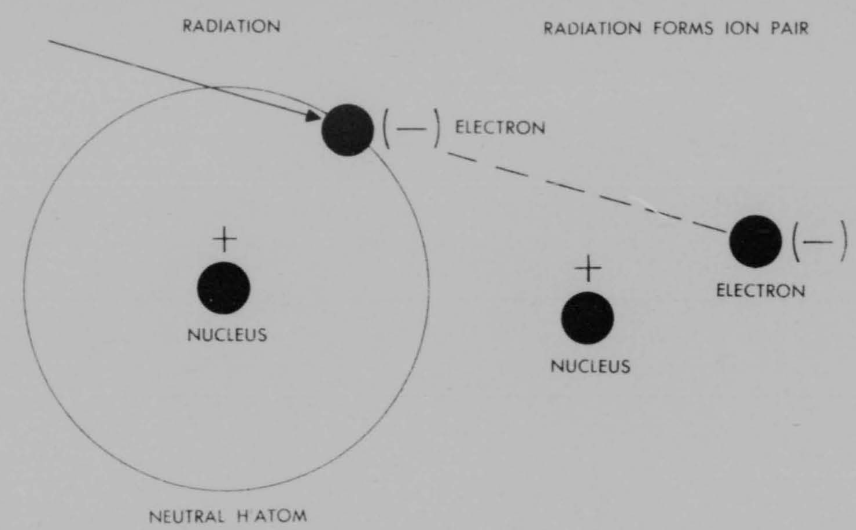
The G-M type instrument uses a G-M tube as a detector. This tube is normally constructed of glass. It is about six inches long and one inch in diameter. The glass tube is carefully cleaned of air and then filled, to a pressure of about one-fifth atmospheric, with argon, neon or helium. The gas is deliberately contaminated with a trace of other gas and also with a trace of a heavy organic vapor such as the vapor of one of the alcohols. Inside the glass tube a very lightweight cylinder of metal is fitted against the tube wall. This constitutes the cathode. A wire of very small diameter runs the length of the tube. This wire is so connected to the battery that it carries a positive charge. Thus it constitutes the anode. Radiation, which penetrates the



tube, forms free electrons and ions and these migrate to the anode and cathode respectively. The G-M tube, in the field-type instrument, will not detect alpha particles since the alpha particle does not have sufficient energy to penetrate the glass wall of the tube. (Figure 8-7).

To this point in the discussion it appears that the G-M detector behaves much like the ionization chamber. However, there are great differences. In the ionization chamber there is no gas amplification. That is, the electrons and ions which are formed by the radiation, are collected in the chamber. In the G-M tube, due to lower gas pressure and high applied potentials, there is gas amplification. This means that in the G-M type tube the electrons, which are formed by the original radiation, succeed in forming more electrons. Thus, in a good G-M tube a single electron which might be knocked from an orbit of an atom, may be amplified by the gas and a million electrons might be collected at the anode. It is obvious that the greater the amplification in the body of the gas, the less amplification that will be necessary in the auxiliary electronic amplifier.

Since the G-M detector requires less auxiliary amplification, the 263A type instrument is lighter than the 247 type. Also, the 263 instrument will measure much weaker radiation intensities that can be detected by the 247. However, the 263 instrument has certain disadvantages. It will not measure high intensities of radiation. The G-M tubes wear out rather rapidly. This is due to the loss of the organic vapor in the tube. Also, in order that they may detect low energy beta particles, the G-M tubes are constructed with a very thin glass window and are therefore easily broken. (Figure 8-9).



Neither of these detection instruments is satisfactory for field use. This was amply demonstrated in the Bikini tests. They are too delicate, their battery requirements are too high and they are far too costly. A great deal of work is now being done on instruments which operate upon different principles and it is quite likely, that within a year or two, instruments will be designed which are much more satisfactory for field use by military personnel.

Both the 263- and 247-type instruments measure the radiation intensity at a point and at an instant of time. Neither will furnish any indication of the **total** amount of radiation to which an individual has been exposed **during** a period of time. It is often necessary to know this. Thus, if an individual were to board one of the radioactive ships after Bikini he would want to know how much radiation he had been exposed to during his stay aboard. If the total amount exceeds one-tenth roentgen, for one day, he has received too much. If the excess were not too large he would be kept out of radiation for a day or so and then allowed to reenter the hot zone. If the excess were quite large he would be placed in a hospital for observation and if necessary, treatment.

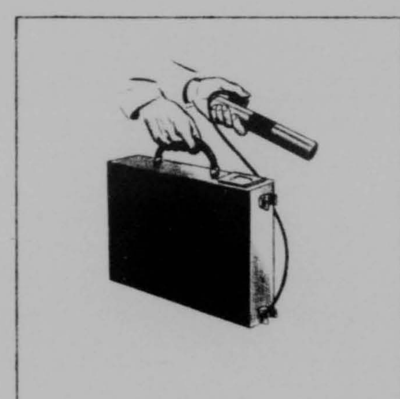


Figure 8—9. The 263-Portable Beta and Gamma Geiger-Mueller Counter.

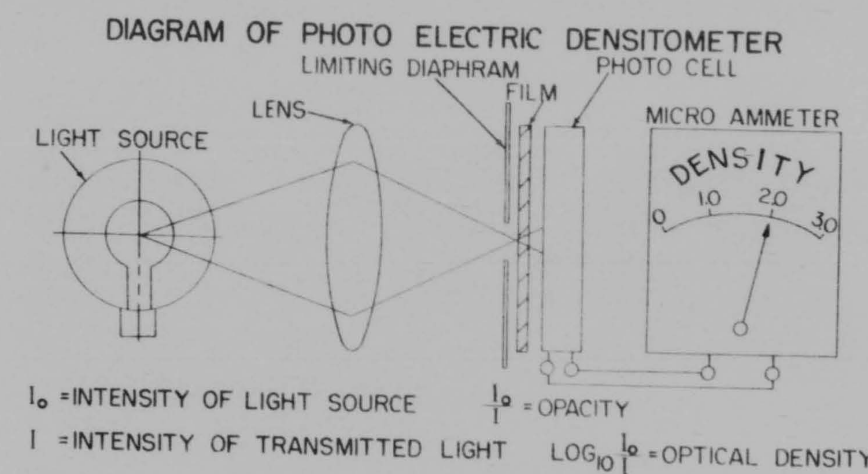
2. TOTAL-RADIATION MEASURING INSTRUMENTS

There are instruments which will measure the total radiation during a period of time. This is commonly referred to as the dose or dosage and the instruments which measure it



are known as "dosimeters" or dose measuring instruments.

Dosimeter

A common type of dosimeter is made up in the form of an oversized fountain pen. It consists of a metal cylinder which supports a wire probe. The probe runs the length of the cylinder and is supported upon electrical insulators. Thus, the outer cylinder is the case and supports the wire probe and its insulators.

This dosimeter is used in conjunction with another instrument which is called a "minometer." At the beginning of a period the dosimeter is inserted in the minometer and a positive charge is placed upon the central probe of the dosimeter. Then, as radiation passes through the cylinder the electrons formed travel to the probe and neutralize the charge. Thus the amount of charge which is neutralized, in any period, is a measure of the total amount of radiation which passed through the dosimeter during the period from the time it was charged until the remaining charge was measured. The remaining charge is determined by again inserting the dosimeter in the minometer and reading the deflection of an instrument which is built into the minometer (Figures 8-10A, B, C).

A dosimeter is now being used for those devices which are direct reading. Charging boxes used with these so-called "minometers" are used to charge and read pocket chambers.

The dosimeter, therefore, gives an indication of the radiation dose which an individual receives during any period of time. It's small and may be carried in the pocket as a fountain pen is carried. They have been used by work-

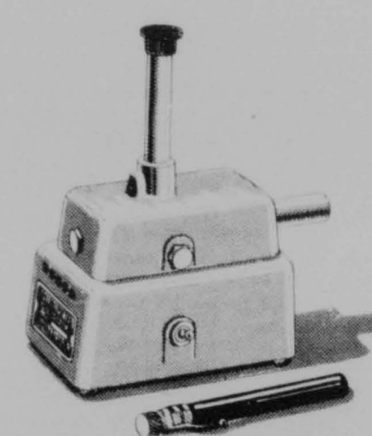


Figure 8—10 A- Minometer.

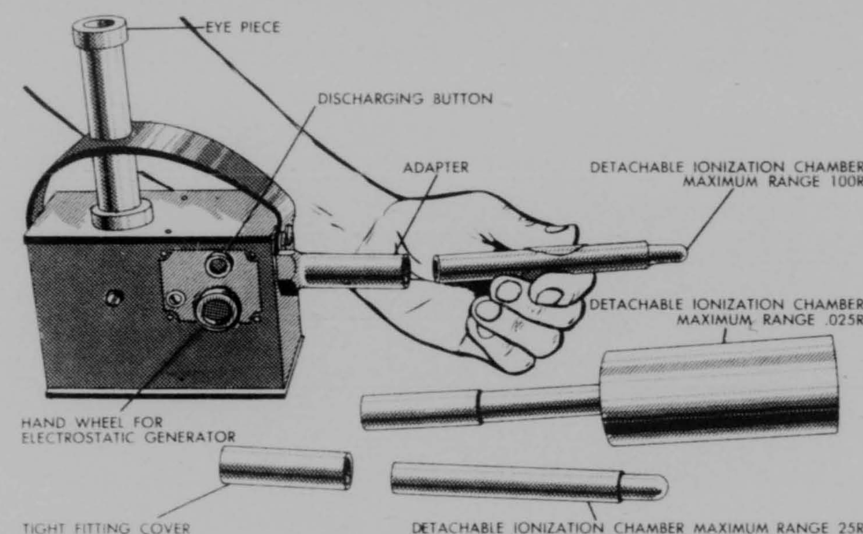

Figure 8–10B. Condenser r Meter,

ers in cyclotron laboratories and x-ray laboratories for years. The instrument does, however, have some disadvantages. It is difficult, due to the rather small size of the insulators, to prevent leakage of charge in damp climates. Also, if the instrument is dropped it may discharge itself.

Film Badge

There is one more dosage-measuring device. This is the film badge. It is the lightest and cheapest of all. It is, at least in theory, simplicity itself. Ordinary dental x-ray film is used. The film is partially covered with a piece of thin lead sheeting. It is carried in the pocket for a time and then developed. The amount of blackening of the film is a measure of amount of radiation to which the wearer was exposed during the time he carried the badge. It is obvious that this device measures the total radiation.

As has been noted, this device is light in weight and cheap. It has another great advantage. In itself, it constitutes a permanent record of the amount of radiation to which the wearer was exposed during the time he wore the badge. Further, this record has been admitted in evidence in the courts. However, the film badge does have some disadvantages. The technique used in developing the film is critical and if not followed precisely errors can be introduced. Also, the film manufacturers have not succeeded in standardizing their film and each lot of film must be calibrated before it is used. Even so, the film badge appears to be the only instrument which is now available for large numbers of individuals. The films were widely used at Bikini and Sandstone.

Calibration of Radiation Instruments

All of the devices mentioned must be calibrated. This is not a difficult process. The instrument is placed a known distance away from a small sample of radium. About one milligram is sufficient for the Geiger-Mueller but not for the ionization chambers. The reading of the instrument, at the point, is then taken. The instrument is then moved to a new location which is nearer, or further, from the sample and process is repeated. In this fashion a series of readings is taken. It is known that the intensity near the radium sample is given

by $(8.4 \times M)r^{2}$, where M is the mass of the radium sample in milligrams and r is the distance of the instrument measured in centimeters. This formula gives the intensity in roentgens per hour. The dosimeter, or the film badge, is calibrated by placing it in a position and calculating the intensity of the radiation in terms of roentgens per hour and then leaving for a measured time. In this fashion the total radiation is calculated, the film is developed, and the blackening produced in the particular lot of film by this amount of radiation is measured.

SECTION VI—SURVEY AND DECONTAMINATION PROCEDURES

1. GENERAL

Preceding sections of this chapter have presented the nature of atomic explosions, radiation hazards and radiation detection equipment. This section is devoted to a consideration of two additional major problems which confront personnel charged with maintaining our defenses against radiological attack, whether by atomic bombs or other means. These problems are:

The determination of whether or not radiological contamination of an installation, ship or area has occurred, and if so the type and extent. This is necessary so that the commanding officer may be appropriately advised concerning the employment of personnel and materiel and the extent to which rescue, evacuation, decontamination and salvage are necessary and possible.

The decontamination of personnel and materiel which have been subjected to radiological attack.

2. SURVEYS

In attempting to obtain and evaluate information regarding the degree of radiological hazard existing following an atomic explosion or other radiological attack it is necessary to conduct a systematic survey of the area involved. A few haphazard instrument readings will not suffice to give a clear picture of the degree and probable types of contamination present, nor will they indicate the measures which should be taken for the protection of personnel remaining in, or likely to enter, the area. In general there are three types of surveys which should be included in any plan for obtaining the information desired:

A survey of meterological and terrain factors and of initial reports on the location and nature of the primary source of the hazard (i.e., atomic explosion, radiological dust, etc.). This survey, which can be partially accomplished in advance of actual attack, should lead to a quick prediction of the location of the "fall-out area." (Fall out is the downwind precipitation over an area of a vast number of very tiny radioactive particles from the radioactive cloud created by atomic explosion.)

A rapid survey of gross contamination in the local area, in order to determine the immediate safety precautions and rescue operations necessary.

A detailed and accurate survey over a considerable period of time to obtain information on the exact nature and rate of decay of the radioactivity present. This survey may include laboratory analysis of contaminated samples, and should be carried out.

Survey Procedures

Procedures involved in each type of survey may now be briefly examined:

Fall-out, previously defined, can be a source of hazardous contamination, varying greatly with the height of an atomic detonation and whether the detonation was over land or water or underwater. The calculation of the fall-out area is beyond the scope of this discussion, but can be roughly estimated by trained personnel, should be estimated at the command post or damage control center (nomenclature depending upon type of unit involved, and should be estimated under the direction of a meteorological officer. The predicted fall-out can be the basis for evacuating personnel from the estimated fall-out area before fall-out occurs and thus avoiding personnel contamination, or for warning ships or aircraft to stay clear of or evacuate the estimated fall-out area, whichever the case may be.

The second type of survey is the rapid analysis of gross contamination in the local area which may possibly proceed simultaneously with the first or fall out survey. This survey applies to either land or sea areas. Radiological defense officers must be capable of planning and carrying out such surveys. It is apparent, however, that in order to obtain a significant amount of data in a short period of time, it will be necessary to have a number of trained "monitors" to take measurements of radioactivity throughout the area suspected of being contaminated. These monitors usually will be enlisted men, well-trained in the use of instruments and in making accurate reports of the observed data. A monitor should also know how to interpret the results of his findings in a degree sufficient to be responsible for his own immediate safety, and that of others near him, should he find himself in a region of great radiological hazard. The instruments to be used by such monitors have been discussed previously. The subject of the organization and training necessary to carry out their mission will be taken up in a later period.

Monitors' Survey Procedures

Monitors should be assigned to each unit area on the basis of a grid system previously designated. Following radiological attack each monitor should proceed to, and conduct his

survey within, his assigned area with a high intensity survey meter, taking frequent readings, until he reaches an area in which radioactivity is above the military tolerance level. He should report his findings to the command post promptly and frequently by whatever means of communication is available, and must especially report the line of demarcation of military tolerance level, if it is within his area. If the monitor finds that he already is in an area above military tolerance then he should evacuate to an area of lesser intensity, warning others to do likewise as he goes. If he finds that his entire area is below military tolerance he completes the monitoring and reporting unless otherwise ordered.

Assuming that the rapid survey within any given unit area has been completed and that the monitor is still within his area or that he has re-entered an area where the intensity has decayed (fallen off) sufficiently to permit at least short duration operations, the monitor will proceed with the third type of survey, the more detailed accurate survey. This time he may use a more sensitive, lower intensity survey meter, such as a G-M type, taking readings at more locations and with greater regularity. It is important that he continue to report his results to the command post or damage control center. If there should be no radiation evidenced, except normal background count, within the area under survey, monitors must nevertheless make continuing surveys of their entire area if it lies within the region of possible fall-out. This is necessary in order to detect any later increase of intensity and thereby warn of approaching fall-out and possible hazard. It should be remembered that both positive and negative indications of radioactive contamination are of importance to the Radiological Defense Officer who is plotting the overall situation.

During this detailed survey the monitor should select some samples of earth, water, or small exposed objects and transmit the samples through his command post or damage control center to a radiological laboratory where they may be checked for type of radioactivity. In this way the presence of alpha radiation, especially harmful to the body when alpha emitters are absorbed internally, may be discovered. Alpha radiation cannot be accurately detected and measured by present day instruments even though these instruments meet the requirements of field usage. Laboratory analysis may also lead to certain conclusions as to the types of materials constituting the contamination procedures to be employed. This information, together with carefully recorded intensity readings taken at regular intervals at a few points specified by the radiological defense officer, will form the basis for calculating the time which must elapse before a radiologically hazardous area may be again safe for occupancy.

3. DECONTAMINATION

The subject of decontamination offers many problems. Research in the subject is continuing and some progress has been made in resolving the problem. At present the wisest counsel is to avoid contamination if physically possible. There is no practical means for destroying radioactivity. Since radioactive decay, a nuclear process, is entirely unaffected by chemical reactions, decontaminating solutions such as are used in neutralizing mustard-gas contamination are of little value in this new situation. Radiological decontamination has as its objective the freeing of an area from persistent radioactive agents. This involves the actual removal of induced radioactive isotopes, fission products and or unfissioned parts of the fissionable material of this bomb itself.

Principles of Decontamination

Currently accepted principles of decontamination include the following procedures:

a. **The immediate reduction to a minimum of that contamination of personnel and vital installations which cannot be or has not been avoided.** This may include **complete bathing, monitoring, reclothing, administering medical treatment**, where required, and **evacuation** of affected personnel, **washing and scrubbing down** exposed surfaces to free them of loose contaminating particles, and **temporarily covering short range (alpha, beta) emitters** with a coating, such as paint, which will provide at least a partial shield against the emissions. This will prove useful in shielding beta emitters, but not necessarily alpha emitters due to the very short range of the alpha particles.

b. **Subsequent thorough decontamination of areas important enough and of low enough radiation intensity to warrant attempting such procedure**, which is likely to be costly and time-consuming. This may include **repeated scrubdowns, removal of closely adhering particles by chemicals such as citric or hydrochloric (muriatic) acids which render the particles more soluble, and the removal of the surface to which the particles are clinging by the use of paint-removing solutions, scraping or, possibly, wet sandblasting.**

The value of such operations always should be weighed against the possibility of temporary or complete abandonment of the area or installation, or of prescribing certain maximum periods of working time for personnel absolutely required to enter dangerous areas.

The Prevention of the Spread of Contamination

This is accomplished through **preventing access to particularly "hot" areas by proper isolation which will include plainly marking off dangerous areas, using great care in disposing of grossly contaminated objects** and the waste water and waste materials used in removing contaminating particles, **carrying out a carefully prescribed ventilation doctrine** in the case of ships or air-conditioned shelters, and **improvising a "change station" or "decontamination center"** for the thorough decontamination of personnel and of their clothing and equipment before returning to a clean or uncontaminated area after exposure to possible contamination. Contaminated personnel must wash themselves, possibly many times, until, upon being monitored, their bodies are found to be at a safe level (e.g., at Bikini—twice background count.) Clothing must be changed and the contaminated clothing laundered, or if repeated laundering fails to decontaminate, must then be destroyed.

4. SUMMARY

Considerable original thinking and experimentation is still needed in order to give practical answers as to what corrective measures can be applied in future situations involving radiological hazards. Current and future development of radiation detection equipment probably will result in more practical and more effective instruments than those now available to assist the monitor in the conduct of a radiological survey. Surfaces of such smoothness and low porosity that they can easily be decontaminated will be developed for structures and equipment, or perhaps surface finishes which can be removed when necessary, carrying the radioactive particles with them, may prove one answer to the problem of radiological decontamination. The student should seriously consider these problems. He also may be assured that research on these matters is continuing, both in the laboratories of the Atomic Energy Commission and in such installations as the U. S. Naval Laboratory in the San Francisco Naval Shipyard, which is endeavoring to shed light on the best methods and materials to use in decontaminating radioactive surfaces.

SECTION VII—DESTRUCTIVE CAPABILITIES OF AN ATOMIC WEAPON

1. THEORETICAL EXAMPLE

It is important that one appreciate the real power of an atomic bomb, and the purpose of this section is to present a realistic picture of the damage which a typical American city might suffer were such a bomb detonated above it. Without going into a detailed study of the problem it will be assumed that an atomic bomb, twice as powerful as the type

used against Nagasaki, is detonated some 2500 feet above the center of City X. City X may be thought of as one of our typical industrial cities with a population of over 200,000 people. With the foregoing facts in mind, it is possible to examine what would happen to X if it were subjected to attack. Let us assume that the attack takes place at noon when the downtown area is most heavily populated.

Initial Damage

The city is enjoying a pleasant sunny day with a cooling breeze coming in. The streets are thronged with thousands of shoppers in the downtown and "point zero" areas. Then suddenly and without warning the bomb is detonated high above the city.

A dazzling bluish-white flash blinds those people on nearby streets and sears them at the same time with its million-degree heat. Almost within a thousandth of a second the small ball of fire shoots out to form a sphere of flame one hundred yards in radius. Simultaneously the color of the ball changes, going over to a varicolored seething mass which spreads outward and downward at terrifying speed. Above it all, a huge pinkish white mushroom "atomic cloud" forms and climbs toward the stratosphere.

Directly under the blast, the instantaneous flash of heat sears all pedestrians into unidentifiable charred and grotesque forms. Those shielded from the heat are momentarily conscious of a terrible pressure wave that topples taller buildings and crumbles others into rubble. Within a second a blast wind of near supersonic velocity rushes in and demolishes these buildings untouched by the primary blast wave. The air is thick with dust from pulverized buildings and the crashing of surrounding buildings creates a din which is soon followed by the ominous noise of fires ignited by the flash.

Secondary Damage

To feed the multitude of fires, air rushes in from the surrounding area, even overcoming the prevailing breeze, and so on a firewind of gale proportions sweeps the city. This unusual firewind persists for several hours and makes the entire area near the center of blast, inaccessible to what fire-fighting equipment is available. Streets made impassable with debris, the failure of the water pressure, disrupted communications all prevent fire fighters from reaching the stricken area

Within a three-mile radius of the center of blast, the number of dead and injured is staggering to the imagination. Those who were within one mile of the blast center, while still surviving, are living on borrowed time. When the brilliant flash of light occurred, those living within a mile of the blast center were exposed to a deadly dose of penetrating radiation. Unseen, unheard and unfelt these deadly rays penetrating the human tissue had left their mark. Perhaps the survivors would linger for a few days, or even a few weeks but they are doomed.

Much of the enormous damage is due not so much to the primary effect of the bomb but to the secondary effects. In this category, one would list fire damage, injuries due to collapse of fire-gutted buildings, deaths from burns, suffocation and lack of medical care. Much of the effectiveness of the A-bomb is due to is instantaneous and widespread action. A modern and efficient fire department, such as "City X" has, can cope with a few outbreaks of fire within the city, but when hundreds of fires are simultaneously started miles apart in an impassable area, it is a hopeless task to stem the on-rush of the holocaust. The fires will continue to burn until the next day, at which time it will be possible to re-enter the area, critically examine the ruins and evaluate overall damage. To insure systematic evaluation each type of damage must be analyzed separately.

Blast Damage

Since it is difficult to separate the individual effect of the shock wave from that of the blast wind, their combined effect will be considered.

Damage at Point Zero.

From the center of blast to a distance of one mile there is heavy blast damage. All frame and brick buildings are demolished and only those sturdy, reinforced-concrete struc-

THIS PAGE IS DECLASSIFIED IAW EO 13526

tures on the periphery of this zone escape complete destruction. Within the zone the interior of all buildings is subject to intensive damage. Both the downtown and the Point Zero shopping centers on the periphery of this zone sustain extensive damage ranging from total destruction to heavy damage. In some cases the walls of the buildings remain standing but the roofs and floors are missing. Able Street is a scene of utter desolation. From the City Hall to Baker Street it is impassable. Streetcars and automobiles, many with their occupants lying dead inside them, stand out in the rubble-strewn streets.

Damage One Mile From Point Zero.

Farther out from the center of the blast, within the one- to two-mile radius, heavy damage is sustained. Included within this zone is the downtown area of the city. Here some of the larger, well-built structures seem to be intact but closer examination shows that their interiors are extensively damaged and many are gutted by fire. At the lower end of Main Street, the beautiful Memorial Auditorium is in ruins, but many of the buildings along Main Street even closer to the center of blast are almost untouched. Apparently these were shielded by other buildings or merely escaped blast damage by virtue of having been "skipped".

The neon beacon high atop the Charles Building has been ripped asunder and lies in the street below. The main structures remain more or less intact with greatest damage being apparent on the upper part of the building. In spite of the appearance of the exterior of the modern structure, there were many casualties in it and due to the fires which raged throughout the downtown area it was impossible to evacuate all of the occupants of the building.

To the east, the Central Terminal still stands, but severely damaged. Without any shielding from the blast wave, parts of the structure collapsed. The railroad yards are inoperable with twisted rails jutting up from the ground. Apparently many of the railroad ties in the bed were burned by the flash.

Damage at a Distance. Between two and three miles distance from the center of blast, moderate blast damage is evidenced among the ruins. Most of the blast damage is concentrated on frame dwellings and plants of light construction. Brick houses in this zone still stand but show some signs of interior damage.

More than three miles from the point of bomb detonation there are still signs of blast damage but for the most part they are minor and are masked by damage from fire.

It is possible for blast effects to be felt at as great a distance as eight miles from the epicenter, but such damage would be slight and rare.

Fire Damage

When the bomb explodes a vast quantity of radiant energy (light) is liberated in the form of ultraviolet, visible and infra-red radiation. This radiation causes intense surface heating of all objects which it strikes within a three-miles radius of the center of blast. In some cases, depending on the local conditions, this surface heating is sufficient to ignite the material. Thus, within a circle roughly six miles across, there may be hundreds or even thousands of fires started and of these several hundred will persist and spread.

The effect of such intense burning over such a wide area is to cause a mass influx of air from outside the region. This movement continues if it overcomes the prevailing winds and an enormously destructive fire-storm results and whole areas untouched by the blast are burned out.

In "City X" the prevailing southwesterly wind would overcome the fire-storm after a few hours and tend to sweep the blaze into the B section of the city. To the north, Forest Lawn and Dog Park would act as natural fire breaks and to the southwest, the South Park section would be shielded by the prevailing winds.

Effects of Radioactivity

All persons living within a radius of about $1\frac{1}{3}$ miles of the center of blast would be exposed to a lethal dose of radiation provided they were not shielded by thick brick or concrete walls. A wood-frame wall offers little

shielding from this radiation. Therefore most of the people surviving the combined effects of fire and blast in this area would probably die within a few days or weeks from the effects of the penetrating radiation.

Those living in the zone from $1\frac{1}{3}$ miles to 2 miles from the center of blast, while not receiving a lethal dose of radiation, would receive a considerable exposure that would complicate their recovery if they suffered any other injuries. Many would show obvious signs of radiation damage, such as loss of hair, but they would later recover and live apparently normal lives.

Outside of the two-mile radius, there would be no effect from the primary flash of radiation, but it is possible that a fall-out of radioactivity would occur. If so, varying intensities of radioactivity might be found ranging from harmless to dangerous amounts.

Village Y would lie directly in the favored path of the fall-out and if conditions were such that a rain storm occurred carrying down vast quantities of radioactivity with it, then the entire populace of Village Y and surrounding territory would have to be quickly evacuated.

It will be recalled that in the case of the New Mexico atom-bomb test, some of the atomic cloud settled out miles away from the detonation point and cattle in the path of this fall-out later were found to have white backs where some of the radioactive particles adhered.

Casualties

In summing up the supposed atom-bombing of "City X", one can most readily realize the terrific striking power of the new weapon by estimating the total casualties caused by the explosion—about 100,000. Of these, about 50,000 would result in fatalities. The number of fatalities would run as high as this because of the lack of proper medical facilities at the time they are needed most, i.e., the day of the explosion. At Hiroshima there were only a few hospitals in usable condition out of about fifty. Of 1780 nurses, only about 100 were available for duty after the explosion.

The staggering figure of 100,000 casualties would mean that every family in the city would be directly affected by the explosion. Many civic leaders, key industrialists, and thousands of skilled craftsmen would succumb to the disaster. Thus while the Section A steel plants would still be intact and outlying factories would be undamaged, the city would require many months before it could rebuild the bombed-out area, replace personnel, and repair public service throughout the stricken community. "City X" would have been effectively knocked out by one bomb!

SECTION VIII—ORGANIZATION AND TRAINING FOR RADIOLOGICAL DEFENSE

1. ATOMIC ENERGY COMMISSION

The Manhattan District was responsible for the correlation of the effort which led to the production of the atomic bomb. This organization has now been dissolved, and its mission has been taken over by the Atomic Energy Commission. One difference should be noted: The Manhattan District had the mission of producing a bomb; the Atomic Energy Commission (AEC), however, has the task of providing weapons and developing atomic energy in the broadest possible manner. The AEC not only is interested in atomic weapons, but also in the development of atomic power, the use of radioactive tracers in medicine, the use of tracers in biological research, and a score of other problems. The AEC is responsible to the President (Figure 8-11.)

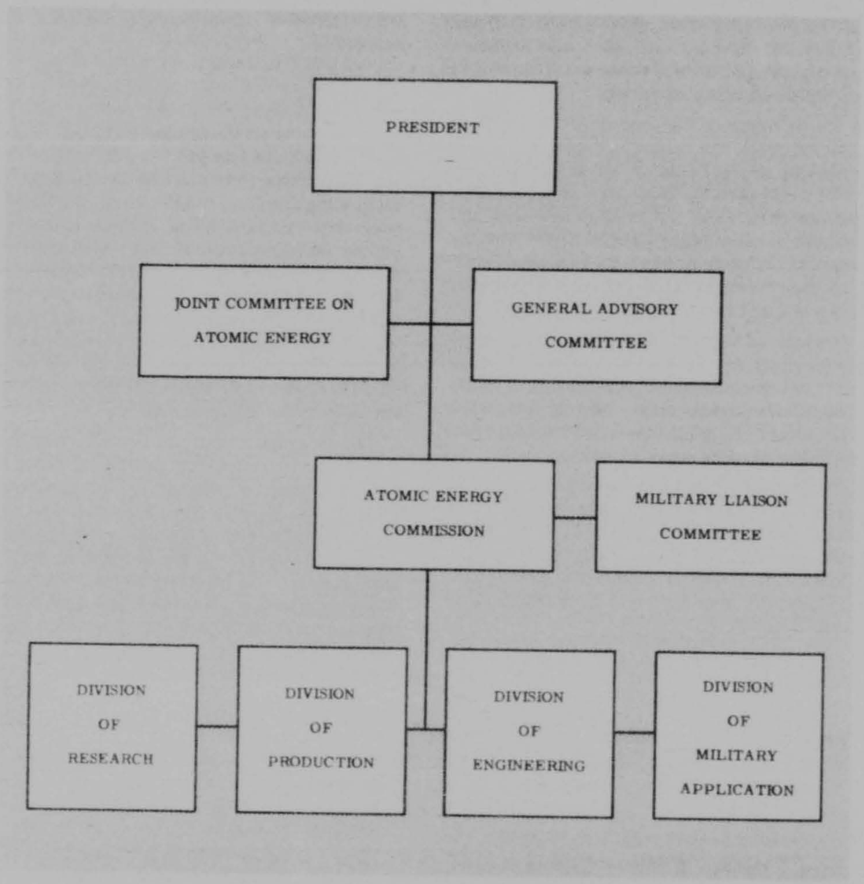

Figure 8–11. Organization of the Atomic Energy Commission.

2. POWERS AND RESPONSIBILITIES OF THE AEC

The broad powers and great responsibilities of the AEC are shown by the fact that it has divisions of research, production, engineering, and military application. It also includes a Military Liaison Committee, which has a twofold responsibility: to keep the military informed of any development in atomic energy that might be useful to them and to keep the commission informed of the needs of the military services.

3. THE AFSWP

The Armed Forces Special Weapons Project (AFSWP) has been organized to carry out certain military functions of the old Manhattan District, which were not delegated to the Atomic Energy Commission. These functions includes coordination within the three

components of the armed forces of their requirements for atomic offense and defense; training of technical personnel necessary in the armed forces for handling and delivery of atomic weapons; training and coordination of joint radiological defense; coordination of military development of offensive and defensive equipment between the armed services, coordination with the Military Liaison Committee to the Atomic Energy Commission, the Research and Development Board, and other high level agencies and staff coordination of joint projects arising in the military application of atomic energy development.

4. ORGANIZATIONAL REQUIREMENTS FOR RADIOLOGICAL DEFENSE

It is now estimated that the following personnel will be required in the radiological defense organization of the armed forces:

Radiological Defense Engineer

This title is applied to the officer who has graduated from the six-week Radiological Defense Officers Course and the three-year course consisting of one year at the Navy Postgraduate School and two-years divided between postgraduate work at a civilian university and field work. The field work is to be approximately seven months with the AEC or the AFSWP.

Radiological Defense Officer

This title is applied to the officer who has graduated from the six-week Radiological Defense Officers Course. This course, conducted under the supervision of the AFSWP, is intensive and difficult. The officer must have one year's college credit in physics, chemistry, and mathematics in order to meet the minimum entrance requirements for this course. It is highly desirable that he be a college graduate in engineering, physics, chemistry, or mathematics.

Monitors and Instrument Repair Men

These will be individuals who are trained to make radiological surveys and to use and maintain the radiation detecting instruments. They will not be well-trained in the underlying theories of radiation (nuclear physics) but they must understand instruments and how to use them. They must further be carefully trained in the personal protection techniques used in radioactive areas.

5. RADIOLOGICAL SCHOOLS

At the present time, as an interim measure, two types of schools have already been activated. The six-week course for radiological defense officers is being offered at Treasure Island, Army Chemical Center and Keesler Air Force Base. Classes of up to fifty officers were admitted to the Navy Postgraduate School in the fall of 1947. A new class will be admitted annually in July.

Proposed Schools and Courses

The final form of the joint training for monitors has not been determined. Consideration and planning on this problem, which is closely related to intraservice organization, is being conducted. Meanwhile, several experimental courses have been offered at Treasure Island to obtain information of future use in conducting this training. It appears likely that when such schools are opened, they will offer a four-week course of study organized to include instruments and their use and repair. The entrance requirements can therefore be much less stringent than for either of the other two schools. The problem of training monitors, and they inevitably must be largely enlisted men, is a big one. It must be decided whether they will all be trained at corps or army level, or air force or fleet level. It is probable that the first such schools will be set up at existing service schools where the training problem will be studied and plans made to decentralize such training. There is no possibility of setting up many such schools at the present time. Adequate numbers of trained instructors and instruments are not available. The problem of training monitors will be somewhat simplified by the advent of simpler and more rugged instruments.

The problem of training personnel of the civilian components is also being studied. The schools at Treasure Island, Army Chemical Center, and Keesler Air Force Base, are conducting two-week courses in radiological de-

THIS PAGE IS DECLASSIFIED IAW EO 13526

fense for reserve officers (Navy, Air Force, and Army). A series of extension courses is being drafted which can be used by the officer of the civilian components for the study of physics and nuclear physics. In a two-week course, he can be given the fundamentals of explosion phenomena, medical effects, and the use of instruments. It is likely that this procedure would graduate officers of the civilian components with training approximating that of the regular officer who has the six-week course. It should be mentioned that a part of this series of extension courses can be used by the regular officer as a review of his mathematics and physics before he enters upon the six-week course of study.

6. ORGANIZATION FOR RADIOLOGICAL DEFENSE

There is no firm policy at the present time covering organization for radiological defense. Each service has announced an interim policy, but any organization must be studied and tested in operation. It would probably undergo many changes before it becomes a firm policy. For this reason, such possible organizations will be only briefly discussed here.

Planned Naval Organization

The Navy has ordered a shipboard organization for radiological defense superimposed on damage control organization. They take the attitude that many of the problems of radiological defense are identical with those of defense against chemical warfare, and they have decided that the radiological defense shall be a part of the ship damage control organization. They plan initially to assign two trained monitors to each damage control party and eventually to train all damage control personnel to act as monitors.

Planned Air Force Organization

The Air Force favors a plan which is interesting and instructive. It is contemplated that a radiological defense officer, a graduate of the six-week course, will be assigned to the staff of a wing. He will be asisted by three enlisted men. Each group headquarters within the wing will have a radiological survey officer assigned, who will be equivalent to a Navy monitor. He will have two enlisted monitors as assistants. The airdrome group will have, in addition, three photodosimeter specialists, and the station hospital will have a radiological survey officer, two enlisted monitors, and three photodosimeter specialists. Each combat squadron will have two enlisted monitors as will most other squadrons. The maintenance squadron will have, in addition, nine instrument repair specialists.

Planned Army Organization

The Army has announced no plan as yet. From a study of the Navy and Air Force plans, however, such a plan can be sketched in broad outline. It is likely that the army commander will need a small radiological defense staff, headed by an officer who is a graduate of the three-year radiological defense engineers course. He should have assistants who are trained as instrument specialists, report writers, and monitors. It is likely that the special staffs of corps and divisions will have to have a radiological defense section. Such a section can be made small and could be headed by officers who are graduates of the six-week course. The question as to whether the regiment and battalion will require officers trained in radiological defense is being debated. It would seem that the Air Force plan might be a good one, and that regiment and battalion should have officer monitors. The smaller units will require sufficient instruments and trained enlisted monitors so that they can determine when the command is endangered by radiation. The commander must be kept informed of such hazards, and he should have the means at his disposal for making at least hurried surveys of limited areas.

There are many who believe that the problem should be given to the present gas and chemical officers. The radiation problem and the gas problem have much in common; there is a detection and a decontamination problem for both. The present Air Force system for defense against chemicals is well-organized, and it would be fairly easy to give the gas and chemical officers and airmen the additional training required and to increase their numbers until they could handle the new problems when supplemented by appropriate additional technical specialists at the proper level.

SECTION IX—COMMAND PROBLEMS OF RADIOLOGICAL WARFARE

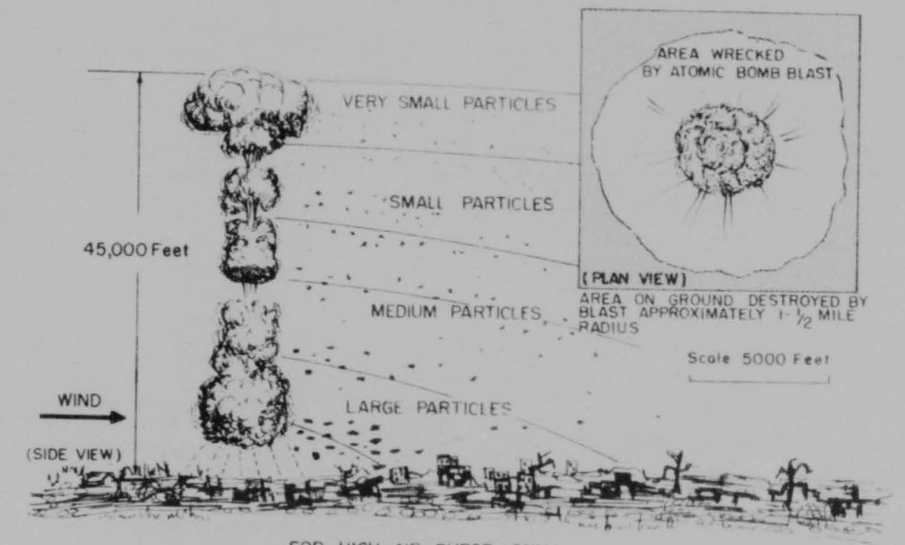

Figure 8—12. Airburst of Atomic Bomb and Areas of Destruction.

1. GENERAL

In the previous lessons, certain aspects of a new weapon whose order of magnitude and special character introduce new factors in the waging of war have been discussed. The purpose of this lesson is to emphasize certain command problems arising from the radiation hazard and present them from the commander's point of view.

Atomic attack, as has been indicated, may come in a variety of forms. Depending upon the method of employment, the extent and characteristics of the damage are generally known. There will be areas that are marked by atomic bombs for catastrophe, but not necessarily for doom. It is the problem presented by these areas that directly concerns radiological advisers.

Air Burst

In an air burst of an atomic weapon, the effects of blast, radiant heat, instant radiation, and secondary fires are predominant, while the radioactive contamination is relatively small and secondary (Figure 8-12.) In the downwind direction, areas will be found contaminated by fall-out of radioactive material; the degree of this type of contamination may not be a primary hazard.

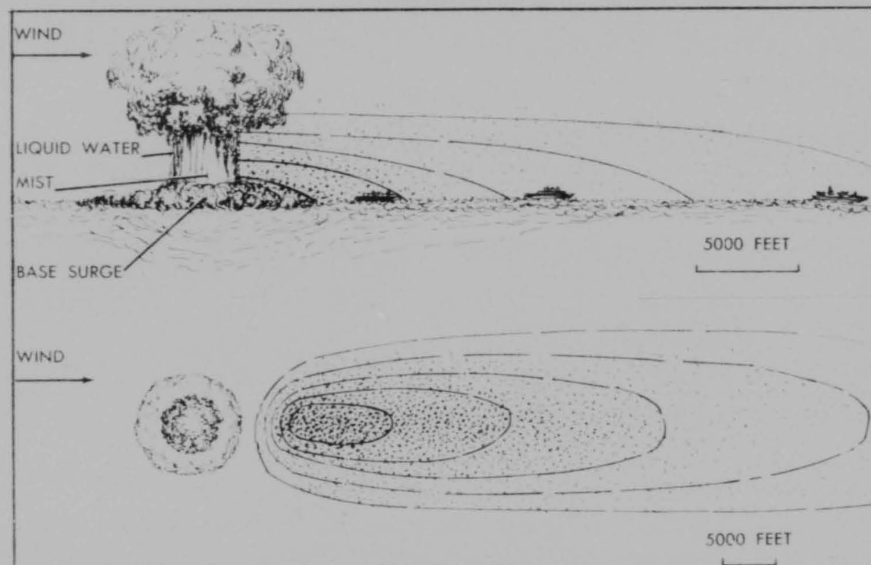

Figure 8—13. Underwater Burst of Atomic Bomb.

Underwater Burst

In an underwater burst, the effects of radioactive fall-out contamination and water-propagated blast are predominant and constitute an extremely serious threat (Figure 8-13.) The effects of instant radiation, air blast, radiant heat, and secondary fires are absorbed, shielded, or minimized by the water. In order to obtain an extremely large volume of highly radioactive material on a target, the effect of blast and heat is reduced. Should the underwater burst occur in sea water or a salt lake, the degree of contamination is tremendously increased by the fall-out of radioactive sodium.

The probable results of a sub-surface burst are purely speculative; however, one can arrive at some broad conclusions by analogy with the underwater burst (Figure 8-14.) The resultant radioactive contamination by the fall-out of soil-trapped fission products, plus neutron-induced reactions in the elements of the soil and, to a less extent, air and ground shock wave would be predominant. The instant radiation, radiant heat, and secondary fires would be secondary effects. Since the dissipation of the heat generated in a sub-surface burst could be expected to be slower than in an underwater burst, the cloud would rise higher and would be influenced greater by wind conditions.

Considering each of the effects of the various probable methods of employment of an atomic weapon, it is seen that they impose large problems on the military commander. If it is further logically assumed that the civilian defense organizations will no doubt rely strongly on the zone of interior commander for advice, coordination, and assistance, the task assumes huge proportions. For the commander outside the zone of interior, there may be a necessity for combining effort with that of a friendly power. This would further add to the responsibilities of that commander.

2. HOW A COMMAND MAY BE AFFECTED BY AN ATOMIC ATTACK

It is not the intention of this paragraph to emphasize the problem of radiation above all others, but to present the problem as one requiring judicious and thorough action on the command level.

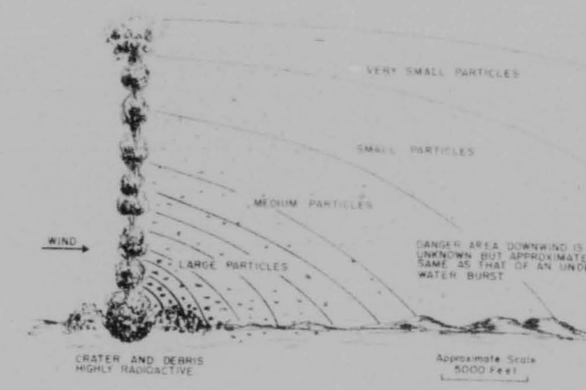

Figure 8—14. Estimated View of an Underground Atomic Bomb Burst.

Command Responsibility for Defense Requirements

At the present time, atomic warfare is experiencing a stage of development, calibration, and field testing. Much of the detailed work and specific tests is highly classified and will undoubtedly remain so for a long time. The results already known from previous tests impose new requirements upon our national defense organization and will eventually add to the specific responsibilities of our senior military commanders. These defense requirements cannot long be overlooked. Radiation can impose serious physical and psychological damage on a command not fully prepared to cope with it.

The most encouraging fact concerning the radiation hazard is that it has a workable solution, for, although the hazard is new and unique, our present military standard method of coping with conventional problems on the staff and planning level can adequately handle this new problem with little or no change. Some additional and specially trained personnel may be required on the troop level.

Possible Means for Implementing a Defense Program

The initial impetus that might energize a commander into implementing a radiological defense program could occur in any of several ways. He may be influenced by one of his staff officers who has returned from some form of radiological defense schooling, or he may acquire the desire through close work with civilian defense agencies on parallel problems. More than likely, however, he receives a directive from a higher command broadly outlining a requirement to be fulfilled under a set of policy conditions. Assuming, therefore, that a directive is received, this lesson reviews the commander's possible actions with a view towards introducing command problems due to radiation hazard. The following discussion cites examples only.

3. EXAMPLES OF A COMMAND'S PROBLEMS AND SOLUTIONS

How does this new threat of radiation affect accomplishment of the command's mission? This is the commander's first question. He

THIS PAGE IS DECLASSIFIED IAW EO 13526

calls in his chief of staff and his radiological defense officer and, if possible, arranges for the presence of the radiological defense officer of his next higher command. At this conference, the command's mission is thoroughly reviewed, and the radiological defense officer is requested to submit the recommendations necessary to circumvent or minimize the radiation hazard. In all probability, the radiological defense officer is given a free hand to consult with other special staff officers on technical matters. In the event a radiological defense officer is not assigned to his staff, the commander assigns a suitably trained officer from within his command or, if none is available, proceeds as is customary in filling staff vacancies.

At the time the radiological defense officer submits his recommendations, the commander calls in his chief of staff and formulates a general policy based on the approved recommendations. The chief of staff prepares a staff memorandum informing the various staff members of the task to be accomplished and requests recommendations in order to form the basis of a command SOP or an organization bill.

Problems to Be Solved in Forming an S.O.P.

Personnel and Administration Considerations: Placement of the radiological tables of organizations. (For example, in the Navy, he would be in the damage control section; in the Air Force, under the chemical officer; and in the Army, in the chemical section.

Number and type of trained radio-logical personnel and their assignment.

Table of organization, either tentative, provisional, or approved, showing all radiological defense vacancies.

Roster indicating radiologically expended personnel

Stabilization of key radiological defense personnel in important positions.

Personnel requests by specialty to fill vacancies.

Intelligence and Security Considerations: Establishment of a policy on the amount of classified information absolutely necessary to disseminate to accomplish the task. (In most instances, this limitation may be unnecessarily restrictive).

Manner of reporting areas of radiation contamination for intelligence purposes.

Procedure of reporting by subordinate units of new or unexpected means of employment of atomic weapons by an enemy.

Countersabotage and countersubversive plan.

Dissemination of information concerning the enemy's capability of employing atomic weapons, including possible targets, means of employment, and timing of attack.

Plans, Operations, and Training Considerations: Requirements for personnel trained outside the command (radiological defense officers, instrument repair technicians, and radiochemists).

Specialized training requirement for the command, such as monitor training, decontamination training, and photodosimetry training (all training to be done at specialist schools).

Training within the command, such as general indoctrination, unit training, combined training, and exercises.

Operating procedure for monitor teams and decontamination teams.

Establishment of an alarm system.

The alert plan and active defensive plan.

Supply, Logistics, and Evacuation Considerations: Instrument, special clothing, equipment, and special supply requirements.

Replacement and repair requirements.

Special storage facilities, such as conditioned rooms for instrument repair and storage, and dark rooms for film badge processing.

Provision of decontamination equipment and estimate of supply requirements.

(A number of special staff officers will be affected by the new requirements of radiological defense in accordance with specified policy or the wishes of the commander in the absence of specific instructions).

4. REQUIREMENTS OF PERSONNEL IN RADIOLOGICAL DEFENSE

Radiological Defense Officer

The radiological defense officer would act primarily as a staff adviser in radiological defense, and many of the operating procedures would be based upon his recommendation. He should have a thorough knowledge of the policies of his commander and should be acquainted with subordinate commanders and their units. He should be an active, well-informed assistant to the commander and a helpful adviser to subordinate commanders. His main responsibility is to insure that all necessary and feasible radiological defense measures are implemented and efficiently carried out.

Medical Officer

The medical officer would primarily be interested in the health and physical condition of the command. He may provide for the development of film badges and maintain exposure records on members of the command, if so designated. He advises the commander when radiation exposure constitute a damaging physical hazard. In accordance with directives from higher authority, he establishes the exposure limits for the command.

Construction Personnel

The construction personnel would supervise the construction of installations required for radiological defense. The engineer also consults with the radiological defense officer concerning the optimum protection to be gained through special types of construction and the location of new construction.

Communication Officer

The communication officer would probably be responsible for providing storage and repair of instruments on the command level. He might also receive and issue, in bulk, film badges and photodosimetry equipment. He also may be required to provide photographic dosimetry facilities.

Other Officers

The many other special staff officers would have individual problems which would be worked out by coordination with the radiological defense officer or by direct instruction of the commander.

After all members of the staff have submitted their recommendations, they are consolidated, and the operations officer translates them into an SOP or organization bill which forms the basis or foundation of radiological defense within that command. This plan gradually undergoes changes as it is repeatedly put to test or as the command receives new instructions, until it is eventually sound and practical.

5. SPECIAL PROBLEMS

A great deal of profitable information and guidance can be extracted from past experiences in operations involving large area radiation contamination.

A command problem which was potentially very serious arose at the Baker Test of Operation Crossroads. The Baker Test was different from Hiroshima and Nagasaki; water trapped the radioactive materials from the bomb and rained on the target vessels, producing an invisible hazard. Radioactive material was scattered over the decks of the ships. Men walked through it, tracked it around, and got it on their clothing and hands and faces. They could not see it, feel it, or smell it. They did not respect it, but they could eat it and they could inhale it.

Bikini

At Bikini, when it was realized that plans, group training, and operational techniques were inadequate to insure complete protection to personnel, operations could be brought to a halt. This lesson cannot be ignored, and for combat, planning and training must be such that an organization can continue to function.

Kwajalein

After the Bikini operation was discontinued, the target vessels were towed to Kwajalein and anchored in the lagoon for long-term storage. The need for further work on the vessels was apparent, and it was also evident

THIS PAGE IS DECLASSIFIED IAW EO 13526

that a complete quarantine of the ships would not remain practical. The ships contained large amounts of high explosives, including some experimental ammunition and some obtained from foreign navies. Removal of this ammunition would be necessary, and the longer operations were deferred, the more dangerous the work would become.

Frequent briefings of the men were held by the officers to impress the need for caution, not only against the dangers from radioactivity but also from the explosive materials they were handling. The protective restrictions which had been established were more severe than those used at Bikini. Every tendency to relax precautions had to be countered by a psychological campaign on the part of the officers to insure compliance. This is typical of what may be expected in the future. If the nature of the danger is not directly observable, the control of the troops will present a complex problem. There is a great difference between impressing a man with the **fear** of observable physical injury and **respect** for radioactivity. If **fear** of radioactivity is taught, the efficiency of atomic weapons will be increased. If proper **respect** is not taught, the toll of lives will be increased.

It seems that the command difficulties to be encountered and the lessons to be learned in atomic warfare will include a repetition of some of the difficult experiences at Kwajalein. There will be others that are more complex.

6. CONCLUSIONS

Sound principles demand that the value of any objective be weighed against the cost of achieving it. The new problem at hand can be recognized when consideration is given to the fact that the costs of achieving radiological objectives are not readily observable. When a man has been subjected to some cumulative absorption, which is referred to as "military tolerance," his radiological usefulness is impaired. Further exposure will entail an increasing probability of injury. When a commander has held his troops in an area of high radioactivity until he can observe the physical effects upon them, he had held them too long.

The commander of the future must have an understanding of the nonsensory hazards of atomic warfare and how to evaluate them accurately, and he must know how to pursue his objective without exceeding the normal, calculated risks balanced against the value of the objective. He must understand the nature of radioactivity and the slowness with which it acts and makes itself evident. He must be willing to accept the advice of a technical staff in such matters just as certainly as, under other circumstances, he would accept the advice of dispatches informing him of troop losses. He cannot shift to technical personnel the responsibility for failing to drive on to his military objectives, but he must give proper significance to the advice of such personnel. Military command remains in his hands and cannot be usurped by the adviser or the radiological monitors, but the commander cannot efficiently act in ignorance of the advice of such technical personnel, who in such instances would actually give far more advice. They would tell the commander the absolute facts, which he could not immediately see but which he could not ignore later when the toll was reported from the hospitals; facts which he could not ignore when his reserve troops would be demoralized and beaten without ever having faced an enemy.

During Operation Sandstone, just concluded, there was considerable evidence that the lessons of Bikini were profitably used and contributed to a very efficient, adequate, and commendable radiological defense operation. From Operation Sandstone will come additional valuable lessons pertaining to radiation, lessons that cannot help but improve and perfect the over-all concept of radiological defense.

CHAPTER 9—GUIDED MISSILES AND PILOTLESS AIRCRAFT

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION I—HISTORY

1. GENERAL

The present technological revolution, superimposed on the industrial revolution, the growth of populations, and the rise of nation-states, has made war both "total" and "global" at once.

The technological revolution has brought with it four new and important weapons. These are the atomic bomb, the long-range plane, guided missiles, and the various biological agents developed for destructive purposes. They are not, of course, to be considered as the sole weapons of any future war. They supplement the more standard weapons and multiply the force of warfare to such a degree that future warfare is alarming to contemplate.

This chapter is devoted to the third of these new weapons, guided missiles. The military desire for a guided missile is perhaps as old as warfare, however, it did not become a practicability until the present era of electronics, and jet propulsion. Because the Germans have popularized so many new weapons, the idea is quite prevalent that they also pioneered in the development of guided missiles. Actually, the first crude guided missiles were begun during World War I by the United States. Shortly after the United States entered World War I, the Aviation Section of the Signal Corps became interested in the development of flying bombs. The leader in this field was the well known C. F. (Boss) Kettering of the General Motors Corporation who devised and tested a small biplane type of preset flying bomb. These early tests of 1918 and 1919 were not very successful and were subsequently abandoned. A most important result of these tests was the recommendation that any future work should be done with radio-controlled aircraft which could be given the necessary adjustments while in flight. This earliest known test showed that the preset type of missile was of almost no value. (As will be discussed later, the German V-1 and V-2 were very effective—when they hit the target area.)

As a result of the recommendations made on the early tests, the Engineering Division of the Army Air service in 1924, initiated a program for the development of radio controls. By 1928 attempts were made to fly a commercial-type Curtiss "Robin" monoplane by remote control. By 1932 this project had not produced any outstanding results and was dropped for lack of funds. From a guided missile viewpoint this program was perhaps not achieving the desired results, however, it did lead to the development of the very important automatic pilot, which was the forerunner of those used in modern aircraft. For six years nothing further was done in an attempt to construct a guided missile. Then in 1938, the Chief of the Air Corps directed that the development of radio-controlled, bomb-carrying "aerial torpedoes" should be continued. No satisfactory designs were submitted at this time; but through the sustained interest of Mr. Kettering and General H. H. Arnold the project was kept alive during 1938 and 1939. In 1940 a new set of military characteristics was initiated and a contract was negotiated with the General Motors Corporation for the fabrication of ten aerial torpedoes and related control and launching equipment. This was a major step in their development. Late in 1940, the Materiel Division of the Air Force embarked upon a greatly expended program which encompassed the development of a variety of remotely controlled targets, aircraft, and also offensive weapons of the guided missile type. The Equipment Laboratory of the Materiel Division was assigned the task of controlling this development work. Colonel George V. Holloman was in charge of the new Special Weapons Branch which was then established to handle the administration, development, and tests associated with these projects.

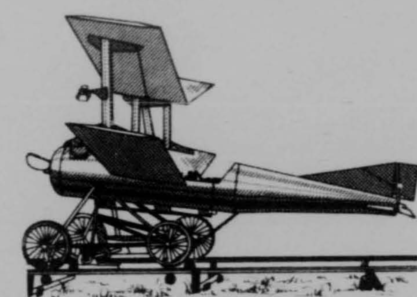

Figure 9—1. First Guided Missile (Pilotless Aircraft) Built in the U. S. Arcadia, Florida (Carlstrom Field—1918-19).

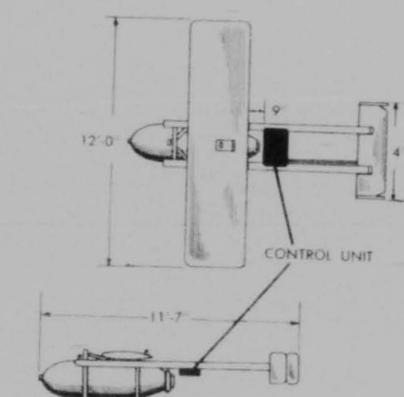
Among the several projects started at this time was the development of radio-controlled target planes, a glide bomb (GB-1), a controllable high-angle (free falling) bomb known as AZON, a "buzz bomb" (later called the General Motors "Bug"), another glide bomb known as the "Bat," and several other projects which were later discontinued.

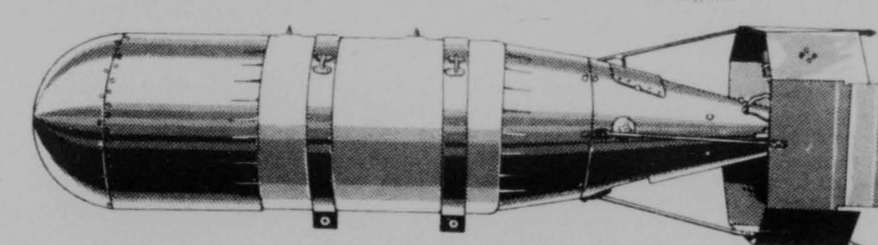
By September 1941 a group of engineers and technicians from Wright Field, augmented by technicians from the National Defense Research Council, and from the General Motors Corporation gathered at Muroc, California, to conduct the initial tests on the "special weapons" being developed.

The first of these "special weapons" to be tested was the GB-1 glide bomb. The object of this device was to enable a plane to drop the bomb at a considerable distance from the target, well outside the ring of heavy anti-aircraft fire, and have it glide to the target on its plywood wings. These early drops were made from a converted B-23 and the results were encouraging. During October and November of 1941, several of the "Bugs" were launched, several experimental AZON bombs were dropped, and a radio-controlled target plane (an old biplane trainer) modified with a tricycle landing gear, was flown. Because of the excitement caused on the west coast by the attack on Pearl Harbor the experimental group moved back to Wright Field. Here during the next three months they worked to improve and redesign various parts of the flight-control equipment which were used in conjunction with the "special weapons" being developed at that time.

Next the experimental group left Wright Field to continue their work at Eglin Field, Florida. In addition to the work which continued on those types already mentioned, they began work on the "Bat." The "Bat" project was successful and later was turned over to the Navy to undergo further development for use against surface targets.



BOMB, DEMOLITION, 2000 LB. M34



"AZON" BOMB

THIS PAGE IS DECLASSIFIED IAW EO 13526

During this same period, success was achieved with the GB-1 and it was ready for production by the early fall of 1942. The AZON tests had been continuing and in 1943 it was considered ready for tactical use. At the same time the "Bug" was successfully launched and radio controlled, but since this missile was quite complicated and costly to produce, the project was abandoned.

In the fall of 1942 and into the early months of 1943, work was initiated on a radio controlled version of the GB-1 Glide Bomb. The regular GB-1 was aimed by a bomb sight and after release flew on a straight line course to the target. The radio controlled version was intended to allow correction after the dropaway, thereby making it possible to hit a moving target and to permit a greater degree of accuracy.

2. DEVELOPMENT OF HOMING DEVICES

In addition to the earlier glide bomb projects, attention was also being focused on the use of heat, light, and radar homing devices to control the glide bomb. The GB-5, the GB-12, and the GB-13 utilized light-seeking homing devices which had been developed. Equipment utilizing light differentiation as a means of direction was under development by a civilian contractor as early as March 1941. Light-seeking devices continued in a developmental stage through 1943. During this period these various light seekers were not developed to a point of tactical utility. However, light seekers were sufficiently simple in design and construction, and offered the advantage that they could be produced quickly in comparison to other more complicated types of seekers.

The application of radar target-seeking devices to the glide-bomb vehicle represents a phase of the glide-bomb development toward which an appreciable amount of attention was directed by the Air Forces, the Navy, and various sections of the National Defense Research Council. In April 1942 the Air Forces requested that NDRC initiate a project to develop radar seeking equipment. Two types of this equipment, termed "RHB" (Radar Homing Bomb) and "SRB" (Send Receive Bomb), were eventually perfected for use on glide bombs. Sufficient quantities of seekers were procured from time to time to carry out the necessary testing programs for RHB and SRB. However, lack of technical personnel for the program, among other factors, slowed the progress of the work during 1944 and 1945. Both RHB and SRB were dropped to a lower priority in November 1944 because it was felt that the development had not progressed to a point where either equipment could be tactically useful in the near future.

With the conclusion of World War II the guided missiles program was greatly accelerated. To provide for the fact that there are basic differences between the aircraft program and the guided missiles program, formal recognition has been accorded the program by the establishment of various guided missiles offices.

3. OPERATIONAL USE OF GUIDED MISSILES BY THE UNITED STATES

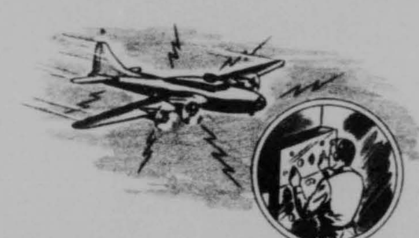
Prior to the end of World War II the Air Force had the following guided missile research and development projects, expected to be used in combat placed with industrial and educational institutions.

Jet Bomb

This missile was similar to the German V-1 weapon.

Abusive Project

A project which required the use of craft which had been equipped with radio controls, to be used on "one-way" missions with a full load of bombs, directed to the target by a mother ship and crashed into the target.



"WEARY-WILLIE" PILOTLESS AIRCRAFT

Figure 9–2. This Composite Shows Most of the Early Operative American Guided Missiles

GAPA Project

A project underway to build a weapon which could be used against enemy aircraft.

Vertical Control Bombs

These were the free-falling bombs of the AZON, RAZON and TARZON type.

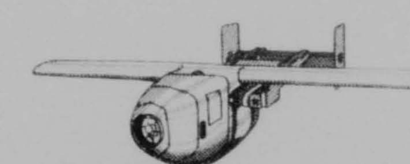
Glide Control Bombs

These were the glide bombs with or without control.

Glide Torpedo

Like the glide bombs this was a non-powered weapon which glided to sea targets—an airborne torpedo.

The Air Force guided missiles projects, in all agencies, prior to the end of the war totaled fifty-five. Of the fifty-five only the following were actually used in combat operations:



TELEVISION CONTROLLED GLIDE BOMB

GC-1—A glide bomb without control.

GB-4—A glide bomb with television control.

Abusive—Radio controlled aircraft.

GT-1—Glide torpedo.

VB-1—The AZON free falling bomb with aximuthal control only.

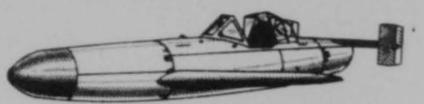
Many other guided missiles had completed the test and training stage and were ready for use when the war ended but were not used operationally.

This summarizes, briefly, the work in the United States Air Force, from the first experiments with guided missiles to the end of the war. While the program was progressing in the Air Force there was a considerable amount of work being carried on by other countries along these same lines, especially in Germany.

4. FOREIGN GUIDED MISSILES

As far back as 1932, German scientists and government officials realized the potential of rocket-propelled weapons. In that year, Walter Dornberger obtained support from the German Army to develop liquid fuel rockets for war purposes. Prior to that, other German scientists had done considerable research on rocket propulsion. Rocket research, however, should not be confused with guided missiles research. The principle of reaction (rocket propulsion) is at least two thousand years old, however, the ability to guide rockets or any other missiles while in flight is new. After the Germans had succeeded in building good rocket motors and jet-propulsion engines they turned to the development of guided missiles. They had previously tried with some success, the guiding of free-falling glide bombs by wire. However, their greatest achievements came in the field of the V-1 and V-2 missiles.

According to the strict definition of guided missiles as listed below, neither of these missiles qualifies as a true guided missile because neither could actually be guided in flight. However, the Germans were making great



JAPANESE PILOTED "BAKA" BOMB

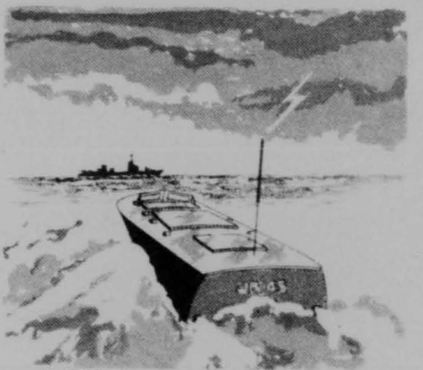
strides in this direction and it is believed that had the war lasted much longer they might have had a true guided missile in operation which could in all probability have changed or prolonged the course of the war. This fact has been reiterated by many of our military leaders, who have since viewed the work the Germans were doing at the close of the war. They had an air-to-air missile in the final stages of development which easily might have ended our air supremacy over Germany, had it proven successful.

The Germans had made attempts to control the supersonic V-2 weapon, but by the end of the war they had not been successful. Since the end of the war, American scientists have succeeded in controlling the weapon and probably our first really successful guided missiles will be similar to the German V-2 rocket.

The Japanese also attempted to introduce guided missiles into warfare. In the Pacific they used the BAKA bomb in some instances with great effect. This was a glide bomb having a small rocket motor for extra thrust. It contained a small warhead and was piloted by a "suicide" pilot. The missile was capable of being guided and might eventually have been used as a true guided missile. It could perhaps be classified as a powered glide bomb.

SECTION II—DEFINITION

Literally speaking most of the weapons known to mankind have been missiles of one form or another. Perhaps the oldest weapon was a stone thrown at an adversary. It might also be added that these missiles, prehistoric or modern, were guided in one manner or another. For example, when David hurled a rock at Goliath it was well-aimed or guided by a sling, which was in turn guided by his arm. When the earliest artillerymen, the crews of the ancient catapults, wished to control the range of their weapons, they plucked the leather thong which was used to pull the lever back and judged its tautness (therefore range) by its pitch. They too were guiding the missile in the crude, but very effective catapult. However, the term "guided missile" is now used more specifically. The missile is



T-BOAT RADIO CONTROLLED TORPEDO BOAT

considered to be a device for transporting a warhead to a selected target. By guidance is meant that the missile is controlled or guided after it has been launched. The official definition as prepared for the glossary of terms put out by the Joint Chiefs of Staff is as follows, "GUIDED MISSILE: a missile containing a device designed to steer and or change its acceleration in response to signals received during flight." (Dictionary of U.S. Military Terms for Joint Usage, dated 17 May 1948.) Even this meaning may be further defined.

A true guided missile is one which is not controlled by an automatic device which has been preset but by a device which is continually controlling the missile in its flight to seek out its target, and which can correct errors or change the course as the missile progresses along. For example: the V1 "Buzz Bomb," used so successfully by the Germans during World War II was a preset missile. Its course was set, corrections for wind were made, and the exact range (time in flight) were all precomputed. These data were then set on the controlling mechanism of the missile. When the bomb was launched from the ramp, or from the air, these timing devices made the necessary corrections. When it had flown its predetermined time, the fuel was cut off and the bomb went into a steep glide toward the target. If everything went as had been computed, the bomb would hit the target. But many factors, which occurred in flight, served to add error to error with the result that these missiles were very inaccurate. Changes in wind either increased or decreased ground speed, and altered the course. Variable airspeed characteristics of individual missiles changed ground speeds. Countermeasures either knocked many down or veered them off course. Therefore, these missiles were not really guided, but preset, missiles.

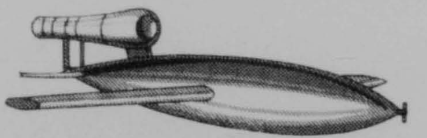
True guidance, furthermore, means that the missile is **continually controlled** and corrected without a human pilot during its entire flight to the target. "Continually controlled and corrected during flight" is a phrase which must also be further defined. (Actually on some missiles the control may not be applied until the missile is near the target; but it is capable of being controlled.) This control may come in three ways as follows:

Signals may come from an outside controller, or controllers, while the missile is in flight. In such a case a controller, or several controllers, would transmit impulses to the missile which would guide it to the target.

Signals may come from devices completely self-contained within the missile. In this case the internal devices pick up impulses from various sources and guide the missile during flight to the target. (This should not be confused with "preset" in which the devices do not "think" or react to various impulses; but do only what has been set on them prior to launching.)

Guidance as a combination of both methods. In this type the missile could be guided both by outside impulses and by its own internal mechanisms.

There are other kinds of so-called guided missiles which are continually controlled from the time of launching up to the time of hitting the target, which do not come within the scope of this course. These are land and sea guided missiles. The armies of many countries have used remote-controlled tanks as guided mis-



GERMAN "V-1" BUZZ BOMB

THIS PAGE IS DECLASSIFIED IAW EO 13526

Figure 9—3. "Homing" Device Directs Missile to Target.

siles and many navies have used remote-controlled torpedo boats as guided missiles. Perhaps these are rightly termed "guided missiles" but for the purposes of this text only those using the air or space as their zone of action will be considered.

To summarize, the definition of guided missiles as employed by the Air Force: a missile which (a) travels through the air, sometimes into space, which (b) carries no human pilot, which (c) is continually controlled, or under control (either from the outside or from internal devices) from the time of launching, during flight, and all the way to the target.

Target identification itself also may be a function of the missile. In some cases the target will be determined beforehand and the missile will be launched at the selected target. If the missile is controlled from the outside the controller will direct it to the target, but if the missile controls itself, it must have a means of locating and identifying its target. Many types of missiles are constructed to be guided in this manner.

In other cases the target may not have been determined beforehand. An example of this would be the use of guided missiles against enemy aircraft. The missile would be launched at the enemy formation and would then, either be controlled toward one of the aircraft, or it would direct itself toward one of these aircraft. For the latter method the missile must be capable of locating its own target.

SECTION III—GUIDED MISSILES DESIGNATION

1. OFFICIAL DESIGNATIONS

The following system of designating guided missiles has been officially adopted for joint Army, Air Force and Navy use. The basic designations shall be a two-letter combination of the three letters A (Air), S (Surface), and U (Underwater) in which the first letter designates the origin of the missile and the second letter designates the objective. This combination of two letters shall be followed by the letter "M" indicating "missile." The possible present combinations are:

AAM—Air-to-Air Missile
ASM—Air-to-Surface Missile
AUM—Air-to-Underwater Missile
SAM—Surface-to-Air Missile
SUM—Surface-to-Underwater Missile
SSM—Surface-to-Surface Missile
UAM—Underwater-to-Air Missile
USM—Underwater-to-Surface Missile

Each basic designation shall be followed by a service letter and the model number. For example:

A for Air Force
B for Army
N for Navy
ANG for joint use of the missile

Therefore, a missile designated as SSM-A-3b would be a Surface-to-Surface Missile of the Air Force, the third model of this series, and the second (b) modification of that third model.

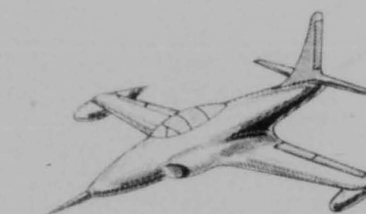
Furthermore, to designate the status of development of a missile, the following prefix letters shall be used:

X for Experimental
Y for Service Test
Z for Obsolete

If the above mentioned missiles were obsolete, it would be listed as:

ZSSM-A-3b

In cases where conventional aircraft are used as missiles, the standard or basic aircraft designation will be prefixed by the letter



MF-80—JET FIGHTER USED AS PILOTLESS AIRCRAFT

"M" to indicate "missile aircraft." For example:

MF-80 for an F-80 used as a missile

2. NORMAL CLASSIFICATION

The normal classification of guided missiles is based on the official designation as listed above. The present missiles all fall into one of the above categories.

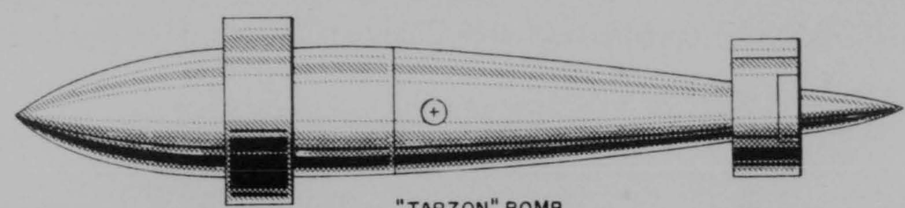
Air-to-air—Offensive

This missile is used offensively by one aircraft against an enemy aircraft. It is launched from a friendly aircraft to overtake or intercept an enemy aircraft. Air-to-air offensive missiles may be guided by many of the guiding methods to be discussed later, and will probably depend most upon internal homing devices or beam riding devices, because at the very high speeds at which they must operate, a human controller would hardly be able to correct for any changes in course. These offensive missiles generally will be supersonic since they must be capable of overtaking the fastest enemy aircraft. In some cases the target may be other high-speed missiles. Air-to-air offensive missiles will perhaps replace the guns used on today's conventional fighter aircraft.

Air-to-air—Defensive

An air to air defensive missile is used by one aircraft to shoot down an attacker. It would be used primarily by bombers in place

THIS PAGE IS DECLASSIFIED IAW EO 13526



"TARZON" BOMB

of the turret guns which were used in World War II, principally to protect the bomber from fighter aircraft and other missiles in any type of combat. Air-to-air defensive missiles must also have supersonic speed to overtake the fastest enemy aircraft and missiles.

Air-to-surface

These missiles will be launched from aircraft at a surface target and their range will vary according to the mission and the type of missile used. The carrying aircraft should be able to remain beyond the zone of enemy anti-aircraft defenses. At the present time TARZON, AZON, RAZON, and the glide bombs (to be identified later) that have been developed are missiles of this type. For air-to-surface missiles to be most effective, their range and means of control must be increased and improved. These missiles generally will take the place of aerial bombs as used in World War II. The earlier missiles in this category will be subsonic but as they improve they will be supersonic for better results. To be effective these missiles will have to be very accurate, for they will be launched at a considerable distance from the target.

Air-to-underwater

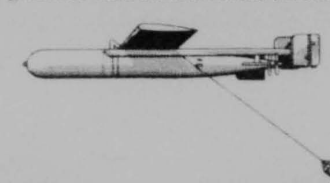
These missiles will be similar to the air-to-surface type described above, with the added capability of being able to operate underwater like a torpedo. These will be advanced models of the present aerial torpedoes.

Surface-to-air

This missile will be one of the most valuable of all the missiles under development. When scientists and military intelligence leaders went into Germany after the end of the war they found there the early models of the "Wasserfall," "Enzian," "Rheintochter," and "Feurlilie,"—all surface-to-air missiles. They stated that had the war lasted six months longer, or had our strategic bombing of German industry been less effective, the Germans might conceivably have rid the air over Germany of Allied bombers. This was not irresponsible talk, but was the considered opinion of experts. All of these missiles had been flight-tested and some had been given initial guidance trials. All of these missiles were supersonic but all development was curtailed because of the incessant aerial bombardment of Germany and the advance of the ground forces. Our 160 to 200-mile per hour "Fortresses" and "Liberators" would have had no chance at all against such opposition.

What might have been true of World War II will most certainly be an actuality if there is a World War III, because this type of missile has been improved over the work begun by the Germans, and probably will be operational in the near future.

These missiles are to take the place of anti-aircraft guns as they will afford much greater range than the standard guns, and with accurate guidance each missile should account for

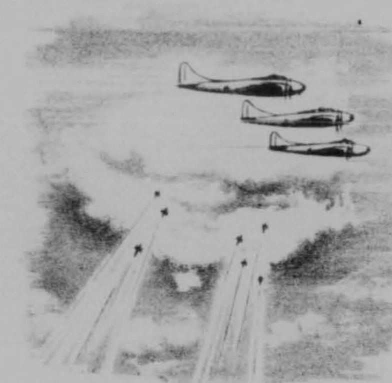


an aircraft. Because this missile can be launched from the ground and because it can be guided by several effective methods, it represents one of the "ideal weapons of warfare." A surface-to-air missile should be the perfect defense against the massed bomber formations of World War II, and when developed further should prove a valuable defensive weapon against other missiles.

Surface-to-surface

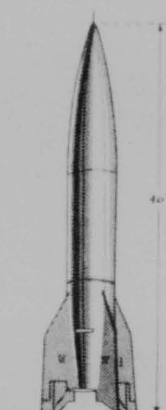
This missile perhaps represents the ultimate in weapons of war. When a missile is created which can travel 5,000 or 6,000 miles at a speed of approximately 10,000 miles per hour, and when this missile has been equipped with a guidance system which will deliver it on or very close to the target area, warfare certainly will have reached the "pushbutton" stage. Warfare then will have become so effective that after a few moments of such a war there could hardly be an opponent remaining.

Of course, the above represents the ultimate in a surface-to-surface missile. The first major attempt at a long-range missile of this type was the German V-1 "Buzz Bomb." This missile had a range of 120 to 160 miles, a warhead of less than one ton, a speed not higher than 400 miles per hour at an altitude of only 2,000 feet, and no guidance except for preset stabilizing and timing controls. The damage these missiles alone did in England during World War II was considerable, but the psychological impact of the German V-2 Rocket was even more devastating. One morning very early in September 1944 a stunning explosion sent hundreds of Londoners to their telephones to call the Ministry of Information for an explanation. There had been no air-raid warning, no sound of aircraft, not even the terrifying drone of the dreaded "buzz bomb." What had happened? To avoid giving aid to the enemy intelligence service the Ministry of Information told these callers that the detonation had been produced by the explosion of an illuminating-gas tank. The truth was almost too fantastic for belief. From a point on the European continent, perhaps two hundred miles from London, a cigar-shaped rocket forty-six feet long and six feet in diameter had been arched through space, reaching



GERMAN SURFACE-TO-AIR MISSLES
(ALL WERE IN PLANNING AND TEST STAGE)

an altitude of over fifty miles and a speed of 3500 miles an hour, before descending at a velocity many times that of sound upon a point within two miles of that at which it had been aimed. The V-2 rocket, as this second in the series of German vengeance weapons was termed, weighed fourteen tons at launching and consumed five tons of liquid oxygen and four tons of alcohol in its rocket motor. This



THE GERMAN V-2, MOST SUCCESSFUL ROCKET WEAPON OF WORLD WAR II

THIS PAGE IS DECLASSIFIED IAW EO 13526

nine tons of fuel had been consumed in the sixty seconds that the motor operated. This huge expenditure of fuel and the high cost of the rocket (in the neighborhood of $60,000) seems scarcely justified by the modest one ton of explosive which the V-2 carried as a payload. In addition, each of the 3,600 V-2 weapons launched against the Allies (2,000 at London and 1,600 at Antwerp) required six hours of elaborate preparation at the launching site prior to firing. And all of this effort despite the fact that the V-2, like the V-1, had no system of guidance in flight other than stabilization and fuel cutoff.

Weapons of the V-1 and V-2 type which are being tested today will be guided by several devices and will be much more reliable and accurate. The ratio of V weapons fired which were effective, to those which hit even close to the target, was never very high, yet they did considerable damage at no cost in lives to the Germans. Imagine what these same weapons could have done had they been more reliable and had they been guided accurately. This type will be the surface-to-surface weapon of tomorrow.

Already we have been assured of a range from five to six thousand miles; in the laboratories and on the proving stands the prototypes of these missiles are being tested. Elaborate guiding systems are being put into operation and will be ready by the time the missiles have been perfected. When fuels, temperature controls or safeguards, and methods for guidance are ready this long range "ultimate" in weapons will be ready for use. Even with the present developments the remaining technical problems are so complex that ten years would probably be considered an over-optimistic estimate on the length of time required to have these weapons in operational use.

Surface-to-underwater

This missile will be very much like the surface-to-surface missile described above with the added feature of being able to proceed to an underwater target after it has plunged beneath the water surface. In addition to being an aerial missile it will also be some form of torpedo. The surface-to-underwater missile will be used against enemy naval vessels both on and under the surface, and against enemy shipping.

Underwater-to-air

This missile will be similar to the surface-to-air missile with the added advantage that it can be fired from underwater and then after reaching the surface it will be able to launch itself into the air and seek out its target. This missile, like the surface-to-air missile, represents one of the ideal weapons of warfare, because the launching force is quite secure while the enemy would have little hope for accomplishment of his mission, or escaping.

Underwater-to-surface

Everything that was discussed about the surface-to-surface missile would apply to this missile with the additional advantage that this missile could be launched at a surface target from underwater.

SECTION IV—GUIDANCE SYSTEMS

1. ELEMENTS OF MISSILE GUIDANCE SYSTEMS

Tracking System

In order that the position of a missile in flight may be known at any time, a tracking system is used. If possible, the missile could be tracked by means of visual aids as in the case of a glide bomb. After a glide bomb has been launched the controller follows it visually and makes corrections as it drops toward its target. This system also might be used with surface-to-air missiles. The controller would follow the missile visually and make corrections with the aid of a computer. The weakness of visual tracking lies in the fact that it

is limited by the reflex time of the human controller, if the missile is being tracked for control purposes. However, in many instances the missile may be tracked merely to log its course.

A radio beam or radio direction finder may also be used for tracking purposes. In such cases the missile would emit radio impulses which would be picked up by the loop-antenna and would indicate on the radio compass the direction of travel, and could, by a method of triangulation, indicate the distance of the missile with respect to the receiving station.

The most advanced system for tracking missiles is with the use of radar. By means of a radar scope the missile may be tracked and have its direction and distance computed directly. The limit of this system is that radar range is "line-of-sight" or limited by the horizon, since radar impulses cannot follow the curvature of the earth. However, for a high-angle missile, radar could be used to plot the course for most of the trajectory.

Computing System

There must be a computing system incorporated into the guidance system of a missile in order that the controller, or the internal devices of the missile itself, may constantly keep the missile on its course at the right altitude and at the correct power setting (controlling acceleration or deceleration). This system would correspond roughly to a log kept by a navigator. It would record these data for the controller to aid him in correcting the course of the missile.

The computing system also might be given the task of determining the correct direction and distance to the target, especially if the target is moving. The computer would then contain a homing, or timing, device which would compute these facts and cause the guidance system to act accordingly.

The primary task of the computing system is to determine the course to the target.

Directing System

This system works directly with the computing system. If the missile is being guided by a controller he will direct the missile by means of this system. It may consist of a radio linked directly with the controls of the missile. In some of the missiles, planned direction was to be achieved by electrical means through a wire which was unwound as the missile sped toward its target. One advantage of using wire is that it cannot be "jammed." Whatever system is used, the directing system is that system which keeps the missile on its course.

2. CLASSIFICATION OF GUIDANCE SYSTEM

Initial

An initial guidance system will be installed to control a missile for the first part of its course. Usually this will be only for the early part of the launching or ascent, and will control the missile at its slower speeds. After the initial control, it will become inoperative. This system may be internal, acting merely as a stabilizer, or it may be operated by a controller who will direct the missile during the first phase of its flight.

Mid-course

The purpose of a mid-course guidance system will be to confine the missile to its predetermined course or flight line. This system also may be either internal or operated by a controller. If proper control can be achieved, this phase of the trajectory of the missile would benefit from a human controller, because he could make major corrections to set the missile on its proper course. After this the missile itself would perhaps make the quicker, "close-in" corrections, if properly equipped.

Terminal

This system would be responsible for the short range, "close-in" control of a missile at the time that it approached its target zone. A human controller would not react quickly enough during the close-in to make high speed corrections and the devices built into the missile would have to take over. This would most likely be a homing, or seeker, system of guidance.

3. TYPES OF GUIDANCE SYSTEMS

Present

(Although the latest definition of a guided missile does not include preset missiles as real guided missiles, there remains at the present state of development a place for mention of preset missiles.) The preset mechanisms are internal and must be set by the operator immediately before launching the missile, thereby performing three principal functions:

Stabilization. The preset device stabilizes the missile during its flight by a system of gyroscopic controls which act to prevent roll or dip in flight.

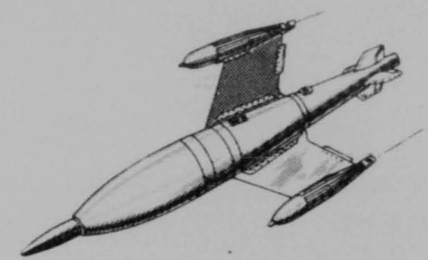
Flight Paths—Constant Altitude. This form of stabilization directs the missile on a prescribed flight path. An example of this was the V-1 weapon which maintained an altitude of two thousand feet to the target, for a given time, and in a given magnetic direction.

High Trajectory. This form of stabilization directs the missile on a prescribed trajectory which is designed to give the rocket the desired range. A timing device and a directional device direct the missile to a given target.

Command Guidance

This system employs a means within the missile for reception and execution of commands arising outside the missile.

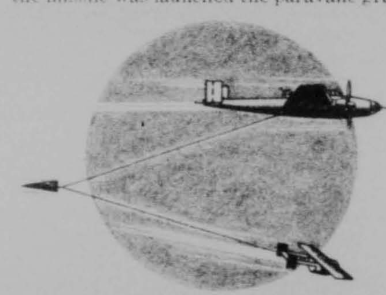
Wire. Some missiles have been designed with spools of fine wire which are unreeled as



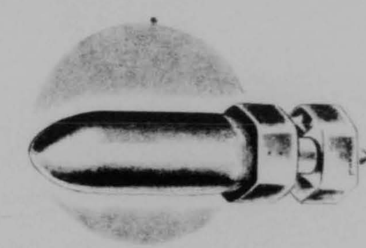
THE GERMAN X 4

the missile is launched for a distance of approximately three miles. Control of the missile is by direct electrical transmission along this wire from the operator to the control devices of the missile. The Germans had a missile of this type, the X-4, which was an Air-to-Air rocket propelled winged missile. The X-4 was a relatively small missile with a weight of about 132 pounds and was propelled by a liquid-fuel rocket capable of high speeds. The wire extended three miles giving the operator control for that distance. It had been tested and might have been a valuable air-to-air missile if the project had been continued.

There are records of a much earlier wire-controlled missile of the glide bomb type which was rather crude by present standards. When the missile was to be launched the wire was trailed out first by use of a paravane (like a wind sock). This paravane was on a wheel and pulley arrangement so that it stayed at the loop of the wire as the wire trailed out. When the missile was launched the paravane gradu-



EARLY GERMAN WIRE CONTROLLED GLIDE BOMB



RAZON AMERICAN BOMB WITH "TWO WAY" RADIO CONTROL

ally was pulled forward by the fact that the missile fell further and further below the plane, until the limit of the wire was reached. Control of the missile was again by direct electrical transmission.

Radio. Missiles designed to be controlled by radio are similar to those which are guided by wire in that electrical impulses are transmitted to the missile controlling its flight. Commands are transmitted to the missile by the controller who is directing it to the target. The early American missiles AZON and RAZON were radio-controlled free-falling bombs. As they fell toward the target they could be corrected in flight. In order to control these missiles the controller must have them in sight all the way to the target. In the case of AZON and RAZON each bomb was equipped with a very powerful flare which helped the controller follow it to the target. Radio control is limited by the ability of the controller to keep the missile on its way to the target and by his ability to keep it in sight by visual or other means. In operational use radio control runs into many troubles because "jamming" or radio countermeasures are so effective.

In the early days of World War II the Germans guided their bombers over England by radio beams. Soon however the English learned to divert these beams and to lead the German bombers astray. By 1941 the Germans had all but abandoned the radio beam system of guidance. Then by 1943 the Germans had perfected another system of radio guidance which used a number of wave lengths which permitted them to use radio-controlled glide bombs of the Heinkel type. Following this temporary success the Allies again perfected a means of jamming the system. The Germans then turned to the development of ultra-short wave control for their new surface-to-air missile, the "Schmetterling". As was stated earlier, had this missile reached the operational stage the Germans might have found the much sought-after defense against the Allied massed bomber attacks.

Each of the radio-guidance systems mentioned above is strictly a "command-guidance" system. It depended on a controller from the outside to do the correcting in flight. There are other radio-guidance methods not of this type which will be mentioned in a later section.

Television. A television system of guidance is closely allied to radio control, because the television device is used merely to aid the controller as he applies guidance by radio transmission. The television camera is mounted in the missile and picks up an image of the scene before it and transmits this information back to the operator, where it appears on suitable viewing equipment. By the appearance of this reproduced picture the operator can determine just how the controls should be moved to correct the aim of the missile. This type of equipment is suitable for self propelled missiles, glide bombs, or vertical bombs and has been tested in all three of these carriers.

At first thought this system seems to be the answer to the controller's problems. But missiles of this class have a number of serious limitations by being technically complicated, susceptible to "jamming" and interference. It is limited by the reflex action speed of the controller, which is a serious handicap to high speed operation and is satisfactory only against targets which are clearly visible on the screen. The proponents of this type of guidance, while admitting the above handicaps, point out the following very considerable advantages: First, it allows very accurate selection of the target or in some cases even the point on the target at which the bomb will be directed. Second, because this bomb is controlled by an operator, he may use his judgment in selecting the target and the path to the target, thereby avoiding decoys and perhaps interception. Of course, this re-

THIS PAGE IS DECLASSIFIED IAW EO 13526

quires a high degree of skill on the part of the operator.

These advantages, plus the availability of the equipment, make television an appealing aid to missile guidance and perhaps it will be used on many of the missiles being developed.

Direction Along a Beam (Beam Way)

For this system of guidance the missile contains all the guidance devices that are used. There is no human controller, therefore, no "command guidance." However, the beam is directed before and during the flight of the missile. A radio or radar beam is set up leading to the target. Then the missile operates somewhat on the same principle that is used by a pilot when he is making an instrument landing. The missile follows this beam, or perhaps more than one beam, to the target. In the case of radar beam the beam may be moved, steadily fixing itself on a moving target in the same way that it is possible to keep a flashlight beam on a rabbit running across a lawn at night. The radar impulses would then direct the missile to the moving target.

The great advantage of this system of guidance is that any number of missiles may be directed toward the target at the same time. The beam acts as a path along which these missiles are channeled to the target.

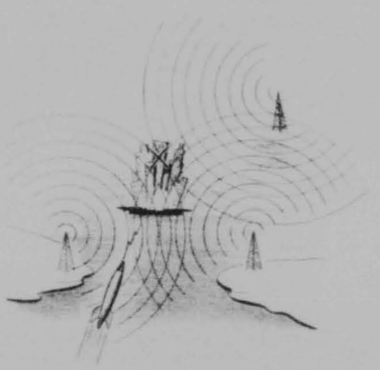
The disadvantage of the system is that most radio and radar systems are subject to "jamming," thus causing all the missiles to go astray and completely nullify the system.

Direction by Navigational Net

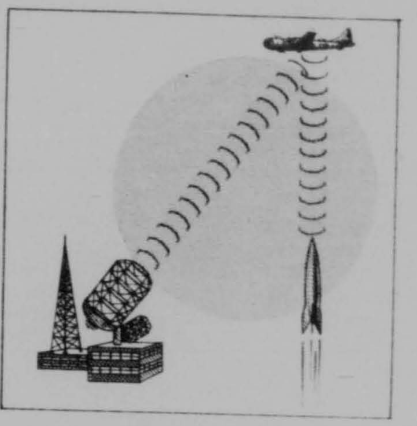
This system is closely akin to the beam way system. However, the missiles are set up to proceed along a course consisting of a series of radio navigational fixes rather than just along one beam. In this manner, it would be more complicated to jam because the enemy would have to jam every station in the net at all times. By this system the guidance equipment of the missile would operate in such a way that it would follow a series of fixes in its route to the target.

A more elaborate system of this kind is the Loran system. This is a long-range system which with present equipment is good up to eleven hundred miles, utilizing "master" and "slave" stations and accurate controlling mechanisms; but in operation it would be very effective, very accurate, and could channel any number of missiles to a given target. The "master" and "slave" stations could be widely dispersed and the launching sites need not be in the same area. All missiles would follow the same impulses and converge on the target zone, also the net could be swung so that an area target could be covered. In such a system the personnel at the launching station need have nothing to do with the localization of this rain of bombs on the target.

Another advantage of this system is that



LORAN CONTROL FOR GUIDED MISSLES



the bomb itself need not emit any signal which might give its position away to the enemy and it is also most effective in any weather. At the present time Loran navigation for aircraft is a proven, long range, all weather system.

Loran (Long Range Navigation) is, like radar, a discovery that was born of World War II but it must not be confused with radar. Loran makes use of long- and medium-length radio waves, the wave lengths on which ordinary musical or news programs are broadcast. On these waves Loran superimposes extremely short electrical impulses (one millionth of a second) emitted by several stations. Because of this method of transmission, Loran may be camouflaged as a musical program or as a news broadcast. This makes it almost impossible to detect. The only way that it could be jammed would be for the enemy to jam every broadcast that was going on, a stupendous undertaking.

Celestial Navigation System

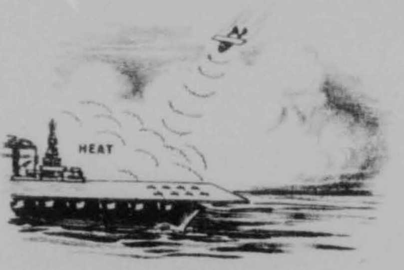
By this system the missile is equipped with an automatic device which calculates the position continuously by means of celestial navigation. In operation the route which the missile takes to the target would be set up in the missile. Then as it went along it would take continuous readings which would compare the present position with the intended position. The guidance mechanism of the missile would make any corrections that would be necessary. This system is being developed as a possible solution to long-range guidance problems. With the proper propulsion there is no limit to the range at which this type of guidance would operate. Another advantage is that there could be no jamming because there would be no radio signals.

Radar Navigation

A new type of radar guidance is being tested. This system is not dependent on radar to channel the missile to the target, but operates on a send-and-receive basis with self-contained equipment. The basic operation depends on the use of a "radar strip map." As the missile travels along the prescribed course, its guidance mechanism would "match the image" on its own scope with that of the strip map. In order for this system to be effective an extensive radar mapping coverage of target areas would be necessary. It would be of little use over ocean areas.

Homing Devices

A homing or seeking device consists primarily of a system which enables the missile to distinguish the target from the target background. There are many tested and operational homing devices integral with the missile which operate on the following principles. As the missile approaches a given target the seeker assumes control of the missile and directs it to the target. If the device is a heat seeker, it will lead the missile to the greatest source of heat in the vicinity. Similarly, if the



"HOMING" DEVICE—HEAT SEEKER

THIS PAGE IS DECLASSIFIED IAW EO 13526

device is a light seeker, it will lead the missile to the greatest source of light.

Heat (Infrared) Seekers. This type of homing device is sensitive to heat or infrared waves. The detector is capable of registering very minute quantities of heat, and of selecting the greatest quantity of heat from among a background of several sources of heat, such as the heat arising from large industrial areas, steel mills, oil refineries, etc. On a sunny day even large factories, railroad yards, railroad crossings, highway intersections, the center portions of long bridges, shore installations, docks, navy yards, etc., all give up enough heat radiation to attract these devices from a distance. These devices can become confused by a background of several thermal areas, or the atmosphere on a cloudy day may absorb or distort so much of the heat waves that the missiles would not be used to best advantage at that time. **Heat detectors are perhaps best applied to targets at sea where there is but one source of heat in a uniform background of the sea.**

Light Seekers. Another type of homing device is the light seeker. This device is set up to attract itself to the greatest source of light in the target zone. It consists of a type of optical instrument which scans the area and detects through photoelectric means the intensity and direction of a source of light. Through recent electronic improvements these devices have become extremely sensitive and can detect even the most minute amounts of light. When this light source is located, the mechanism within the missile controls the missile in the direction of the target.

Audio (Sound) Seekers. This is another application of the same idea. This time the detector is constructed to determine the direction to the greatest source of sound. This device would seem most ideally suited to detect aircraft and would probably be used in surface-to-air missiles with greatest effect. Here again a device scans the target area and determines the source of the greatest sound. Then having determined this source it would control the missile to this source.

Radar Seekers. This type of homing device operates by the use of radar. This system employs a radar transmitter to scan the target area. When the echo from the target area corresponds to the desired echo, or simply in some cases (surface-to-air) when there is an echo detected by the receiver unit, the control mechanism then takes over and directs the missile to the target. In some cases this might operate on the beam way principle, because a controller could direct a radar beam to the target and the missile could then "climb" along this beam to the target.

The guidance system is perhaps the most complex problem facing the engineer in this field today. The desirable guidance and control system will be determined by the traffic-handling ability of the system, by the range desired to control a given missile, the effect of countermeasures such as radio jamming on the control system, and the degree of accuracy which is desired of the system. Now that methods of propulsion have been improved to such an extent that even space travel is no longer referred to as something impossible, much of the over-all research and development in the guided missiles field is being concentrated on the guidance phase of study.

SECTION V—MISSILE PROPULSION SYSTEMS

1. GRAVITATIONAL SYSTEM

Gravitational propulsion is the simplest means of all. It requires no motor in the missile, depending entirely upon the gravitational pull of the earth. The force of gravity is constant, therefore, the time it takes the missile to reach the target can be computed very accurately. Of course, in order to use missiles which depend upon gravity as their only source of power, these missiles must be carried aloft by some other means. There are two types of gravity-propelled missiles: the free-falling missile, or bomb, and the glide bomb.

GLIDE BOMB LAUNCHING FROM AIRCRAFT

Free-falling Missile

The free-falling bomb or missile has no wings or other lift surfaces. It is controlled by a device in the tail. In operation, a free-falling missile must be dropped almost over the target and control is applied with just enough effect to make minor corrections. The AZON and RAZON bombs used by the Air Force during World War II were of this type, as is the new TARZON.

Glide Bomb

The glide bomb is wing supported. It may be released some distance from the target and then allowed to glide in on a course set by the controller or by the homing device in the missile. Glide bombs have been used in operation and have served as test vehicles for many types of guidance systems.

2. PROJECTILE SYSTEM

This is not a common type of missile and for the most part exists only on the planning table. However, control and perhaps even additional propulsion, added to the projectile of a big gun would have tactical significance. This form of propulsion arises from the detonation of powder inside the chamber of a gun. A missile of this sort would not have a motor.

3. RECIPROCATING ENGINE

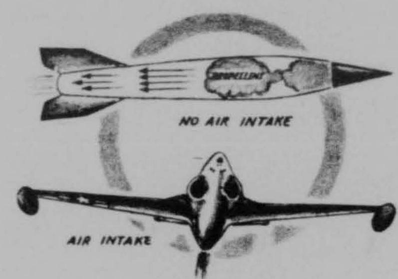
The reciprocating engine is often said to be different from the reaction engine. Such a statement should be qualified by a study of the terms. Actually nearly everything that moves operates on the reaction principle. Following this mode of reasoning closely it might be stated that a reciprocal engine is a form of reaction engine. This would not be a false assumption but it would not follow the generally accepted idea that there are two major types of internal combustion engines in use today, reciprocating and reaction (rocket and jet propulsion). Common usage, therefore, separates the two. A guided missile powered with a reciprocating engine is one which is propelled by a standard aircraft engine. These are normally radial air cooled engines or types of liquid cooled engines. These engines turn a shaft which in turn drives the propeller. Some of these engines have utilized the thrust of the exhaust for additional power. Missiles powered with reciprocating engines are propeller-driven, and are subject to the limitations of the propeller. This means that they would fly at subsonic speeds and would not be efficient at very high altitudes.

Some of the earlier guided missiles were powered with reciprocating engines. The first guided missile attempt ever made was with a model designed by C. F. Kettering; this model was powered with a reciprocating engine. During World War II the "Wearie Willie" project was initiated to utilize modified conventional aircraft as pilotless aircraft to be directed to a target by radio control and then to be directed at the target in a crash dive. These ponderous pilotless aircraft were not very successful, so the project was shelved in favor of faster missiles.

One use of reciprocating engine pilotless aircraft which was very important was the target aircraft project, which used small fast radio controlled planes as targets for anti-aircraft training. With the speed of airplanes moving through the sonic stages at the present time even these target planes of tomorrow will be jet or rocket propelled.

Recent experiments with new type propellers have shown that it may be possible for a propeller-driven aircraft to exceed the speed of sound. This had always been considered beyond the limitations of the propeller. If this should prove to be feasible the propeller driven plane with a reciprocating engine, using ad-

THIS PAGE IS DECLASSIFIED IAW EO 13526



ditional exhaust thrust or perhaps a prop jet, would seem to be a valuable addition to our air arm. However, it should not change any of the plans made for guided missiles because the speeds sought here are so much higher.

The altitude limitations of the reciprocating engine and the propeller are also to be considered. In thin air, the efficiency of the propeller is reduced and the reciprocating engine, even with a turbosupercharger is not able to operate at its best. Long-range guided missiles are planned to fly at altitudes far exceeding these limits.

Another limiting factor on the use of the reciprocating engine for guided missiles is that the missile normally is scheduled for a one-way flight. Most reciprocating engines are so complex and expensive that they could not be used economically. Whereas, new jet engines such as the ram jet are very simple to construct and inexpensive.

4. REACTION MOTORS

Here again we must accept certain common definitions in place of the overall terms that are sometimes confusing. The "Dictionary of Military Terms for Joint Usage" published by the Joint Chiefs of Staff defines "reaction propulsion" as: "A propulsion system in which a forward motion or thrust is produced by the expulsion of propellent gases through nozzles or venturi, generally longitudinally opposed to the intended line of travel." This definition in effect draws a line between the reciprocating engine and the reaction engine although they both depend upon the reaction principle for their power.

Reaction motors are commonly considered to be rocket and jet motors. Many texts and many scientists use the term "jet propulsion" for both rockets and jets. Here again we find that the definition accepted for joint military usage draws a line between the two, as follows:

Jet Propulsion

"Reaction propulsion in which the propulsion unit obtains oxygen from the air as distinguished from rocket propulsion in which the unit carries its own oxygen producing material. In connection with aircraft propulsion, the term refers to a gasoline or other fuel turbine jet unit which discharges hot gas through a tail pipe and a nozzle, affording a thrust which propels the aircraft".

Rocket Propulsion. "Reaction propulsion wherein both the fuel and the oxidizer, generating the hot gases expended through a nozzle, are carried as part of the rocket (motor) engine. Specifically, rocket propulsion differs from jet propulsion in that jet propulsion utilizes air as an oxidizer whereas rocket propulsion utilizes nitric acid or a similar compound as an oxidizer".

The difference between jet propulsion and rocket propulsion then is principally the one fact that the **jet is dependent upon the air for its oxygen** and the **rocket carries its own oxygen** as a component of its fuel.

The recent ascendancy of the reaction motor as a means of propelling aircraft has done more than any other thing to hasten the development of guided missiles. Powered with a reaction motor the guided missile can now become a tremendous weapon.

The principle of propulsion for both rockets and jets is exactly the same. There is a common misconception that the thrust from a jet engine arises from the fact that a stream of air rushing from the nozzle of the motor pushes very hard on the mass of air behind the plane, and that this "push" drives the plane forward. If this were true, then a jet plane should take off quicker if it were backed up against a wall. If this is not true then, what is the explanation?

PRINCIPLE OF REACTION - FIRST PHASE-"A BODY AT REST TENDS TO REMAIN AT REST"

The following example will help to explain how the reaction principle operates. If you were in a small rowboat in the middle of a calm lake and you had no oars, how could you make this boat go? For this example we shall say that the boat is full of large boulders weighing around forty or fifty pounds each. If you wish to make the boat move forward, you pick up these boulders and throw them over the stern, one at a time. With each one that you throw over the stern the boat will get a slight push forward. This is reaction.

Where does the push come from? If the boat were backed up against a wall or some other fixed object, you could push against the wall and the boat would move forward, or away from the wall. But this was not a wall that you could push against which made the boat move, it was a boulder which you threw overboard. But the principle is the same. The boulder has mass, fifty pounds, and every mass has inertia. As you held the boulder in your hands before you tossed it overboard it remained there by its own inertia. You were merely overcoming the force of gravity. But when you threw this boulder, **when you accelerated it,** over the stern of the boat, you put force into your action. The force which you applied to the boulder to throw it overboard was equalled by a force of exactly the same proportion in the opposite direction which constituted the boulder's push on you, or resistance to your push. This force made the boat go forward. This is the force of reaction.

$(M_1 V_1 = M_2 V_2)$

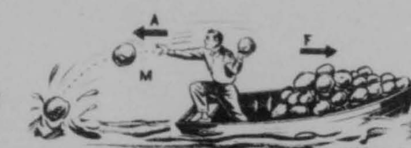
M_1 = Mass of boulder

V_1 = Rearward velocity of boulder

M_2 = Mass of man and boat

V_2 = Forward velocity of man and boat

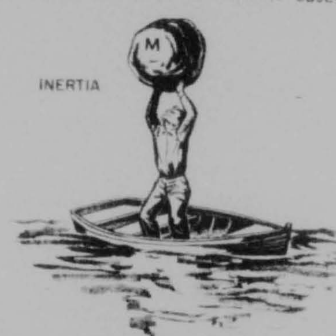
Furthermore if you just dropped the boulder overboard, you would get no force



PRINCIPLE OF REACTION - SECOND PHASE - "FOR EVERY ACTION THERE IS AN EQUAL AND OPPOSITE REACTION"

PRINCIPLE OF REACTION THIRD PHASE "THE PRINCIPLE IS READILY APPARENT WHEN PRESSURE IS APPLIED TO A SOLID STATIONARY OBJECT"

INERTIA



PRINCIPLE OF REACTION - FOURTH PHASE - A BODY AT REST HAS INERTIA AND THEREFORE WILL RESIST MOTION AND PROVIDE "PUSH" AS ILLUSTRATED IN (FIG 9-27)

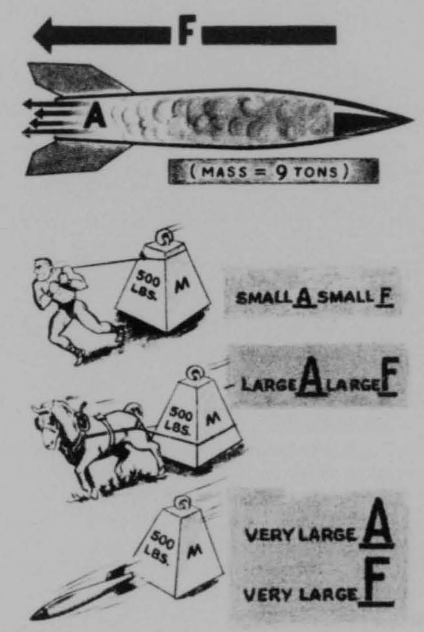
PRINCIPLE OF REACTION-FIFTH PHASE "THE MORE THE MASS IS ACCELERATED, THE MORE PUSH IT WILL GIVE IN RETURN"

THIS PAGE IS DECLASSIFIED IAW EO 13526

because you had applied no force. If you just tossed it in gently you would get a little force because you had put some push on it. But if you heaved it with all your might, you would get back an equal amount and you would find yourself catching on to the side of the boat to keep from falling, because the boat would be moving rapidly due to the acceleration from the reaction to the force that you had applied against the boulder.

This example of the boat (aircraft), the boulder (fuel and air), and you (motor) is directly applicable to guided-missile propulsion. Let us apply this to a German V-2 weapon. Here the missile (boat) contains in its tanks nine tons of propellent (boulder). When this propellent is burned by the rocket motor (you), this nine tons is expended (thrown over the rear) in from fifty-five to seventy seconds. This tremendous thrust drives this huge missile into the atmosphere at speeds up to 3,800 miles per hour. It is the same idea as the boat example. The thrust is the reaction to the force applied to throw this nine tons overboard in fifty-five seconds; it is not a result of a pressure of some sort built up outside after the gases have left the missile.

Returning to the boat idea again, we see that if you just barely push the boulder over the back of the boat, the boat receives only a little forward motion. That brings in another factor. The very important factor of acceleration. The basic law is stated, $F = MA$. This means that Force (F) equals the product of Mass (M) times Acceleration (A). If the mass remains the same (the size of each boulder is the same) then it is acceleration which must increase if you want to increase the Force. When you heaved with all your might against the boulder, you accelerated it as fast as you could. In return you received the maximum force that you, as the motor, were able to achieve. That was your rated thrust. Likewise with a rocket or jet. If the V-2, which weighs at take-off approximately fourteen tons, is to have the necessary force, or thrust, to drive it forward for 200 miles at the unequalled speed of 3,800 miles per hour, the relatively small mass of nine tons of propellent must be accelerated at the highest rate possible. This is why the type of propellent is most important. It must be a propellent which will burn

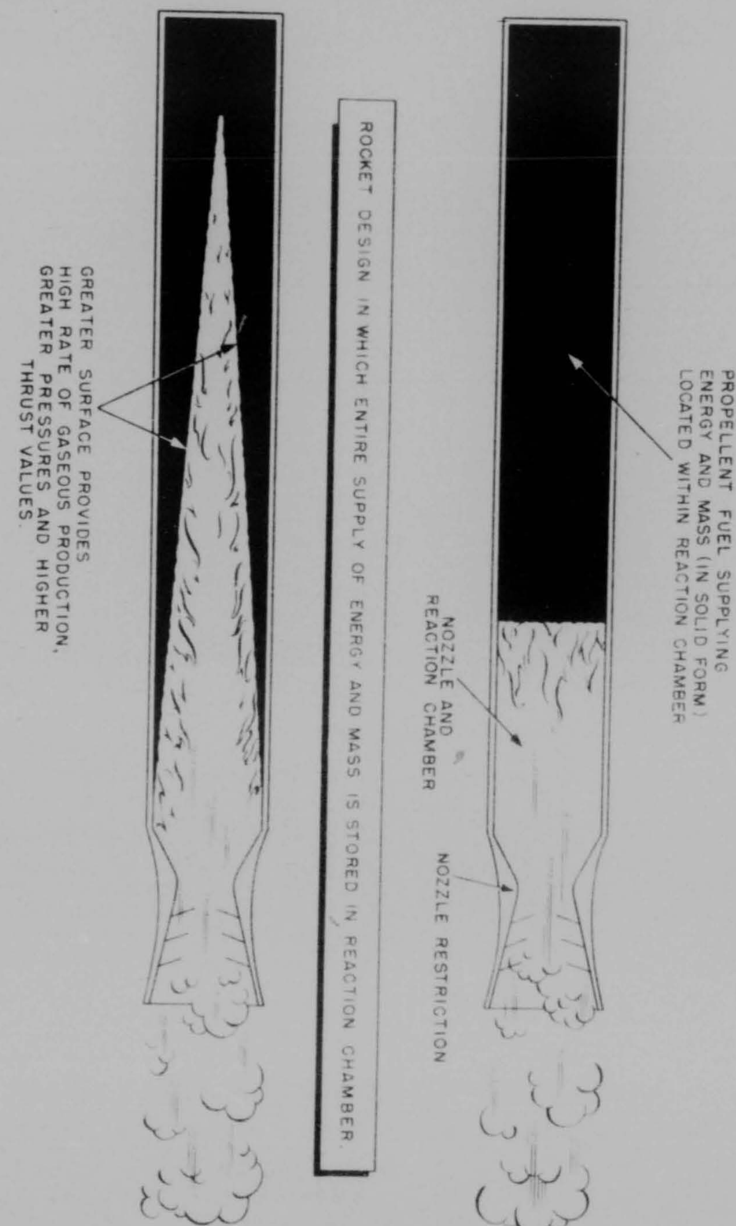


PRINCIPLE OF REACTION—IF THE MASS IS THE SAME, FORCE INCREASES AS ACCELERATION IS INCREASED

at a very high rate, rapidly enough to be consumed in fifty-five seconds, and will expand with high efficiency during the fifty-five seconds interval. The rapid expansion creates the very high acceleration required and drives the V-2 forward. The rapid acceleration is the key to successful rocket propulsion. The very high acceleration (a) multiplied with the mass (M) gives the high force (F) which propels these missiles at the highest speeds that have ever been obtained by man made objects.

Rocket Propulsion

The simple rocket motor is the easiest arrangement of all. A tube, packed tight with some slow burning powder and some sort of a wick to ignite it, is all that is required. Such a motor is centuries old. The rockets fired against Baltimore which provided the setting for our national anthem were old weapons of



THIS PAGE IS DECLASSIFIED IAW EO 13526

warfare in 1812. Today's rockets are a far cry from these powder rockets.

The modern era of rocket development dates back to the experiments of a Massachusetts college professor, Dr. Robert H. Goddard, who in 1914 began experimenting with rockets. After several experiments with powder rockets he gave them up as not practical for long range research, and devoted the rest of his time experimenting with liquid-fuel rockets. He is credited with the first successful take-off of a liquid-fuel rocket. This feat took place in Auburn, Massachusetts, on the 16th of March 1926. The history of successful rocket flight by liquid-fueled rockets dates back hardly more than a generation. It antedates the first solo flight of an airplane across the Atlantic by one year. Yet in this brief span, liquid-fuel rockets have led scientists to speak of thirty-minute transAtlantic hops, intercontinental rocket warfare, 6,000-mile controlled flights, and then even without hesitation the possibility of interplanetary travel, all because this obscure college professor had faith in liquid-fueled rockets.

Later, the Smithsonian Institute backed the work of Dr. Goddard and for a time the United States led the rest of the world in the field of rocketry. However, in the early thirties of this century Germany began to work with rockets, and several German scientists, backed by the army and the German government, experimented with them. In 1936 a great experimental program began and Germany made a bid for supremacy in the field of guided missiles. About this time, censorship was clamped down on German rocket development and not much was learned about their advances until they sent some of them over England in 1944.

A simple rocket motor is not very complicated but the liquid-fuel motor is something else. The main problem with a rocket motor is to convert the high pressure gases in the combustion chamber into a high-velocity jet. This problem is principally one of nozzle design. The shape of the nozzle through which the compressible gases are exhausted is important in determining both the mass flow and the exhaust velocity. The most common nozzle in use is the de Laval nozzle.

One should not get the impression that it is easy to design and construct a rocket motor just because the theory is simple. First of all the combustion of the propellent must occur in a very small chamber at temperatures higher than those occurring in any other type of heat engine, and that the high-temperature gases generated in parts of the motor reach supersonic velocities. In addition, the unusual chemical and physical properties of most liquid propellents introduced the designers to little explored fields of physics and chemistry.

There are three types of rockets, classified by the type of fuels used by each.

Solid Fuel. This type is known best as the ordinary fourth-of-July skyrocket. When the fuse is ignited it burns to the powder which in turn begins to burn. The slow-burning powder does not flash at once because it is not sealed, but burns continuously releasing a large quantity of gas at high temperature. The combustion of the powder builds up a high pressure in the chamber; in order to escape from the chamber the gases under pressure pass through the orifice of the nozzle at a very high rate of speed. To obtain the high speed the gases must be accelerated, the acceleration of the gases multiplied by the mass of the gases provides the thrust to drive the rocket into the air. The oxygen necessary for combustion is a part of the chemical content of the gunpowder itself. The rocket is not dependent upon the atmosphere for its combustion nor is it dependent upon the atmosphere for its "push", working most efficiently in a vacuum. This is true because, in a vacuum, the acceleration could be even higher than in the atmosphere as the atmosphere at any altitude has density and pressure which retards the emission of the gases from the combustion chamber.

The solid-fuel rocket became a familiar weapon as the "Bazooka" and as the airborne rockets which were slung under the wings of planes during World War II. These weapons travel at tremendous speeds and have great striking power. The military advantages of the power rocket are: the low cost of production, the ease with which they can be handled, and the fact that they are not easily affected

by temperature and humidity, if protected; they are easy to ship, store, install, and use.

There are disadvantages to the solid-fuel rocket which force it to play a minor role in the rocket field. First of all, unless they are packed very carefully, there is great danger that they will explode like a shell. More important, however, once the powder rocket has been ignited nothing can be done to control its combustion since it cannot be metered or throttled. This means that once the powder rocket motor has been started it will burn until all the propellent is exhausted. Also the impulse-weight ratio of the powder rocket usually is less than that of the liquid rockets. This means that over a given period of time the powder rocket gives off less thrust than the liquid rocket. The previous statement must be qualified, however, as a result of new secret developments. New propellents have been developed, and even with some of the common fuels the powder rocket was about as good as the liquid fuel rocket for the first forty seconds. After the forty seconds, however, the liquid rocket excelled.

In the field of guided missiles there will be few if any solid fuel rocket-propelled major weapons. However, the role of solid fuel rockets in warfare is increasing in other fields.

Liquid Fuel Rockets. As Dr. Goddard and the other early experimenters first learned, the liquid-propellent rocket offers the greatest promise in the field of long-range propulsion. At the present time the propellents used in liquid rockets are three or four times as effective as those used in solid-fuel rockets and better propellents are being developed. Today, one of the major problems is the motor. The very high temperatures and the extreme pressures which must be controlled at those high temperatures make the liquid-fuel rocket motor a very difficult motor to operate.

Essentially, a liquid rocket unit consists of a rocket motor, a propellent feed system, feed-system controls, and a starting system. In the feed system, one of the two schemes is generally used, a gas-pressure feed system or a pump-feed system.

A rocket motor consists of three parts:

Exhaust nozzle, which converts heat energy of the gases into kinetic energy by an adiabatic expansion process.

Combustion chamber, where the transition from the liquid phase to the gaseous phase occurs.

Injector, which introduces the propellent into the combustion chamber.

There are two types of liquid-rocket motors classified by coolant method.

Cooled (the propellent is used by the motor to absorb the heat generated).

Regeneratively Cooled. The coolant liquid absorbs heat as it circulates in ducts around the motor, after which the coolant is injected into the combustion chamber.

Film-cooled. Part of the coolant liquid is injected directly into the motor in such a way as to provide a coolant film on the inner wall surface of the combustion chamber.

Uncooled. The heat is absorbed by the heat capacity of the motor materials themselves.

Gaseous-fuel Rockets

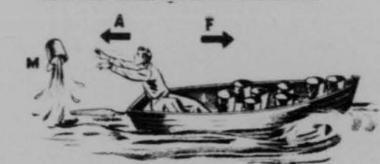
Some consideration has been given to the development of gaseous-fuel rockets. The principle is much the same as in the solid- or liquid-fuel motor. Since very little has been published with respect to this type, we shall do no more than mention it here.

In the future, rockets should develop more efficiently. First of all, new propellents (fuels) are needed to give more power. Next, there should be improvement in combustion. Under ideal conditions today the motors are about 90 per cent efficient. New alloys and other materials are being developed for rocket construction which may withstand the temperatures and stresses involved. These materials must have greater strength at high temperatures and lower heat conductivity in order that the heat will not effect the entire missile. And finally, in order to give a higher pay-load ratio, new light weight motors will be developed.

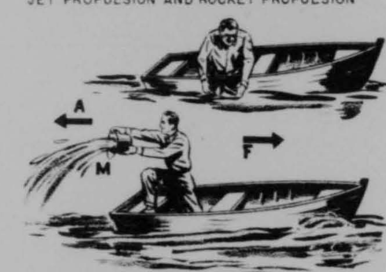
Rocket propulsion certainly offers the

THIS PAGE IS DECLASSIFIED IAW EO 13526

greatest source of power for guided missiles. Already scientists are planning for ascents of rockets beyond the earth's gravitational field. According to these authorities on missiles, there is little difference in design and performance of a space ship and an interplanetary rocket missile.



PRINCIPLE OF REACTION - THE DIFFERENCE BETWEEN JET PROPULSION AND ROCKET PROPULSION



PRINCIPLE OF REACTION - THE JET ENGINE ADDS TO THE MASS (FUEL) BY SCOOPING UP THE SORROUNDING FLUID

Jet Propulsion

The **"Dictionary of Military Terms for Joint Usage"** defines jet propulsion as "Reaction propulsion in which the propulsion unit obtains oxygen from the air as distinguished from rocket propulsion in which the unit carries its own oxygen-producing material." This definition points out the real difference between the two reaction-type engines as the fact that the jet engine is dependent upon the surrounding air for its source of oxygen, and for most of the mass which it accelerates. This means that even though both operate on the same principle, the jet could not operate in a vacuum because the fuel used must depend upon atmospheric oxygen for combustion. This implies that since the jet engine does not carry its own oxygen it operates without that extra load. This means also that the air, only 20 per cent of which is oxygen, provides the jet propulsion motor with a great mass of gas to be discharged from the exhaust, thus providing for the mass in the equation, Force = Mass X Acceleration. As an example, the J-33 engine in the F-80 utilizes $2\frac{1}{2}$ tons of air each minute. This mass of air is accelerated almost instantly by the engine from 0 miles per hour to 1400 miles per hour. The product of the mass ($2\frac{1}{2}$ tons) and the acceleration of the mass (23.3 miles per minute) gives the force or recoil, which drives the F-80.

The jet engine utilizing this mass of air at sea level where atmospheric density and temperatures are high, makes the engine relatively less efficient. As altitude is gained the mass of air processed through the engine per unit of time decreases. Thrust apparently is lost, but not in proportion to the decrease in the density. Acceleration increases due to the reduced pressure of the atmosphere at the exhaust.

Carrying out the previous example of the man in the rowboat, we might say that instead of boulders in the boat to produce reaction propulsion the man has buckets of water. As he heaves the water to the rear, he and the boat move forward — this is rocket propulsion. Now if he has only an empty bucket and scoops up water each time, and then heaves it over the stern, he and the boat will still move forward; this is jet propulsion. The water he scoops up corresponds to the mass of air which the jet engine scoops in, with the accompanying ram drag.

Jet propulsion engines are generally more complicated than rockets. In the more common types there is a compressor, a turbine, and other components. The compressor and turbine rotate at a very high speed. In fact, the high rotational speed of these units is so great that the gyroscopic forces which have to be overcome when the missile or aircraft changes course sometimes causes the engine to fail.

The turbine unit must operate at very high temperature, and except for a few special alloys no common metals will withstand the high temperature.

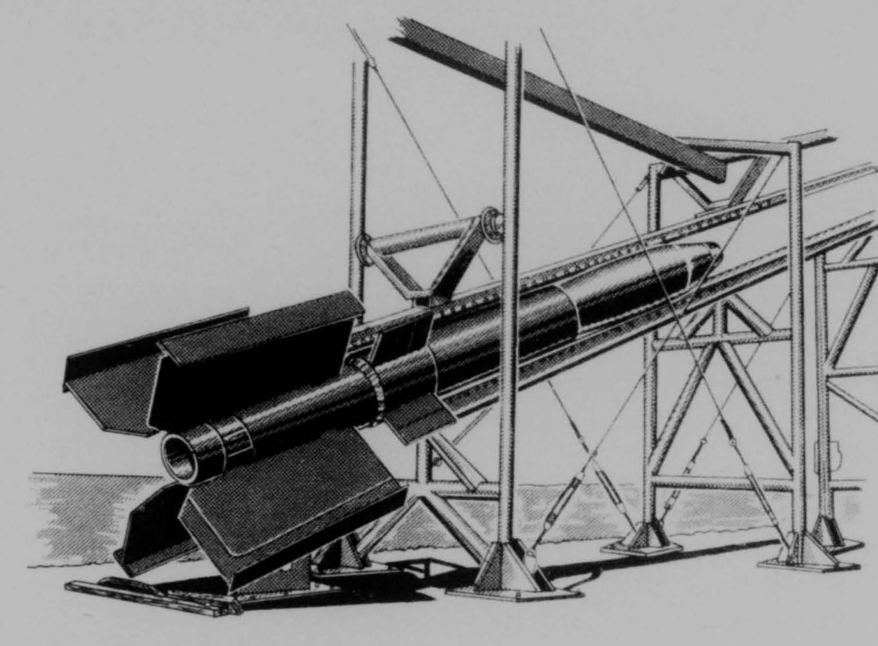


Figure 9–4. A Ram Jet on its Launching Ramp with Rocket Booster Attached

Jet engines are more simple and easy to maintain than the conventional reciprocating engine. Fuel consumption in jet engines varies from very high to low, in most cases it is quite high relative to the reciprocating engine, depending upon the altitude. At high altitudes a jet engine is more efficient on a gallon of fuel per milage basis than it is at low altitude. For example, doubling the fuel capacity of the F-80, with the addition of wing tip tanks, does not merely double the range, but triples the range. This is true because after the plane once reaches operational altitudes (30,000 feet or more), it then proceeds at much increased efficiency.

Also a jet engine may burn all types of fuel from 100-octane aviation gasoline to kerosene and even coal dust or paraffin. However, most jet engines are built to burn a certain fuel, principally kerosene; each type of fuel requires a special nozzle because the spray pattern in the combustion chamber is important.

Ram Jet

The ram jet is the jet propulsion engine which is most applicable to guided missiles. The gas turbine, either with a propeller turbo-prop or simply as a turbojet, may be very useful in missiles designed for speed from 600 to 1000 miles per hour. The German V-1 missile and several American prototypes made use of the pulse jet (intermittent or reed jet) as power plants. This type of jet motor is limited to subsonic speeds by its pulsating mechanism. Other types of jet-propulsion methods, such as the use of the exhaust gases of a conventional reciprocating engine to provide additional thrust, or the use of ducted fans with an axial flow jet engine, probably will not be used with guided missiles.

The reasons that the ram jet propulsion unit has a promising future in guided missiles

THIS PAGE IS DECLASSIFIED IAW EO 13526

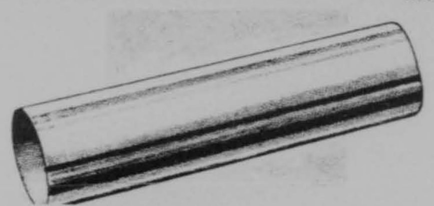

Figure 9—5. Ram-Jet Operation—Combustion in an Open Pipe. At Rest.

are: it is capable of high speeds, it is simple and cheap to construct, and at high speeds and high altitudes it is very efficient.

The main disadvantage to the ram jet is: it does not operate below 400-500 miles per hour, thus its initial operating speed must be obtained by rocket boost or some other auxiliary force.

The ram jet is so simple in construction that it has been called the "flying stovepipe." In order to explain how it functions the four following diagrams and explanations are given:

In Figure 9-5 the stovepipe is standing still, open at each end. The fuel is ignited at point A and the hot (expanded) gas escapes at each end of the pipe.

In Figure 9-6 the stovepipe is now moving forward (to the left) at 400 miles per hour, therefore, rammed air is travelling through the duct at 400 miles per hour without combustion. Now, when the heat of fuel combustion is added at point A, the expanding gas at A seeks to escape in all directions. It is opposed by the walls of the pipe, and in addition it is now opposed by the "head" of air at the front of the pipe. This means that the only means of escape is to the rear. The pressure heat produced by combustion is great and the gas has expanded so much that now it leaves the rear opening at 1400 mph. Thus the mass of air entering at the front is rapidly accelerated to produce thrust.

In actual operation the ram jet has a divergent nozzle in front. This nozzle raises the pressure of the air while decreasing its velocity inside the "pipe" and allows more heat to be added. Also the discharge nozzle is convergent, which increases the velocity of the issuing jet stream. Now as the ram jet goes faster the entry "head" is greater. This cuts

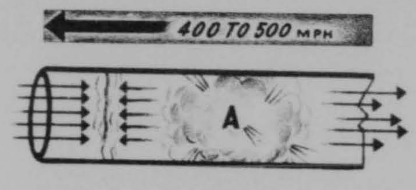

Figure 9—6. Ram-Jet Operation—Moving at 400-500 MPH. There is a Head of Air in the Front of the Pipe Which Resists Expansion (Acceleration) in That Direction.

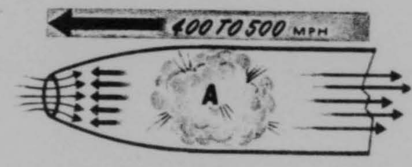

Figure 9—7. Ram-Jet Operation—Divergent Entry Nozzle Orifice Raises the Pressure of the Air "Head."

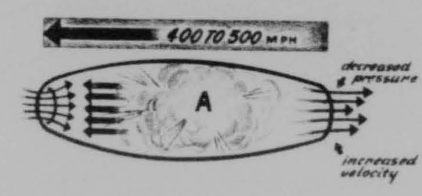

Figure 9—8. Ram-Jet Operation—A Convergent Discharge Nozzle Increases the Velocity of the Air Leaving the Engine.

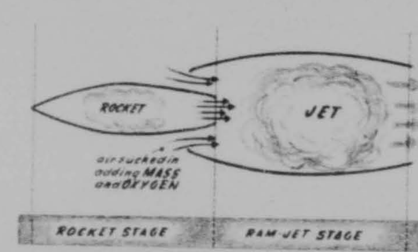

Figure 9—9. Rocket Ram-Jet Combination.

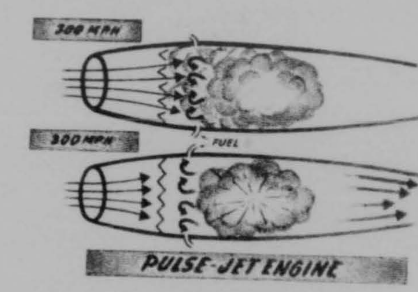

Figure 9—10. Pulse-Jet Engine.

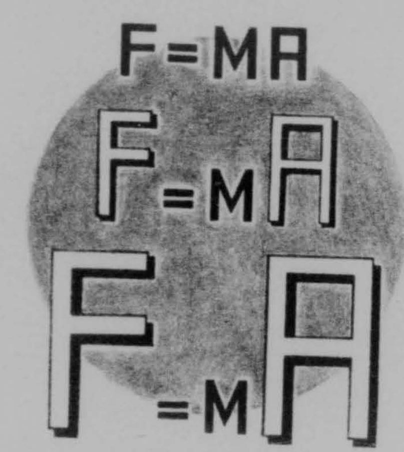
down on the escape of gas to the front and adds to the velocity of the jet stream. Again the ram jet goes faster; the "head" is greater; and the acceleration is greater. Thus the ram jet lives up to its reputation—"The faster it goes: the faster it goes!" All because F—MA.

Where does this end? What is the limit? The answer is truly amazing. First of all, the ram jet must be launched by some thrust other than its own. To launch it requires an abundance of fuel (probably rocket propellent). Next, at low speeds ("low" for a ram jet—500 to 800 mph) the ram jet uses fuel rapidly. However, as it reaches extremely high speeds at very high altitudes the unbelievable happens. The ram jet unit itself gets so hot from "skin-friction" (atmospheric friction on a high velocity body, i.e., meteorites) that this heat provides heat for expansion of the air and little fuel is required. So now we find that the fuel-hungry jet has proven itself to be highly efficient.

There is a limit to this, however, for at this very high speed the temperature of skin friction is so high that the ram jet operates at white heat and soon collapses. In order to benefit from this potential advantage of the ram jet, research will have to create metals which will withstand these extreme temperatures. Despite the magnitude of this task there is hope that it will be achieved. A rocket-ram jet combination, first proposed by a French inventor in 1922, may develop into a very successful power unit for very high speed missiles. This combination would save propel-



lent in getting the missile out of the atmosphere, or would greatly increase range in the atmosphere.

Pulse Jet

All other jet propulsion engines suffer in comparison with the ram jet for simplicity and performance. However, the V-1 bombs made the world realize that the pulse-jet engine is an excellent propulsion unit. This engine can also be compared to a stovepipe, with the addition of shutters.

This pulse jet has a convergent nozzle in front similar to the one used on the ram jet. It also has tailpipe nozzle. The principal difference is the addition of the shutters between the front nozzle and the point of combustion. These shutters are spring-steel wedges, the tips of which touch each other when no air is entering between them. To start the pulse jet, compressed air is forced between these shutters and fuel is added to the combustion chamber. The fuel and air mixture is then ignited. When the expanding gases force against the wedges from the rear, the wedges close and the gases must be ejected through the tail nozzle. As the gases are exhausted the momentum of the exhausting gases lowers the pressure in the chamber, thus allowing a fresh charge of air to enter and the cycle repeats. In flight the incoming

THIS PAGE IS DECLASSIFIED IAW EO 13526

air forces its way between the shutters at about 2,800 cycles per minute. It was this intermittent cycle which made the buzzing sound that gave these bombs the name "Buzz Bombs."

Because of this intermittent burning and the shutter system the pulse jet does not exceed the speed of sound. As a propulsion unit for guided missiles it has its uses, but in the future, with speed being the element in demand it will not be able to compete with the ram jet and the rocket.

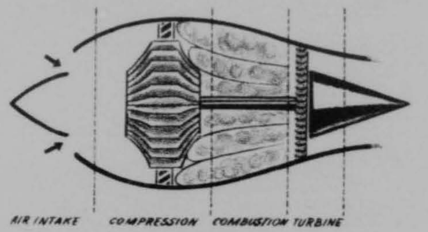
Gas Turbine

The gas turbine is also a jet-propulsion unit of great thrust potential, but at the present time a study of this engine is perhaps better suited to the Aeronautics section, because this engine is presently used predominantly in aircraft units. It can be well adapted to guided missiles; and several specially designed units are being used.

5. NUCLEAR POWER

The Nuclear Energy for the Propulsion of Aircraft (NEPA) Project is one of the most ambitious of the many projects supported by the Air Force. The contract for this project has been assigned to the Fairchild Engine and Airplane Corporation with the cooperation of the aircraft industry and the nation's atomic scientists. The utilization of atomic energy for aircraft or guided missile propulsion is considered to be predominantly an engineering problem rather than a problem of new scientific discovery.

One of the main advantages in the use of atomic power is that it provides an almost inexhaustible "fuel" or heat source. This, in a field that is especially handicapped by high fuel-consumption problems, is most important. In any missile propelled by nuclear energy the fuel supply would remain nearly constant. Enough fuel to start the reaction would



TURBO-JET ENGINE

be sufficient for sustained operation. However some "mass" would have to be carried for this nuclear fuel to accelerate.

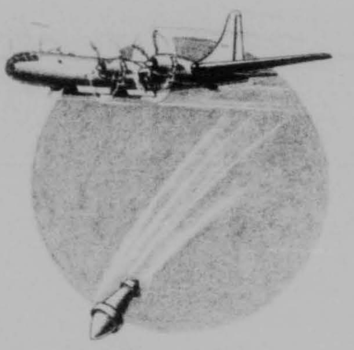
A major problem confronting the engineers is that which is concerned with protecting the crew and instruments from radiation damage. Of course, in a guided missile there is no crew to be considered, but a considerable amount of shielding would be necessary for the mechanism and instruments of the missile. Shielding is required to stop the radiation originating within the reactor, or chain-reacting system which it uses for power purposes. The stopping of electrons is no problem but the stopping of gamma rays and neutrons requires large masses of material. "Canning" the uranium block in the reactor is necessary to prevent the escape of violently radio-active fission fragments beyond the protection of the reactor shield.

When nuclear energy is adapted to missile power plants it probably will be in these types: steam or mercury turbine; turbo jets or gas turbines; ram jets; and rockets.

To date any such development would require a missile the size of the B-36. It will take many years of extensive technical development before nuclear energy is harnessed for missile propulsion. However, the outlook is promising, and the use of atomic energy will certainly make distance a minor factor in missile travel because of the large quantities of power it will develop.

SECTION VI—LAUNCHING METHODS

Because most guided missiles are designed for supersonic flight, the problems of launching these missiles are in most cases quite complicated. In order to study the various means employed, the classification of launching methods will follow the same general outline as assigned to the missiles themselves, i.e., air launched, surface launched and underwater launched.



TARZON

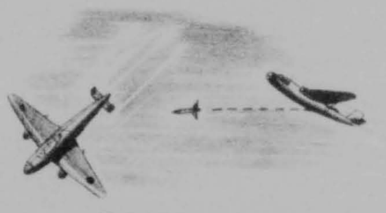
1. AIR LAUNCHED

Gravity

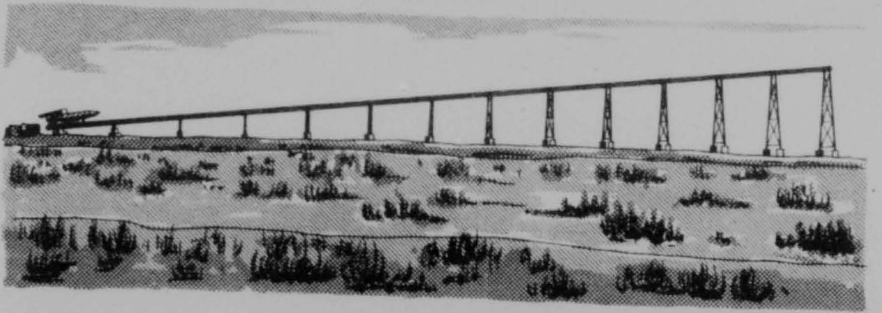
In this case the missile is dropped from the aircraft as a bomb. No further aid is applied during launching. The AZON and RAZON bombs, and the various glide bombs come under this category.

Rocket or Jet Propulsion

This missile carried by the launching aircraft is brought to the desired altitude and air speed. At the time of launching, the missile is accelerated by additional rocket charges. It is currently launched from under the wing or fuselage of the carrier aircraft.



JB-3 AIR-TO-AIR MISSLE



INCLINED LAUNCHING RAMP

Because of the drag on the carrier aircraft which is induced by the launching equipment (guide rails, brackets, etc.), the carrying aircraft is limited in speed. However, new methods are being considered whereby the missile may be carried partly, or completely, within the carrier aircraft.

2. SURFACE LAUNCHED

Gun

In the event an operational guided missile is developed which will operate inside the artillery shell, the missile will be launched from the gun which normally fires this type of shell. The actual launching will be the result of the combustion of the powder in the weapon the same as in the case of any shell being fired from a gun.

Runway

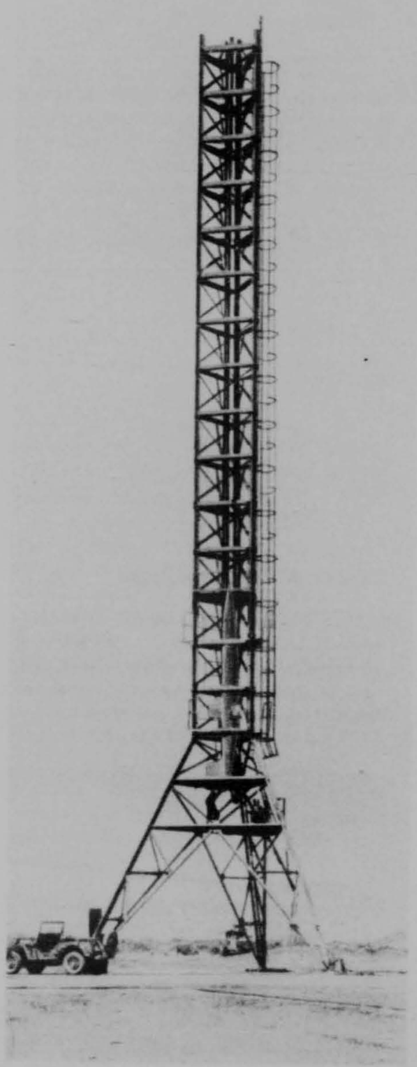
Guided missiles which are similar to conventional aircraft utilize runways for takeoff. They are launched under their own power. The system is subject to certain limitations in that jet- or rocket-propelled guided missiles will not operate efficiently at sea level, and much valuable fuel weight will be expended if this system is required.

Catapult

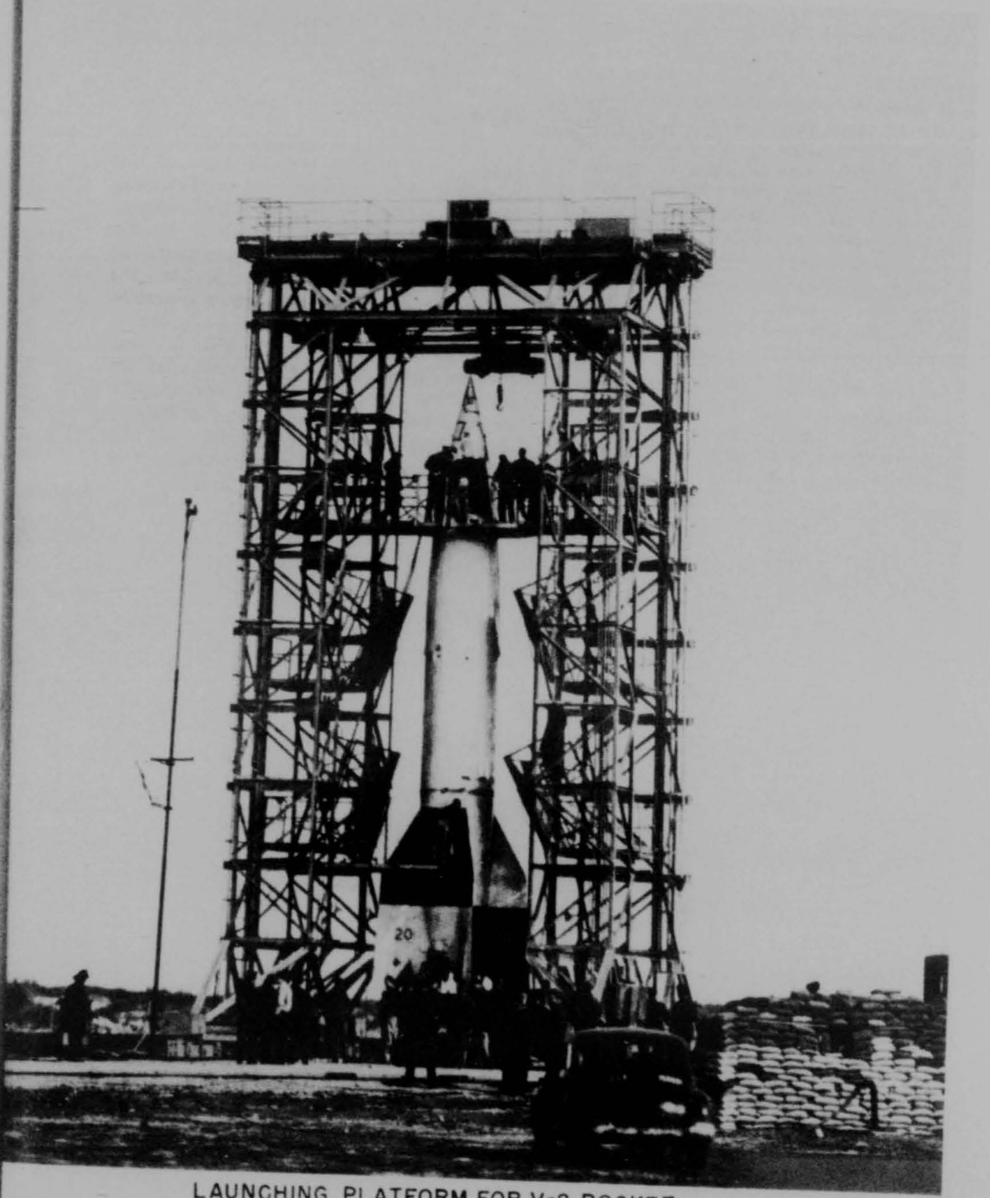
Naval aircraft have been launched successfully from catapults for years. These catapults have been powered by steam, electricity, compressed air, and other mechanical means. Powerful new catapults have been successfully used to launch guided missiles. Catapults are subject to the same limitations which curtail the use of runways for guided missiles. However, they do have the added advantage of providing rapid acceleration in a small distance, and in the case of naval vessels they enable the ship to launch guided missiles without a flight deck.

Ramp

The ramp combines features of the runway and catapult, being especially constructed for use in launching guided missiles. There are two general types.



VERTICAL LAUNCHING RAMP



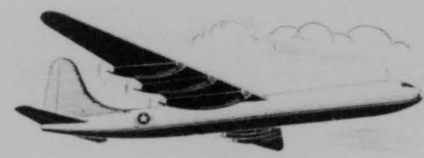
LAUNCHING PLATFORM FOR V-2 ROCKET

Inclined Ramp. This ramp is constructed to give lift to the guided missile as it takes off. The German V-1 was launched from a carefully prepared ramp which was built, aiming at the proposed target. The length of the ramp was determined by the amount of acceleration which was available to launch a given missile into self-sustaining flight. If the acceleration could be increased, the length of the ramp could be decreased. The limit would be either the amount of acceleration available, or the amount of acceleration the guided missile and its instruments could withstand. It is evident that the inclined launching ramp is an aiming device as well as a launching device.

Vertical Ramp. Some guided missiles are launched by means of a vertical ramp which supports the missile during the first part of its course. This type of ramp does not direct the guided missile to its target. Neither does it give it any increased acceleration. Its purpose is to help the missile during its initial vertical movement so that it will not topple or weave off course.

Platform

Vertical launching for high altitude, high-speed guided missile is the most practical. The missile is placed upright on a platform (cement base). Then by its own power it gradually accelerates vertically until it reaches high operational speed. During this method of launching, acceleration is kept low and the structural difficulties of high acceleration launching are avoided. Also, since a launching track is not necessary, the installation is simple and highly mobile. Furthermore, as the sonic flight velocity is passed very rapidly in an almost vertical trajectory, the difficulty of stabilization and control is minimized. For rocket propelled guided missiles this type of launching is perhaps the most feasible.



CONTINENTAL AIR COMMAND
MITCHEL AIR FORCE BASE, NEW YORK
8 June 1949

ConAC Manual 50-11 Vol. III is published for the information and guidance of all concerned. It will be used in conjunction with the current program of instruction pertaining to Air Force ROTC Training.

BY COMMAND OF LIEUTENANT GENERAL WHITEHEAD:

GORDON P. SAVILLE
Major General, United States Air Force
Vice Commander

HEADQUARTERS — OFFICIAL — CONTINENTAL AIR COMMAND

OFFICIAL:

NEAL J. O'BRIEN
Colonel, United States Air Force
Adjutant General

This publication has been reproduced in quantities sufficient only to meet the requirements of the Continental Air Command and the distribution of information copies in accordance with paragraph 5c, AFR 5-22A. Additional copies will be requested in accordance wth paragraph 5c, APR 5-22A.

THIS MANUAL SUPERSEDES ConAC Manual 50-140-1 Vols. I, II, III.

Preface

THIS textbook has been prepared specifically for the college or university student who is participating in the Air Force ROTC program. It is one volume of a series designed to qualify him as an officer specialist in the United States Air Force.

The text is planned to indoctrinate the officer candidate in the fundamental principles of Air Force Armament, rather than to present a detailed treatise of the entire complex field.

In order to achieve maximum efficiency and effectiveness in the performance of his duties, the Air Force officer must be constantly aware of new developments in his specialty and its allied fields. A receptive mind, nurtured by supplementary research and reading, can be a vital force in the personal and professional development of the officer specialist throughout his career.

THIS PAGE IS DECLASSIFIED IAW EO 13526

TABLE OF CONTENTS

CHAPTER 1—PRINCIPLES OF RADAR

SECTION I—ELEMENTS OF RADAR

1. GENERAL

Definition. Radar is an application of radio principles by means of which it is possible to detect the presence of objects, to determine their direction and range, and to recognize their character.

Principle. Detection is accomplished by directing a beam of radio-frequency energy over a region to be searched. When the beam strikes a reflecting object, energy is **reradiated.** A very small part of this reradiated energy is returned to the radar system. A sensitive receiver located near the transmitter can detect the echo signal and therefore the presence of the object or target. The determination of the actual range and direction is based on the facts that radio-frequency energy travels at the **constant velocity of light** and that the receiving system can be made directional.

THIS PAGE IS DECLASSIFIED IAW EO 13526

2. APPLICATIONS OF RADAR

Search

Tactical operations are based on the available knowledge of the enemy's dispositions and movements. Radar can be of extreme importance in providing a continuous flow of accurate information to the commanding officer. The initial location of the enemy and subsequent reports up to the time when action is finally joined is accomplished by search radar.

The problem of locating aircraft targets differs from that of locating surface targets in that the reflecting surface of an aircraft is small compared to that of a naval vessel. Also, since the speed of the aircraft is much greater, information is required at greater ranges in order to take effective action. This factor necessitates the use of early-warning radar for aircraft search. Such systems are intended to determine **range** and approximate **azimuth.**

The accurate-reporting systems permit the location of the target more accurately than do the early-warning systems. A means of measuring altitude is usually included in this type of equipment so that the target position is known in three dimensions. When the available data is used to direct fighter aircraft in the interception of the target, the name ground-controlled **interception** (GCI) is sometimes applied.

The location of surface craft involves the determination of only their range and azimuth. Surface-search radar is employed largely to provide the initial warning of the presence of such targets and to keep track of later movements. Since the speed of surface craft is relatively slow, exact data is not of great importance.

Fire Control

The problem of antiaircraft fire control requires accurate information on **range**, **azimuth**, and **elevation**. The maximum range of radar systems used for this purpose is limited to about 40,000 yards. The radar system is normally linked closely with the guns to be controlled because of the relatively short time during which an aircraft target is within firing range.

The problem of fire control against naval vessels is simpler from the standpoint of determining position and because of the much lower speed of the target. Fire-control systems for use against surface targets measure range and azimuth only, but to a high degree of accuracy. The data is used to compute the firing problem, and the results may be used by widely separated gun batteries.

Fire Control Air-to-Air. Radar is used in conjunction with remote-controlled turrets on aircraft. It provides two important functions: search and gun laying. The indicator of the radar set will present to the gunner information which indicates position and range of the attacking aircraft.

Airborne Use

One of the most important uses of radar is as an aid in the patrol of shipping lanes in search of enemy vessels. Aircraft-to-surface vessels (ASV) radar is able to increase the zone which can be searched by extending the range at which surface targets can be detected well beyond the visual limit. In addition, ASV provides an accurate means for guiding the patrol aircraft directly to the target.

Fighter aircraft can be directed to the general vicinity of the enemy planes by means of early-warning systems, but, unless conditions of visibility are adequate, they may completely miss the target. Aircraft-interception (AI) equipment in the fighter plane permits the crew to locate the enemy at short ranges and to close to the attack. The additional weight of the equipment and the need for an operator requires a special fighter aircraft known as the "night fighter."

Radar Bombing. Modern bombing attacks require that the presence and location of the target be known irrespective of atmospheric conditions and time of day. Radar has provided a source of such information. Bombing techniques involve the use of radar in several ways: (1) Radar sighting by observing the target on the scope. (2) Synchronous sighting with the radar set supplying the sighting information to the bombsight computer. In radar sighting, the slant-range, bomb-release

chart is used to determine the exact instant of bomb release. In synchronous sighting, a bomb-release chart is used to determine specific sighting angles from the plane to the target. The bombing methods just discussed are called direct bombing because they involve aiming directly at the target. However, this is not always practical for there are times when the target does not show up well on the radar scope. At such times, offset bombing is used. In this method, some object that shows up well on the scope and is near the target is taken as the aiming point, and the calculations are based around that point even though the bomb is still directed at the target.

Identification—Friend or Foe (IFF)

Although radar can locate an object such as an aircraft or vessel accurately, it cannot distinguish between friend and enemy. This inability is particularly dangerous in fire-control systems, since the firing may be completely blind much of the time.

Identification—friend or foe (IFF) equipment is used as an auxiliary to radar to identify friendly craft. The IFF system, located on the craft, receives from the radar location a challenging signal by radio means and returns a reply, either visually or by radio. IFF techniques are much the same as those of radar.

Navigational Aids

Radar is in itself a form of navigational equipment, since objects can be located with it. When the objects, such as mountains and prominent buildings, can be recognized, the movement of the vessel or aircraft can be guided accordingly.

Radar beacons are used to supplement the natural fixed targets which act as reference points. Beacons are similar to IFF systems in that they receive signals from the radar set and return other signals to it. Each installation has its own code to identify its location. Therefore, the use of beacons is an improvement over the use of fixed targets.

Radar altimeters are special radar systems used to measure the height above the surface of the earth. Such devices are called absolute altimeters because they measure the true distance to the earth without reference to sea level or barometric pressure. Since range is the only form of data required, and since the earth's surface is the target, altimeters are small and relatively simple.

3. RADAR METHODS

Continuous-wave (c-w) Method

One method of detecting a target makes use of the Doppler effect. When radio-frequency energy which is transmitted continuously strikes an object which moves toward or away from the source of energy, energy is reflected and its frequency is changed. The change in frequency is known as the "Doppler effect." A similar effect at audible frequencies is recognized readily when the pitch of the whistle of a train is heard as it approaches or leaves the listener. The radar application of this effect measures the difference in frequency between the transmitted and reflected energy to determine the presence and speed of the moving target. This method works well with fast-moving targets, but not with those which are slow or stationary. (C-W) systems are therefore limited in present usage.

Frequency-modulation Method

If the frequency of the transmitted energy is varied continuously and periodically over a specified band, the frequency of the energy being radiated by the antenna differs from that being received from the target. This difference occurs because of the time required for the energy to reach the target and return. The frequency difference depends on the distance traveled, and can be used as a measure of range. Moving targets produce a frequency shift in the returned signal because of the Doppler effect which affects the accuracy of range measurement.

Pulse-modulation Method

The radio-frequency energy can also be transmitted in short pulses whose time duration may vary from 1 to 50 microseconds (millionths of a second). If the transmitter is turned off before the reflected energy returns from the target, the receiver can distinguish

THIS PAGE IS DECLASSIFIED IAW EO 13526

between the transmitted pulse and the reflected pulse. After all reflections have returned, the transmitter can again be turned on and the process repeated. The receiver output is applied to an indicator which measures the time interval between the transmission of the energy and its return as a reflection. Since the energy travels at a constant velocity, the time interval becomes a measure of the distance traveled or range. Since this method does not depend on the relative frequency of the returned signal or on the motion of the target, difficulties experienced in the c-w and frequency-modulation methods are not present. The pulse-modulation method is used almost universally in military and naval applications. Therefore it is the only method discussed in this manual.

4. DETERMINATION OF RANGE

Time-range Relationship

The successful employment of pulse-modulated radar systems depends primarily on the ability to measure distance in terms of time. Radio-frequency energy, once it has been radiated into space, continues to travel with a constant velocity. When it strikes a reflecting object there is no loss in time, but merely a redirecting of the energy. Its velocity is that of light, or, in terms of distance traveled per unit of time, 186,000 land miles per second, 162,000 nautical miles per second, or 328 yards per microsecond.

The constant velocity of radio-frequency energy is applied in radar to determine range by measuring the time required for a pulse to travel to a target and return. For example, assume that a 1-microsecond pulse is transmitted toward an object which is 32,800 yards away. Figure 1-1 shows conditions at the instant the pulse is radiated. When the pulse reaches the target, it has traveled 32,800 yards at 328 yards per microsecond, and therefore 100 microseconds have elapsed. Figure 1-2 shows the pulse arriving at the target. The pulse is then reflected, and energy is returned over the same path. Since the return trip is also 32,800 yards, the required time of travel is again 100 microseconds. Figure 1-3 shows the pulse returned to the radar system. The

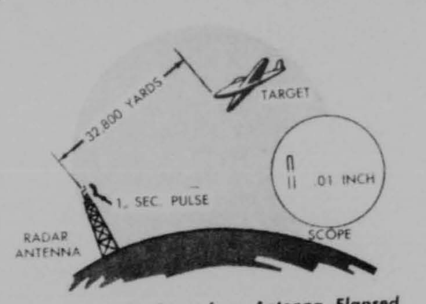

Figure 1—1. Pulse Starts from Antenna, Elapsed Time = O.

total elapsed time is 200 microseconds for a distance traveled of twice the actual range of the target. For radar ranging therefore, the velocity is considered to be one half of its true value, 200 × 164 = 32,800 yards.

Time Measurement

To employ the time-range relationship, the radar system must have a time-measuring device. In addition, since there may be more than one target in the region under search, some means of separating and identifying pulses must be included. The cathode-ray oscilloscope is well suited to such a task, since it retains the information on its screen and also forms a time scale. The time scale is provided by using a linear sweep to produce a known rate of motion of the electron beam across the screen of the cathode-ray tube.

The measurement of time is illustrated in the following example. Assume that a cathode-ray tube is used with a horizontal linear sweep which produces a beam whose velocity across the screen is 1 inch per 100 microseconds. The signals received from a target at a range of 32,800 yards are applied to the oscilloscope as a vertical deflection. Following the same sequence of operations as in the previous illustration, Figure 1-1 shows the radio-frequency pulse leaving the radar antenna and the sweep just starting across the screen. Since 1 microsecond has elapsed, the leading edge of the pulse has moved 328 yards from the antenna, and the sweep trace has moved 0.01 inch across the screen. The pulse is shown on the screen as a vertical deflection, since the receiver detects the pulse which is supplied

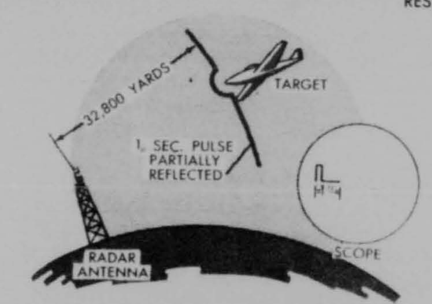

Figure 1—2. Pulse Reaches Target, Elapsed Time = 100 μ Seconds.

to the transmitting antenna. After 100 microseconds elapsed time the pulse reaches the target 32,800 yards away, and the sweep trace has moved 1 inch (Figure 1-2.) Since the pulse energy is out at the target, there is no deflection of the trace vertically. The reflected pulse returns to the radar antenna at the end of 200 microseconds, during which the sweep trace has moved a total distance of 2 inches. For the length of the received pulse (1 microsecond) the trace is deflected vertically Figure 1-3. Thus, with a constant sweep-trace velocity of 1 inch per 100 microseconds, a time scale is produced which is equivalent to 100 microseconds times 164 yards per microsecond equals 16,400 yards per inch of trace. If another target returned the transmitted pulse in 300 microseconds, the return signal would be indicated 3 inches from the start of the sweep, and the range of the target would be 300 × 164 = 49,200 yards.

The single-trace illustration used will not persist on the oscilloscope screen for sufficient time to be useful. Therefore, it is necessary to repeat the pulse transmission and the sweep trace periodically. If the two operations are made to start in the same time relation each time, signals returned from a given target will be superimposed on each other by successive sweep traces. The signals from all targets will be shown on the oscilloscope in their proper sweep-time-range positions (Figure 1-4).

5. DETERMINATION OF AZIMUTH OR BEARING

The measurement of the direction of a target from the radar system is usually given as

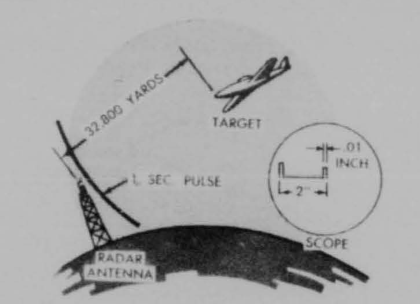

Figure 1—3. Pulse Returns to Radar, Elapsed Time = 200 μ Seconds.

an angular position. The angle may be measured from true north if the installation is stationary, or with respect to the heading of a vessel or aircraft containing the radar set. The angle at which the echo signal returns is measured by utilizing the directional characteristics of the radar antenna system.

The dimensions of the individual radiating element (the dipole) cause it to send out more energy in some directions than in others. When several elements are used togther to form an antenna system, the energy is further concentrated. Radar antennas are constructed of radiating elements, reflectors, and directors to produce a single, narrow beam of energy in one direction. The pattern produced in this manner permits the beaming of maximum energy in a desired direction.

The transmitting pattern of an antenna system is also its receiving pattern. An antenna can therefore be used to transmit energy, to receive reflected energy, or both.

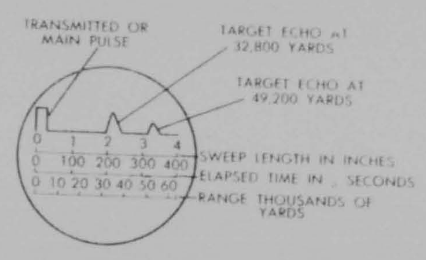

Figure 1—4. Range Indication of Several Targets.

THIS PAGE IS DECLASSIFIED IAW EO 13526

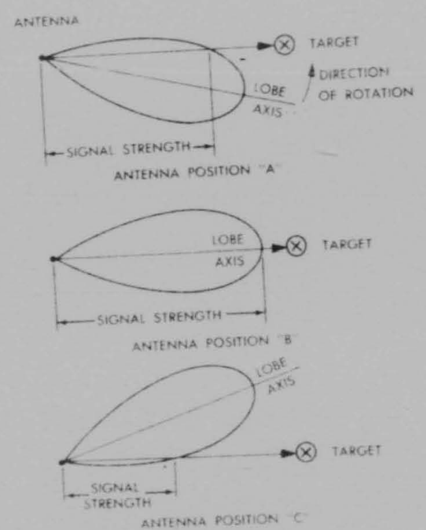

Figure 1—5. Relationship Between Beam Axis and Target Bearing.

Single-lobe System

The simplest form of antenna for meas- uring azimuth or bearing is one which pro- duces a single-lobe pattern. The system is mounted so that it can be rotated. Energy is directed across the region to be searched, and the beam is scanned in azimuth until a return signal is picked up. The position of the antenna is then adjusted to give maximum return signal.

Figure 1-5 shows the receiving pattern for a typical radar antenna. In it, relative signal strength is plotted against angular position of the antenna with respect to the target. A maximum signal is received only when the axis of the lobe passes through the target.

The sensitivity of the single-lobe system depends on the angular width of the lobe pattern. The operator adjusts the position of the antenna system for maximum received signal. If the signal strength changes rapidly with angular rotation, the accuracy with which the on-target position can be selected is great. Thus, in Figure 1-5, the relative signal strengths "A" and "B" have very little difference. If the energy is concentrated into a narrower beam, the difference is greater and the accuracy better.

Double-lobe System

Figure 1-6A shows that the signal strength varies more rapidly on the side of the lobe than near the axis. The greatest rate of change of signal strength per degree of rotation occurs between the angles which gave 50 and 85 per cent of maximum. Radar systems designed for gun laying or fire control require the highest possible accuracy in measuring azimuth angles. Figure 1-6. The double-lobe system achieves this accuracy by using two lobes to form the antenna-system pattern.

The principle of the double-lobe system is illustrated by using two separate antennas whose lobe axes are displaced by some angular distance (Figure 1-6B). The two lobe patterns intersect at one point only, known as the crossover point, at which equal signals are produced by the two antennas for this particular azimuth. At all other positions of the array unequal signals are produced.

The use of two lobes instead of a single lobe greatly increases the accuracy of azimuth

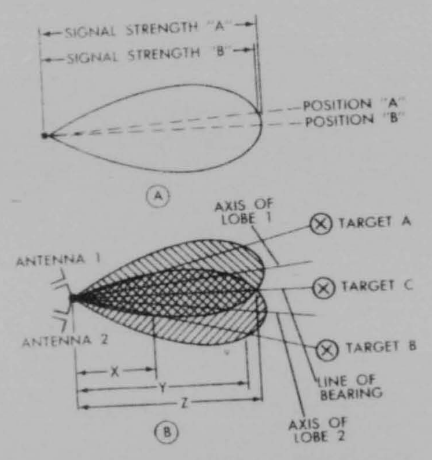

Figure 1—6. Single- and Double-Lobe Patterns.

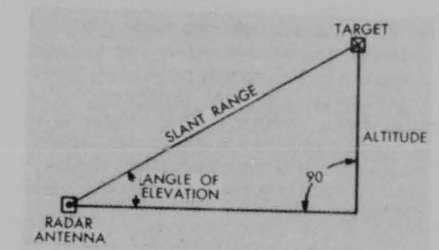

Figure 1—7. Determination of Altitude.

measurement. The amount of increase depends on the configuration of the antenna array. In general, the increase is at least five times, but it can be much greater. In addition to the greater accuracy of the double lobe, there is another advantage in the sense of direction available. If the antenna array is off-target on the side of lobe 1 the signal received by lobe 1 is the larger. Therefore the antenna should be rotated toward the left until the signals become equal.

6. DETERMINATION OF ELEVATION

The remaining dimension necessary to locate completely an object in space can be expressed either as an angle of elevation or as an altitude. If one is known, the other can be calculated from the right-triangle relationship and the slant range (Figure 1-7).

The free-space pattern of an antenna array is based on the arrangement of the individual elements within the system. If the same array is placed close to the earth, however, the vertical, free-space pattern may be changed by the effect of ground reflections. Figure 1-8A represents an antenna above the earth which has been elevated sufficiently so that energy will not strike the earth's surface and be reflected. Therefore the only energy that reaches the target is that which comes directly from the antenna system. If the antenna beam is lowered to the position shown in Figure 1-8B, some of the transmitted energy hits the earth and is reflected back into space. The target now receives energy from two directions and the effective field is the sum of the two fields so produced. The reflected wave travels farther than the direct ray in reaching the target. The addition of the fields at the target depends on the difference in the distance traveled expressed in wave-lengths. For example, if the path difference for a given target position is a half wavelength, the fields cancel. If the position of the target is changed so that the path difference is a full wavelength the fields add. The result of ground reflection is to break the single free-space lobe into a number of smaller lobes, with gaps between them.

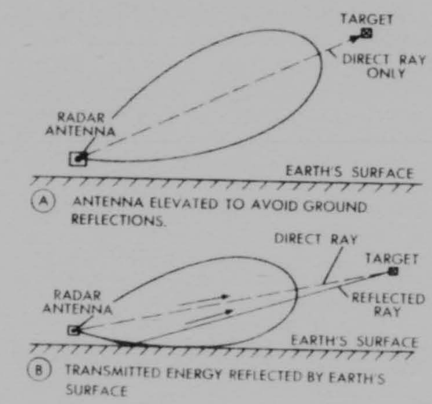

Figure 1—8. Elevation on Vertical Free-Space Pattern.

Methods

Any method used for determining the angle of elevation or the altitude must either make use of ground reflections or completely avoid them. The threshold-pickup method and the signal-comparison method use the effect of ground reflections to find altitude. The tilted-antenna method avoids ground reflections and measures the angle of elevation.

The threshold-pickup method makes use of the vertical-coverage pattern of an antenna system whose lobe axis is parallel to the earth. The positions of the lobes and gaps are determined by flying an aircraft toward the radar installation on known altitudes, and recording the ranges at which a minimum usable signal is returned. A typical plot of this data is shown in Figure 1-9. The chart obtained in this way is used by observing the range at which an unknown target first apears, and then reading its altitude from the chart. This method is very inaccurate, primarily because

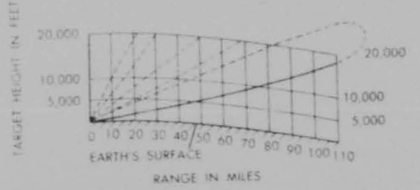

Figure 1–9. Calibration Chart for Estimating Aircraft Altitude.

the graph of the antenna pattern is determined by the use of a single aircraft while the target may be any number of planes. In general, the greater the number of planes, the greater is the strength of the returned signal. Therefore, a large flight of planes at a given altitude will be detected at a greater range than a single plane.

The signal-comparison method is simply an extension of the threshold-pickup method. Two antennas are placed one above the other to give slightly different vertical-coverage patterns. The lobes therefore overlap but do not coincide. The signals received on the two antennas are compared in magnitude, and their ratio, together with the range of the target, is applied to a height-range chart from which altitude is read. Under favorable conditions, the altitude can be determined within 500 feet.

The tilted-antenna method measures the angle of elevation directly in the same way that azimuth is measured. Ground reflections are avoided by using the system on targets which are high enough so that transmitted energy does not strike the ground. The accuracy of this method depends on the free-space pattern and the ability of the operator to locate the on-target position of the antenna array. Double-lobe systems are commonly used to increase the precision with which the antenna is pointed.

SECTION II—FUNCTIONAL COMPONENTS OF RADAR SYSTEM

1. FUNDAMENTAL ELEMENTS

Radar systems now in existence vary greatly as to detail. They may be very simple, or, if more accurate data are required, they may be highly refined. The principles of operation, however, are essentially the same for all systems. Thus a single basic radar system can be visualized in which the functional requirements hold equally well for all specific equipments. The varying details are due to a choice of specific circuits to fulfill these general functional requirements. In general, the degree of refinement of these circuits increases with the frequency, since the microwave region lends itself to a higher degree of precision in angular measurement.

Functional Block Diagram

The functional breakdown of the pulse-modulated radar system resolves itself into six essential components. These are shown in Figure 1-10 and may be summarized as follows:

The **timer** (variously known as the synchronizer, keyer, or control central) supplies the synchronizing signals which time the transmitted pulses and the indicator, and which coordinate other associated circuits.

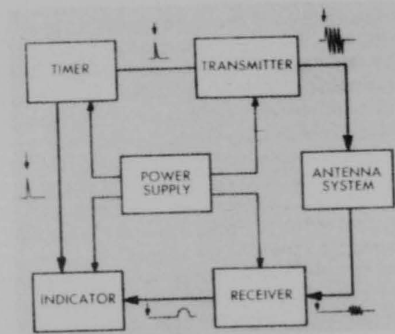

Figure 1–10. Functional Block Diagram of Fundamental Radar System.

The **transmitter** generates the r-f (radio frequency) energy in the form of short, powerful pulses.

The **antenna system** takes the r-f energy from the transmitter, radiates it in a highly directional beam, receives any returning echoes, and passes these echoes to the receiver.

The **receiver** amplifies the weak r-f pulses returned by the target and reproduces them as video pulses to be applied to the indicator.

The **indicator** produces a visual indication of the echo pulses in a manner which furnishes the required information.

The **power supply** furnishes all AC and DC voltages necessary for the operation of the system components.

Any radar system can be subdivided on the basis of the functional block diagram presented in Figure 1-10. An actual system may contain several functional components within one physical component, or a single function may be performed in several physical components. However, the analysis of the operation of a given set is greatly simplified by applying the functional block diagram without considering the physical location of the circuits.

2. SYSTEM CONSTANTS

Any radar system has associated with it certain constants. The choice of these constants for a particular system is determined by its tactical use, the accuracy required, the range to be covered, the practical physical size, and the problem of generating and receiving the signal.

Carrier Frequency

The carrier frequency is the frequency at which the radio energy is generated. The principal factors influencing the selection of the carrier frequency are the desired directivity and the generation and reception of r-f energy.

For the determination of direction and for the concentration of the transmitted energy so that a greater portion of it is useful, the antenna should be highly directive. The higher the carrier frequency, the shorter the wavelength and hence the smaller is the antenna array for a given sharpness of patterns, since the individual radiating element is normally a half-wave long. For an antenna array of a given physical size the pattern is sharper for a higher frequency.

The problem of generating and amplifying reasonable amounts of radio energy at extremely high frequencies is complicated by the physical construction of the tubes to be used. The common triode becomes impractical and must be replaced by tubes of special design. Among these are such types as the "lighthouse" triode, the grounded-grid triode, the klystron, the magnetron, and the "doorknob," "acorn," and "peanut" tubes. In general, the modifications are designed to reduce interelectrode capacitances, transit time, and stray inductance and capacitance in the tube leads.

The lowest carrier frequency normally used is 100 megacycles per second, in order to limit the antenna array to a practical size and yet to obtain the desired directional beam. Frequencies from 100 to 3,000 megacycles are in general use. Toward the upper end of this band, ranges are somewhat reduced because of inherent difficulties in generating and amplifying r-f energy at extremely high frequencies. Sets have been designed to operate up to and beyond 10,000 megacycles in order to produce very narrow beams or to reduce the antenna size.

Pulse-repetition Frequency

Sufficient time must be allowed between transmitted pulses for an echo to return from any target located within the maximum workable range of the system. Otherwise the reception of the echoes from the more distant targets will be obscured by succeeding transmitted pulses. This necessary time interval fixes the highest frequency which can be used for the pulse repetition.

When the antenna system is rotated at a constant speed, the beam of energy strikes a target for a relatively short time. During this time, a sufficient number of pulses of energy must be transmitted in order to return a signal which will produce a lasting indication on the oscilloscope screen. The persistence of the screen and the rotational speed of the antenna therefore determine the lowest repetition rate that can be used.

In a sytem in which the entire interval between transmitted pulses is used in the indicator, the repetition frequency must be very stable if accurate range measurement is desired. Since the oscilloscope screen will normally have a fairly long persistence, successive traces should appear in exactly the same position to avoid blurring.

Pulse Width

The minimum range at which a target can be detected is determined largely by the width of the transmitted pulse. If a target is so close to the transmitter that the echo is returned to the receiver before the transmitter is turned off, the reception of the echo obviously will be masked by the transmitted pulse.

Power Relation

A radar transmitter generates radio-frequency energy in the form of extremely short pulses and is then turned off between pulses for comparatively long intervals. The useful power of the transmitter is that contained in the radiated pulses and is termed the peak power of the system. Power is normally measured as an average value over a relatively long period of time. Since the radar transmitter is resting for a time which is long with respect to its operating time, the average power delivered during one cycle of operation is quite low compared to the peak power available during the pulse time.

A definite relationship exists between the average power dissipated over an extended period of time and the peak power developed during the pulse time. The time of one cycle of operation is the reciprocal of the repetition frequency, T = 1/f. Other factors remaining constant, the greater the pulse width the higher the average power; and the longer the pulse-repetition time the lower the average power. Thus:

$$\frac{\text{average power}}{\text{peak power}} = \frac{\text{pulse width}}{\text{pulse-repetition time}}$$

These general relationships are shown in Figure 1-11.

The operating cycle of the radar transmitter can be described in terms of the fraction of the total time that r-f (radio frequency) energy is radiated. This time relationship is called the duty cycle and may be represented as—

$$\frac{\text{pulse width}}{\text{pulse-repetition time}} = \text{duty cycle}$$

For example, a 2-microsecond pulse repeated at the rate of 500 times per second represents a duty cycle of 0.001, since the time for 1 cycle is 1/500 second, or 2,000 microseconds:

$$\frac{2}{2{,}000} = 0.001 \text{ duty cycle}$$

Likewise, the ratio between the average power and peak power may be expressed in terms of the duty cycle:

$$\frac{\text{average power}}{\text{peak power}} = \text{duty cycle}$$

In the above example it may be assumed that the peak power is 200 kilowatts. For 2 microseconds, then, 200 kilowatts of power are available, while for the remaining 1,998 microseconds zero power is available.

Since:

average power = peak power x duty cycle

Then

average power = 200 x 0.001 = 0.2 kilowatts

High-peak power is desirable to produce a strong echo over the maximum range of the equipment. Low-average power enables the transmitter tubes and circuit components to be made smaller and more compact. Thus it is advantageous to have a low-duty cycle. The peak power which can be developed is dependent upon the interrelation between peak and average power, pulse-width and pulse-repetition time, or duty cycle.

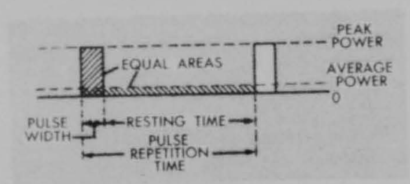

Figure 1—11. Relationship of Peak and Average Power.

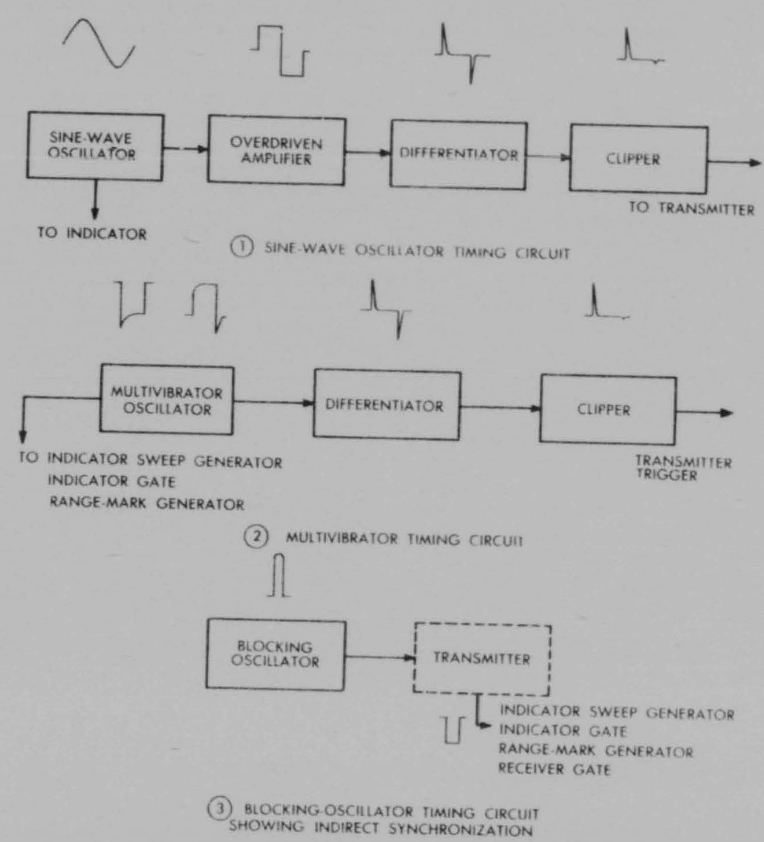

Figure 1—12. Representative Methods of Timing Radar Systems.

3. TIMER

The function of the timer is to insure that all circuits connected with the radar system operate in a definite time relationship with each other and that the interval between pulses is of the proper length. In general, there are two practical methods of supplying the timing requirements.

Timing by Separate Unit

The pulse-repetition frequency can be determined by an oscillator of any stable type such as a sine-wave oscillator, a multivibrator, or a blocking oscillator. The output is then applied to necessary pulse-shaping circuits to produce the required timing pulse. Figure 1-12 shows several typical combinations of circuits which may be used. The timing of associated components can be accomplished with the output of the timer or by obtaining a timing signal from the transmitter as it is turned on.

Timing Within Transmitter

The transmitter, with its associated cir-

THIS PAGE IS DECLASSIFIED IAW EO 13526

cuits, may establish its own pulse width and pulse-repetition frequency and provide the synchronizing pulse for the other components of the system. This action may be accomplished by a self-pulsing or blocking r-f oscillator with properly chosen circuit constants. This method of timing eliminates a number of special timing circuits, but the pulse-width or pulse-repetition frequency obtained may be less rigidly controlled than is desirable for some applications.

4. TRANSMITTER

Self-pulse System

In the self-pulsing radar transmitter the functions of transmitting and timing are carried out by one component. This type of transmitter, in effect, oscillates at two frequencies: the carrier frequency, as determined by the LC constants of the tank circuit, and the pulsing frequency, as determined by the RC constants of the grid circuit. The grid capacitor largely controls the width of the pulse in that its size determines the number of positive r-f swings required to charge it sufficiently to block the tube. The grid-leak resistor controls the pulse-repetition frequency to the extent that it determines the time required for sufficient charge to leak out of the grid capacitor to unblock the tube (the resting time). The timing pulse for other components is developed across a resistor in the cathode circuit of the blocking oscillator.

Externally-pulsed System

In the externally-pulsed type of radar transmitter the function of the r-f oscillator is relatively simple, that is, to generate powerful pulses of r-f energy at regular intervals. As the resting time is very long compared to the transmitting time, the oscillator may be greatly overloaded during transmission to increase the peak power. In this type of operation the r-f oscillator requires power in the form of a properly-timed, high-amplitude, rectangular pulse. In most cases the timing oscillator cannot fulfill this requirement directly, and therefore it is necessary to use a driver and a modulator. A driver is any circuit which, when triggered, drives the modulator with a rectangular pulse of accurately-timed width. A modulator is a circuit which supplies power to the r-f oscillator in the form of a timed, high-amplitude, rectangular pulse. The driver is triggered by the timer in order to maintain the repetition rate of the system. The driver, when triggered, shapes a rectangular pulse of proper time duration which in turn operates the modulator. The modulator then furnishes the high-plate voltage to the r-f oscillator for the predetermined pulsing time. Thus the transmitter function may be carried out by the combined performance of a driver, a modulator, and an r-f oscillator. The modulator acts like a power amplifier for the driver and like a switch for the r-f oscillator.

5. ANTENNA

The function of the antenna system is to take the energy from the transmitter, radiate it in a directional beam, pick up the returning echo, and pass it to the receiver with a minimum of losses. The antenna system may be considered to include the transmission lines from the transmitter to the antenna array, the antenna array itself, the transmission line from the antenna array to the receiver, and any antenna-switching device and receiver-protective device which may be present.

When a radar receiver is operated in close proximity to a powerful radar transmitter, a certain amount of signal inevitably finds its way into the receiver directly from the transmitter by way of the stray capacitance of the input circuit leads. In certain instances such signals resulting from the main transmitted pulse must be entirely eliminated from the output of the receiver. Therefore the receiver must be gated or turned off during the pulse time so that it may be completely insensitive.

It may be desirable to couple a small amount of the transmitted r-f energy to the receiver for timing purposes. However, the signal directly available from the transmission line is so strong that the receiver input circuit may be burned out. Because of the sensitivity of the receiver, the strong signal may also cause blocking of tubes which employ R-C grid circuits. This blocking occurs because

the strong signal will overdrive the tubes, causing grid current to flow which charges the capacitors. After the signal is removed the charge remains for some time as a bias which is much greater than cut-off. Both of these conditions place a limit on the permissible amount of transmitted pulse which can reach the receiver, and are the reasons for employing receiver-protective devices.

Use of Two Antennas

The simplest radar antenna system would contain two separate antenna arrays: one for transmitting and one for receiving. In this arrangement the receiving antenna must be shielded from the transmitting antenna to protect the receiver from the powerful pulses of energy being radiated. In general, the directivity of the antenna is sufficiently great to permit the location of the receiving antenna in a minimum signal region of the transmitting pattern. In aircraft installations the fuselage can be used to shield the receiving antenna from the transmitting antenna.

Use of Single Antenna and Switch

A more practical radar system employs a single antenna and an antenna switch capable of connecting the antenna to the transmitter during the transmission time and to the receiver during the remainder of the pulse cycle. The switch is necessary to protect the receiver from the transmitter during the pulse time and also to isolate the transmitter during the receiving time. Otherwise the weak echoes might be wholly or partially lost in following the transmission line back to the transmitter. The transmitted pulse width and the repetition frequency of the system, which may range from 60 to 4,000 cycles per second, eliminates the possibility of using a mechanical switch. Otherwise a double-pole, double-throw switch would serve the purpose.

A system for using the single antenna for both transmission and reception should be as efficient as possible. In other words, all of the energy produced by the transmitter should reach the antenna, and all of the energy should reach the receiver. This efficiency is most easily obtained by matching the antenna to the characteristic impedance of the transmission line. During transmission of the pulse, the transmitter should be matched to the transmission line and the receiver must present an open circuit or high impedance to the transmission line. During the reception time the conditions should be reversed.

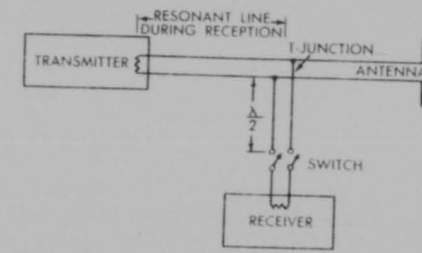

Figure 1—13. Elementary Switching System.

The problem of switching is usually simplified because most transmitters have a different output impedance when they are on than when they are off. If properly matched to the transmission line during the pulse, the transmitter will be mismatched for the receiving time, and the transmission line will become resonant. Figure 1-13 illustrates a typical elementary system in which the receiver and transmitter are connected by branch lines to the antenna feed line. The junction of the three lines is known as the T-junction. During the off period, the switch in the receiver branch is closed and the transmission line from antenna to receiver is properly matched. The resistance seen from the T-junction looking toward the transmitter can be controlled by the length of the resonant section between them. If the transmitter impedance decreases when it is turned off, the length should be a quarter-wavelength, or some odd multiple thereof, in order to see a high impedance. The high impedance presented by the transmitter and its feed line to the T-junction is in parallel with the relatively low-characteristic impedance of the remainder of the transmission line system, but, being high, has little effect. If the transmitter impedance increases when it is turned off, the resonant-line length should be a half-wavelength, or a multiple thereof.

When the transmitter is turned on to transmit the next pulse, it again will be properly matched to the antenna. The open switch (Figure 1-13) will prevent the pulse from reaching the receiver, and will cause a mismatch to the line between the switch and T-junction. By using some multiple of a half-wavelength, the open circuit of the switch will be presented as an open circuit across the transmitter-antenna line.

In a broad sense, then, the switching problem consists of providing what amounts to a double-pole, single-throw switch (Figure 1-13) for connecting the antenna alternately to the transmitter and to the receiver. The switching device must be capable of acting within a time interval of a few microseconds, as the receiever should be in the antenna circuit immediately after the transmission of the pulse in order to detect close-range targets. This microsecond timing requires that the device be electronic in type. Under various operational circumstances it may take the form of r-f amplifiers, klystrons, spark gaps, resonant transformers, spark-gap tubes, and (in waveguides) resonant slits. It is commonly known as the T-R (transmit-receive) switch or T-R box. Other terms frequently encountered are duplexer, reprod, and, in certain instances, polyplexer.

Types of Radiators

The principal types of radiators employed in the radar antenna system include: the stacked-dipole array with untuned reflector, the dipole with tuned reflectors and directors (Yagi), the dipole with parabolic reflector, and various arrangements of dielectric radiators used in conjunction with wave-guides.

A typical stacked-dipole array may be composed of one or more banks of dipoles and may be adapted for lobe switching. The entire assembly usually can be rotated in either azimuth or elevation, or both.

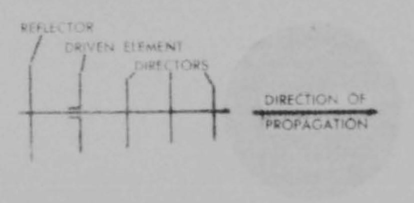

Figure 1–14. Yagi Array.

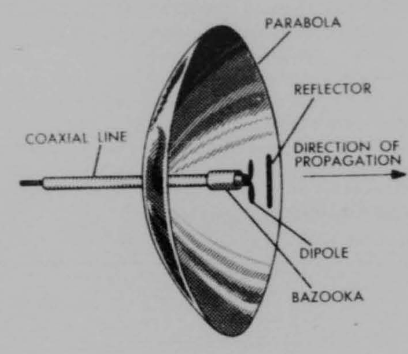

Figure 1–15. Dipole with Parabolic Reflector.

Figure 1-14 shows a type of Yagi array utilizing both director and reflector parasitic antennas in conjunction with a driven element. Only the driven element is connected to the transmission line. The other elements are excited parasitically, picking up energy from the driven element and reradiating it with such a phase relation with respect to the driven dipole that the field is reinforced in the forward direction.

Figure 1-15 shows the parabolic-reflector type of antenna, which is a practical means of producing a narrow beam pattern in the region of the micro-wavelengths. The reffection of r-f energy by the parabola or dish is closely analogous to the reflection of light by a parabolic mirror. The dish is large in comparison with the operating wavelength; in general, the larger the reflector, the narrower the beam pattern. The r-f energy is fed to a dipole located at the focal point of the parabola. A parasitic reflector is placed about one quarter-wavelength in front of the dipole, to reflect practically all of the radiated energy back to the dish from which it is reflected ahead in the form of a narrow beam. Modifications of this type of radiating system include cylindrical and other types of parabolas. Parabolic reflectors are frequently used in conjunction with wave-guides.

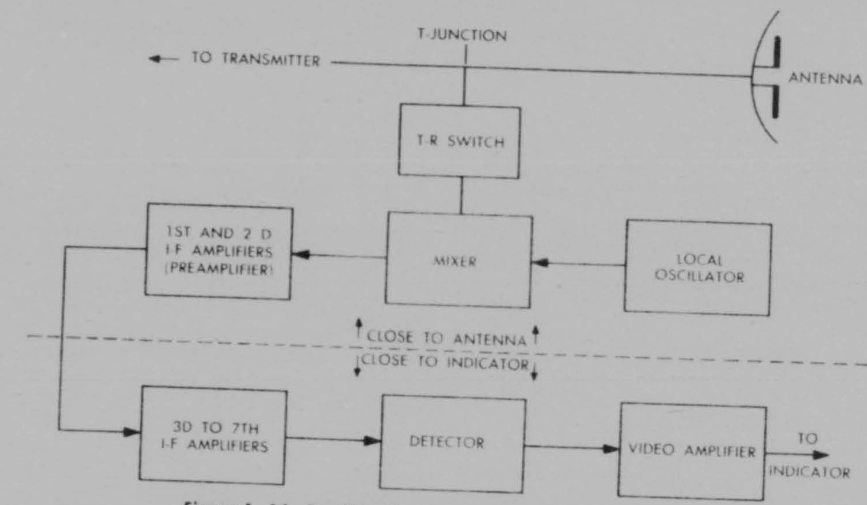

Figure 1–16. Possible Distribution of Receiver Components.

6. RECEIVER

The function of the receiver is to take the weak echoes from the antenna system, amplify them sufficiently, detect the pulse envelope, amplify the pulses, and feed them to the indicator. Since radar frequencies are high it is difficult to obtain sufficient amplification. Therefore, the receiver function of the radar system is performed by superheterodyne components of good stability and extreme sensitivity. The stability of operation is maintained in the microwave range of frequencies by careful design, and the over-all sensitivity of the receiver is greatly increased by the use of many intermediate-frequency stages. Special types of tubes having low interelectrode capacitances have also been developed for use in r-f, local-oscillator, and i-f stages.

Components

The r-f amplifier may not be present in the higher-frequency ranges and thus the received signal may be fed directly to the mixer. In this case, it is desirable to use as short a receiver-input transmission line as the design requirements allow. Thus, the mixer and local oscillator may be located close to the T-junction of the transmission line in order that the received r-f energy may be converted to the lower intermediate frequency before being relayed to the remaining receiver components. One or two stages of i-f amplification are sometimes located immediately after the mixer-local oscillator stage, functioning as a preamplifier to offset the considerable attenuation encountered in coupling the very weak received signal to the remote receiver components.

The components of the radar receiver may be distributed through the system in such a manner that their physical identity becomes lost. Figure 1-16 illustrates one representative distribution of the radar receiver components which makes it possible to locate the frequency-conversion portion in the immediate vicinity of the antenna and the video-amplifier portion in the vicinity of the indicator.

7. INDICATOR

The indicator uses the received signals to produce a visual indication of the desired information. The cathode-ray oscilloscope is an ideal instrument for the presentation of radar data since it not only shows a variation of a single quantity such as voltage, but gives an

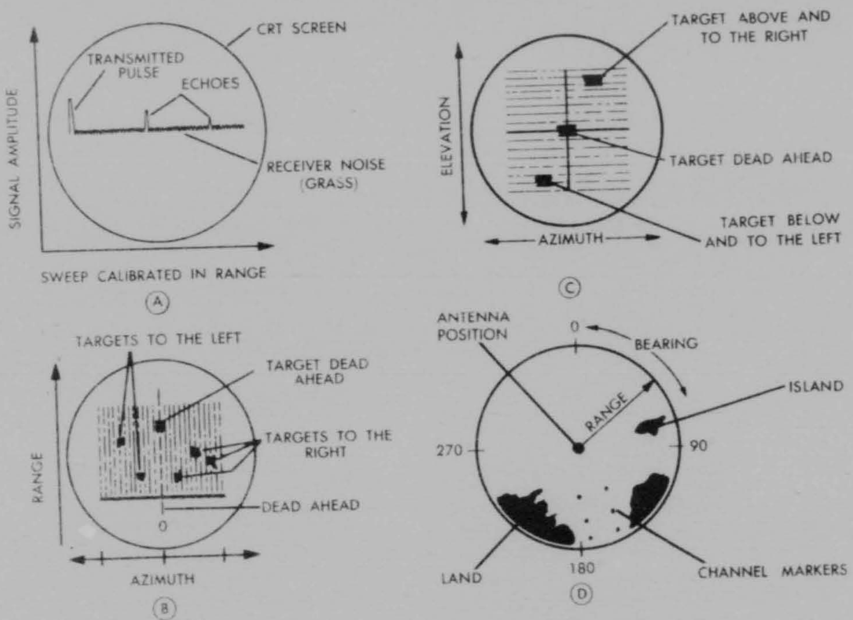

Figure 1–17. Types of Cathode Ray Oscilloscopes.

indication of the relative values of two or more synchronized variations. The usual indicator is basically the same in function as the low-frequency test oscilloscope. The focusing, intensity, and positioning controls are similar. The sweep frequency of the radar indicator is determined by the pulse-repetition frequency of the system and the sweep duration is established by the setting of the range-selector switch.

Types of Cathode-ray Oscilloscopes Used

The simpler systems of data presentation generally use the electrostatic cathode-ray tube in which the electron beam is made to follow some pattern by controlled differences in potential between pairs of deflecting plates.

The more highly-refined systems of data presentation generally utilize the electromagnetic cathode-ray tube with a long-persistence screen. The position of the electron beam at any instant is determined by causing it to pass through a magnetic field produced by controlled currents through deflecting coils mounted outside the tube. If intensity modulation is used, the bias is such that the tube is held just beyond cut-off, and the video output of the receiver is applied to either the grid or cathode with such polarity as to release the beam and allow the trace to appear on the screen. Thus the bright spots on the screen represent returning echoes detected by the radar receiver.

Type A-scan Presentation

The A-scan (Figure 1-17A) uses an electrostatic cathode-ray tube with a linear sweep applied to the horizontal deflecting plates to establish a time base, and with the video output of the receiver applied to the vertical deflecting plates. Since the sweep is linear with time, a scale which is calibrated in range may be placed on the oscilloscope screen. This scale permits the reading of range directly.

Since the antenna beam is highly directive, the maximum received echo appears when the antenna is pointing directly at the target. Thus, by rotating the antenna until the echo pulse produces maximum deflections on the screen, an indication of direction in azimuth or elevation can be obtained.

Type B-scan Presentation

The B-scan (Figure 1-17B) plots range against azimuth. Usually an electromagnetic tube is used. The sweep current flows through the vertical deflecting coils. A positioning current controlled by the antenna position flows through the horizontal deflecting coils, so that the position of the vertical sweep is aligned with the position in azimuth of the antenna, which may scan a region up to 90 degrees on either side of dead ahead. The return signals are used with an intensity-modulated scope to cause the target indications to appear on the screen.

Type C-scan Presentation

The C-scan (Figure 1-17C), developed primarily as a pilot's remote indicator, plots elevation against azimuth. The oscilloscope is intensity modulation by the echo signals. Modifications which present a means of estimating the range in addition to the indication of the elevation and bearing are more likely to be encountered than the basic type.

Type PPI-scan Presentation

The PPI-scan (Figure 1-17D) presents, in polar coordinates, a map of the area being covered with the antenna position occupying the center of the screen. The tube is intensity-modulated with the sweep moving from the center, radially outward. The sweep position is controlled by and synchronized with the antenna position throughout 360 degree rotation. The top of the screen represents dead ahead; if the antenna is pointing dead ahead, the sweep moves from the center of the screen to the top. Likewise, if the antenna points 90 degrees from dead ahead, the sweep moves from the center radially outward at an angle of 90 degrees to the right of dead ahead. Thus, a polar map is developed on which the range

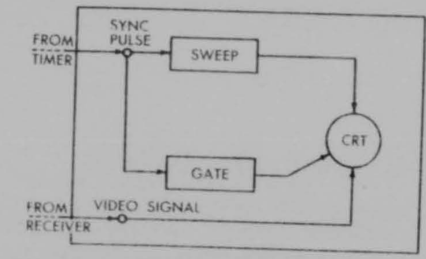

Figure 1–18. Basic Components of Radar Indicator.

is plotted radially against the position in azimuth, or bearing, through 360 degrees. The PPI-scan finds considerable application in equipments designed for search, harbor control, convoy keeping, ground-controlled interception, and navigation.

Components

The basic components of a radar indicator are a cathode-ray tube, a sweep circuit, and a gate circuit. These are illustrated in Figure 1-18. Various refinements may be added to improve the data presentation and to meet specific operational requirements.

In order that the data supplied by the indicator may be useful, the indicator's performance must be synchronized with that of the other components of the system. Thus, the start of the sweep must bear a definite time relation to the beginning of the transmitted pulse. The gating of the cathode-ray tube also must be timed with the sweep duration. Various methods of data presentation requiring sweep controls of varying degrees of complexity may be used.

8. POWER SUPPLY

Distribution

In the functional diagram of the radar system (Figure 1-10), the power supply is represented as a single block. Functionally, this block is representative; however, it is unlikely that any one power supply could meet all the power requirements of a radar set. The distribution of the physical components of the system may be such as to make it impractical

THIS PAGE IS DECLASSIFIED IAW EO 13526

to lump the power-supply circuits into a single physical unit. Thus, different supplies are needed to meet the varying requirements of the system and must be designed accordingly. The power-supply function is performed, therefore, by various types of supplies distributed among the circuit components of the radar equipment.

SECTION III—TIMERS

1. GENERAL

Introduction

Circuits which control and synchronize the operation of the various components of radar equipments are known as timers. The timing circuits are either assembled into a unit which constitutes a separate component of the equipment, or, as in the usual case, they are contained within one or more additional components, such as the indicator, the receiver, and control circuits.

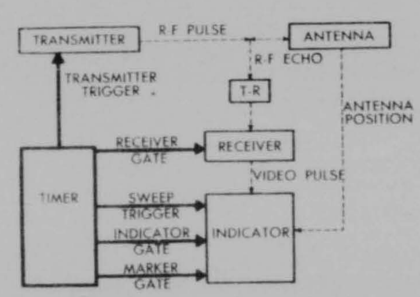
For the purposes of study, timers have been divided into two general types. One is the self-synchronized type in which the timing function is performed within the transmitter circuits. The other is the externally-synchronized type in which a master oscillator in the timer establishes the repetition rate and supplies trigger voltages for controlling the entire system.

Timing Signals

The signals required of the timing circuit depend largely upon the purpose of the set, the type of transmitter, and the method of data presentation. Typical requirements are illustrated in Figure 1-19. This diagram does not necessarily apply to any particular set, but shows the more common timing pulse channels in general use in many systems. In Figure 1-20 these timing pulses are shown in their proper time relationship.

Figure 1-20A represents the time-reference pulse originating in the timer circuit, and shows wave forms typical of the externally-synchronized systems. This figure is equally typical of self-synchronized systems in which the time-reference pulse is developed in the transmitter circuit. The time-reference pulse is used to trigger the various timing circuits into operation. Thus, in the former case, the pulse shown in Figure 1-20A becomes a transmitter trigger, and in the latter case it becomes a timer trigger. In either case, it serves as the reference point from which the other operations are timed.

The second timing pulse shown in Figure 1-20C gates the receiver to make it operative during only the proper portion of the pulse cycle. It may be necessary to gate the receiver in this way in some sets in which short minimum ranges are important. The T-R switch normally limits the amount of transmitter signal entering the receiver to a value which does not damage the crystal mixer, but it may not prevent blocking of the receiver circuits. When blocking occurs, the receiver remains inoperative for an interval immediately following the transmission of the pulse. This interval is required for recovery of the receiver to a state of normal sensitivity. If the plate and screen voltages of the first two or three i-f stages are removed during the transmitting time, receiver blocking is prevented and the minimum range at which targets can be detected becomes simply a function of the pulse width. The timing circuits are made to apply these screen and plate potentials in the form of a positive, rectangular gate voltage during the time interval beginning just after the end of the transmitted pulse and ending after echoes are received from the most distant targets in the operating range. Improvements in radar-receiver and T-R switch design have shortened recovery time to such an extent that, in many recent sets, it is unnecessary to gate the receiver.



*ESTABLISHES THE TIME REFERENCE FOR THE SYSTEM

Figure 1—19. Typical Pulses of a Radar Timer.

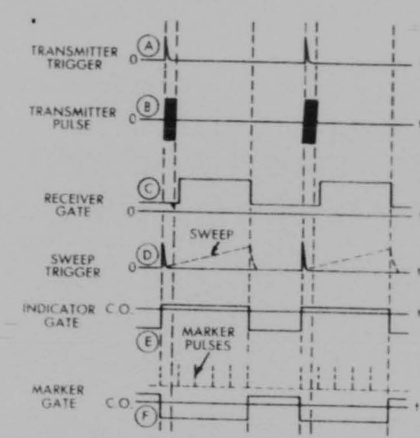


Figure 1—20. Time Relationship of Pulses Furnished by Timer Shown in Figure 1—19.

The timer starts the range sweep in the indicator circuits. The timing pulse may be in the form of a trigger as shown in Figure 1-20D, where it occurs simultaneously with the transmitted trigger, so that the beginning of the sweep and the beginning of the transmitter pulse coincide. If any appreciable delay occurs in starting the sweep in a cathode-ray tube which uses magnetic deflection, the sweep trigger may be made to precede the transmitter trigger to compensate for this inherent delay. The more commonly-encountered alternative, however, is to trigger the sweep coincidently with the transmitter and develop a trapezoidal sweep voltage to overcome the delay.

If the tube remains in an operating condition during the entire pulse period, both the forward sweep and the return trace will be visible, so that signals appearing on the screen from targets outside the desired range will cause confusion in interpretation of echoes. To avoid this, the circuits of the cathode-ray tube permit its operation to be controlled by a rectangular voltage, or gate. In Figure 1-20E this gate is shown to be positive during the sweep time and is applied to the grid of the cathode-ray tube to reduce the bias sufficiently to make it operative. At the end of the sweep time, the grid is returned to a high bias condition and signals returning during the remaining portion of the pulse period cannot appear on the oscilloscope. The same results are obtained by applying a negative gate to the cathode of the indicator tube during the sweep time.

The most commonly used method of estimating range directly on the indicator screen involves the production of range-marker pips in the indicator circuits and superimposing them on the video output of the receiver. The oscillatory circuit which generates the marker signals is gated by a rectangular pulse furnished by the timer, as shown in Figure 1-20F. The marker gate enables the marker circuits to operate during the sweep time only and may be either positive or negative, depending on the input requirement of the marker generator.

To provide the required timing pulses the timer must include the following:

A circuit capable of establishing the pulse-repetition frequency. This may be simply the grid circuit of an r-f blocking oscillator, a rotary spark-gap type of modulator, a sine wave oscillator, a multivibrator, or a single-swing blocking oscillator.

Means of forming the desired signals with the proper time relations. These may include such circuits as limiters, clampers, peakers, amplifiers, controlled multivibrators, and delay networks.

Circuits designed to protect one component from the loading effect of another and to deliver pulses to the loads without distortion, include the buffer amplifiers and cathode followers.

SECTION IV—TRANSMITTERS

1. GENERAL

Selection of R-F Generator

The selection of the r-f generator is governed chiefly by the carrier frequency at which the system is to operate. The carrier frequency depends on several factors, among which are the desired directivity of the antenna, the effect of frequency on propagation, and the tactical application of the system.

After determining the carrier frequency, the next step is to select the r-f generator. The triode oscillator is able to produce high peak power in pulse operation up to 400 megacycles per second. Because of interelectrode capacitances, electron transit time, lead inductances, and stray capacitances, the triode is incapable of producing a pulse of large peak power at higher frequencies. However, triode oscillators may be used to produce pulses of relatively low peak power at frequencies up to 600 megacycles per second. Such an r-f generator is useful in lightweight sets where high-power output is not essential. Above 600 megacycles, the magnetron is by far the most efficient r-f generator known at present, and is used almost exclusively in micro-wave radar. In a few cases a special form of triode, called the lighthouse triode, is used in low power transportable microwave radar sets.

Selection of Method of Pulsing

Three important pulsing methods are in use at present: self-pulsing in a triode blocking oscillator; production of a low-power pulse which is shaped and amplified to the proper magnitude to operate the r-f generator; and the production of a high-power pulse which is applied directly to the r-f generator. The method used depends on the type of r-f generator, the accuracy of range measurement to be obtained, and the minimum range desired.

The triode oscillator is pulsed equally well by all three of the above methods. The method which is used with a magnetron, however, must produce a rectangular pulse with very steep sides in order to apply a fairly constant voltage to the magnetron during the pulse time. Otherwise power is wasted by the production of oscillations of several different frequencies. Early pulsing systems for magnetrons were of the type that produced a low-power pulse and amplified it to the proper magnitude.

The limitation on the use of such pulse-amplifier systems is the amount of pulse power which can be produced without the use of many tubes in complicated circuits. This upper limit is about 200 kilowatts. The high-power pulse-generating systems use spark gaps capable of controlling enormous peak powers. Radar sets are now available which by using rotary gaps to extend the life of the system, produce r-f pulses of peak power exceeding a megawatt.

If extreme precision of range measurement is necessary, the leading edge of the transmitted pulse must be as steep as possible in order that the zero time for each sweep may be accurately determined. In applications where very short ranges must be measured—for example, in aircraft interception—the transmitted pulse must be short and the trailing edge of the pulse must be very steep. This is necessary so that the change-over from the transmitting condition to the receiving condition may be made as rapidly as possible to avoid masking of nearby targets. The self-pulsing triode oscillator does not meet either of these requirements well enough to permit its use in precise range-measuring systems. However, because of its simplicity, this type of pulsing is of considerable value in search systems where a high degree of accuracy and measurement of very short ranges are not required.

2. R-F GENERATORS

Triode Oscillators

Although triode tubes may be operated with their control grids positive to produce very

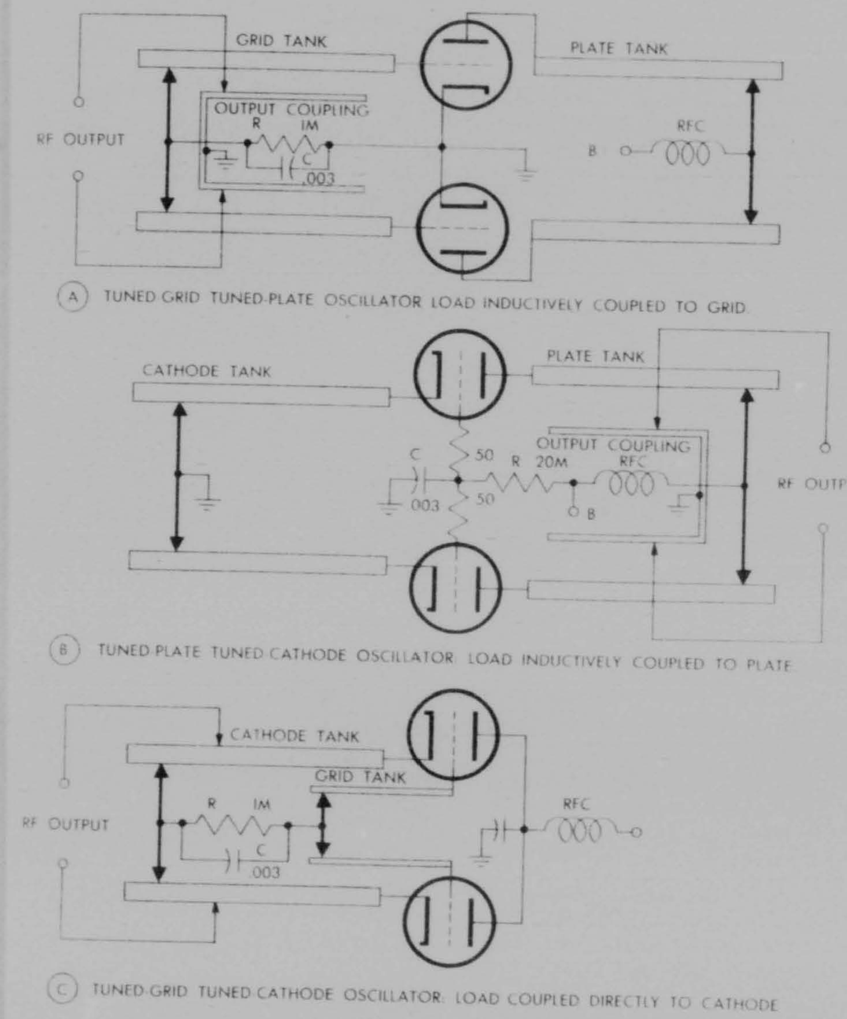

Figure 1—21. Representative Circuits of Push-Pull Oscillators.

THIS PAGE IS DECLASSIFIED IAW EO 13526

high frequency oscillations, as in the Barkhausen-Kurz oscillator, such circuits are not used in radar transmitters because they are too inefficient to supply the high peak power necessary. The triode oscillators which are used are of the negative-grid type, connected in a two-tube, push-pull circuit.

The tuned circuits used in triode radar-transmitter circuits are usually short-circuited quarter-wave sections of two-wire transmission line. These tuned circuits may be connected in the oscillator circuit in any of the ways shown in Figure 1-21. Oscillations are produced by feed-back through interelectrode capacitances. Other connections may be used, particularly when the length of the filament leads within the tube is such that special precautions must be taken to eliminate degeneration in the cathode circuit and the feedback of r-f energy into the power line.

All oscillators shown are self-pulsed. In "B", the grid is connected to B through a high resistance in order to establish a slightly more stable pulse-repetition frequency than is possible with the connections shown in "A", or "C". In all cases the flow of grid current charges capacitor C to produce a bias large enough to stop oscillation. A reduction in the size of the grid-leak resistor or an increase in the size of the capacitor will prevent self-blocking; all types may then be pulsed by common forms of modulators.

Energy may be coupled out of the oscillator inductively, capacitively, or by direct connection. Capacitive coupling is seldom used alone, but it may be used in conjunction with inductive coupling. Inductive coupling to the grid circuit is used in some radar transmitters, but usually this type of coupling reduces the Q of the grid tank circuit so much that it cannot be used to control the frequency of the oscillator effectively. One important difficulty that arises from inductive coupling to the plate tank circuit (Figure 1-21B) is that the voltage between the coupling line and the plate-tank circuit is the sum of the DC voltage and the r-f voltage. Because of this large voltage, the coupling line cannot be moved too close to the plate tank because in some cases flat optimum coupling cannot be obtained. This difficulty is overcome in the direct coupling arrangement shown in Figure 1-21C. There is no DC voltage on the cathode; therefore, the transmission line may be coupled to the cathode tank to any desired degree by adjusting the position of the output tap.

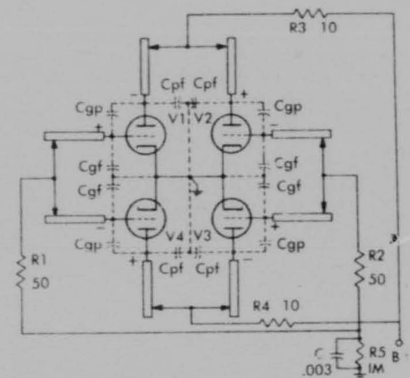

Figure 1-22. Diagram of Tuned-Grid Tuned-Plate Ring Oscillator.

Ring Oscillator

The power output of a two-tube, push-pull oscillator is limited by the peak plate current that can flow in the tubes and the power dissipation of the plate. To increase the power output it is necessary to increase the current-carrying capacity of the tubes, or to increase the number of tubes in the circuit. Because of electron transit time, interelectrode capacitance, and lead inductance, it is undesirable to increase the physical size of the tube to provide greater current-carrying capacity. Although increasing the temperature of the filament will permit greater emission, this change greatly shortens the life of the tube. Increasing the number of tubes by paralleling allows a higher peak power to be generated, but it also increases the effect of the interelectrode capacitances. When it is necessary to build an oscillator of high power, tubes are added in pairs in series to form a ring circuit (Figure 1-22).

The ring oscillator shown is an extension of the oscillator of Figure 1-21A. The effect of the interelectrode capacitances in this type of circuit is half of that for the same tubes connected in a push-pull parallel circuit. Addition of tubes in series to form a ring, therefore, permits a given type of the tube to be used at a higher frequency or allows the use of tubes which are physically large.

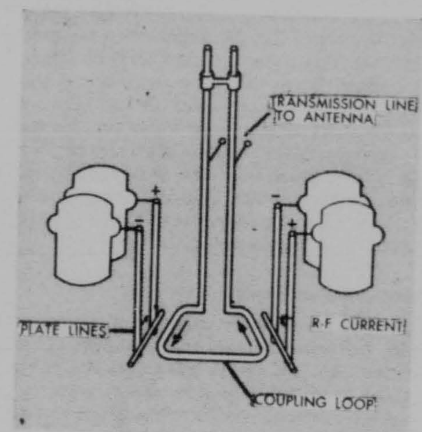

Figure 1—23. Coupling in a Ring Oscillator.

The ring oscillator functions because of the feedback of energy from plate to grid through interelectrode capacitances, and because of the voltage distribution on the plate and grid lines. Proper adjustment of the tank circuits causes a regenerative voltage to be fed back through the grid-plate capacitance. At the same time standing waves of voltage are established on the sections of transmission lines which cause the voltage at one end of the line to be out of phase with the voltage at the other end. Assume that the grid signal of VI (Figure 1-22) is positive at a given instant. The plate signal of VI will be at a minimum or negative maximum. The plate of V2, approximately a half-wavelength away, is positive because of the standing wave of voltage on the tuned transmission line. The signal on the grid of V2 is produced by interelectrode capacitance as a negative maximum, in order to reinforce the plate current. Continuing around the ring in this manner, the grid of V4 is at a negative maximum to close properly with the grid VI, a half-wavelength away. Plate relations are maintained by always adding tubes in pairs, if a larger number is needed.

The physical construction of the ring oscillator normally is arranged to have the tubes placed in an approximate circle with the tank circuits on the inside of the circle. This arrangement permits symmetrical connections between circuit elements, and allows the output coupling to the transmission line to be relatively simple construction. Figure 1-23 shows one method for obtaining energy from the tank circuits. The plate lines are supported vertically between the tubes, with the shorting bars at the lower ends. The polarity of voltage at the plates is as indicated and this causes the currents in the shorting bars to have the relative direction of flow shown by the arrows. A transmission line with a loop in the end is lowered between the plate lines so as to place the loop near the shorting bars, to provide inductive coupling. The magnetic fields produced by the currents in the shorting bars reinforce each other in inducting the r-f voltage in the loop. The line and loop can be made resonant by using a shorting bar a half-wavelength from the loop to insure maximum transfer of energy. The feed line is tapped across the resonant section in this case.

Any of the push-pull oscillators shown in Figure 1-21 may be connected in a ring circuit to produce a high-peak power output. Since the ring connection reduces the effect of the interelectrode capacitance, tubes of fairly large physical size may be used to produce high-peak output power at frequencies up to 400 megacycles. To produce even greater peak-output power than is possible with the four-tube ring oscillator, additional tubes may be added in pairs to the circuit.

The ring oscillator has the disadvantage of having many tuning adjustments in its circuit. If the several adjustments are not made properly, inefficiency will result. Because the ring circuit permits mechanical symmetry in construction, the tuning adjustments may be ganged to a few controls, and the oscillator is relatively simple to operate.

Magnetron

The magnetron is used as an r-f generator at frequencies above 600 megacycles per second. Since statement of the frequency in this range may involve rather large numbers, magnetrons are usually described in terms of the wavelength of the r-f energy they produce. The general range of wavelengths in which magnetrons are practical is called the microwave region. For use in this region, magnetrons have been manufactured which are capable of producing peak output as high as a megawatt. The efficiency of the magnetron as a device for converting DC energy to radio frequency energy is approximately 30 to 50 per cent.

Magnetrons for radar use require high plate voltages to cause oscillation. During the oscillating period, the current drawn is 10 amperes or more. The effective impedance of the magnetron while it is oscillating is approximately 1,000 ohms. Although it is desirable to reduce the magnetron impedance to a low value to eliminate the necessity for extremely high plate voltage, it has been impossible to reduce the effective plate impedance below approximately 500 ohms, even by special design.

It is characteristic of the magnetron that, if the plate voltage falls very greatly during the pulse, modes of oscillation other than the one desired may result. Oscillation in this manner causes serious loss of power, lowered magnetron efficiency, and difficulties in tuning the system, since unwanted frequency components are produced in the output. Therefore, the voltage applied to the magnetron must rise to the full value as soon as possible and remain constant during the pulse, and decrease to zero in a short time at the end of the pulse. Hence, the magnetron requires a fairly rectangular modulating pulse.

3. DRIVER MODULATOR SYSTEMS

The triode type of r-f generator may be either self-pulsed or externally-pulsed, while the magnetron is always externally-pulsed. The general requirements of the modulating or pulsing system are about the same for both types. When the pulse is formed in low-power circuits and then amplified to produce the actual transmitter pulse, a driver is commonly employed to shape the pulse and a modulator is employed to produce the required amplification and apply it to the r-f generator.

If the shape of the modulating pulse need not be controlled accurately, the trigger pulse from the timer may be amplified in a power amplifier. This is the simplest form of driver modulator. When the pulse shape and duration must be accurately controlled, as in radar sets of short range, more elaborate circuits are used. Such applications generally require a driver in which the pulse is formed by an artificial transmission line, and then applied to a modulator. The occurrence of the pulse is controlled by the output of the timer.

Bootstrap Drivers

The bootstrap driver uses the trigger pulse from the timer to start the discharge of an artificial line through a gas tube. The pulse formed is amplified by a bootstrap amplifier from which the driver takes its name, and is applied to a conventional modulator.

A simplified circuit for producing a rectangular pulse by the use of an artificial transmission line is shown in Figure 1-24A. The characteristic impedance of the transmission line is 2,500 ohms. The resistor, R2, across which the output pulse is to be developed is

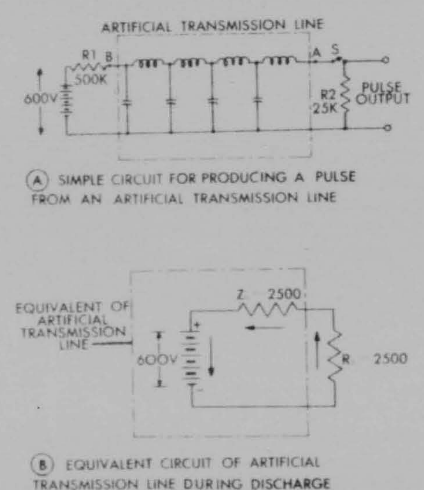

Figure 1—24. Production and Discharge of a Rectangular Pulse.

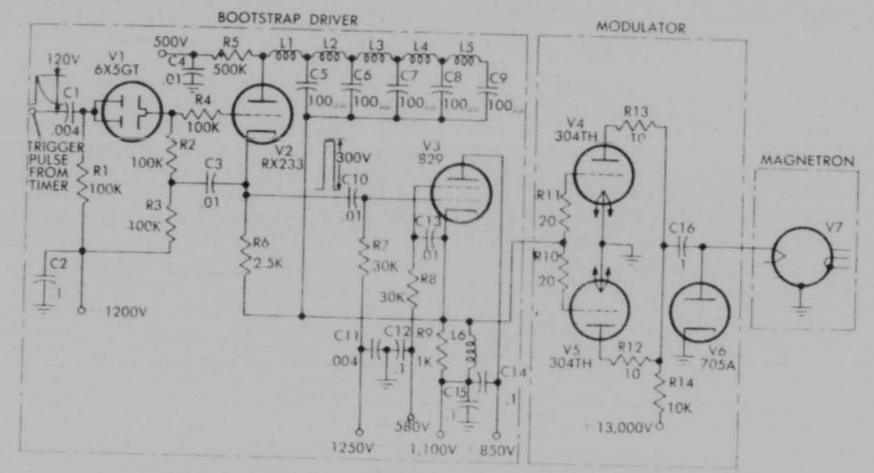

Figure 1—25. Schematic Circuit Diagram of Transmitter with Bootstrap Driver.

equal to this characteristic impedance. Resistor R1, through which the line is charged, is made very much larger than the characteristic impedance so that it is an apparent open circuit during the discharge of the line. The capacitors are all charged to 600 volts if switch S is left open for a sufficient time. If the switch is closed after the line has been charged, a current immediately starts to flow through R2. The line may be considered as a battery with an internal impedance of 2,500 ohms during the discharge time (Figure 1-24B). The voltage across R2 is one-half the voltage to which the line was charged, or 300 volts, since half the available voltage is lost across the 2,500-ohm internal impedance, Z_o. If the network consisted only of capacitors, the discharge would follow an exponential curve, and the voltage across R2 would not be constant. However, the inductance and capacitance of the line are so designated that the discharge rate is practically constant.

The discharge of the artificial line can be explained best as follows: At the instant that the switch 1-24A is closed, the voltage at point A falls to 300 volts. This can be looked upon as a traveling wave of 300 volts applied at point A to reduce the voltage there immediately from 600 to 300 volts. As the wave moves from A to B the voltage across the line is reduced from 600 to 300 volts. On reaching point B, the wave sees an open circuit, since resistor R1 is very large. The wave is reflected without change in sign, and immediately reduces the voltage at point B from 300 volts to zero as the wave travels back to point A, and the remaining 300 volts across the line is canceled out. On reaching point A, the wave has reduced the voltage across all sections to zero, the wave itself disappearing because it is absorbed by a load which matches the characteristic impedance of the line. The pulse formed across R2 by the line discharged lasts for the time required for the traveling wave to move from the switch end of the line to the open end and back.

The complete circuit diagram of the transmitter with a bootstrap driver is shown in Figure 1-25. A thyrator, V2, is used instead of the mechanical switch shown in Figure 1-24A, to discharge the artificial transmission line. The line is connected between the 500-volt and 1,1000-volt taps on the power supply, so that it is charged to a voltage of 600 volts through resistor R5.

A positive-going timing pulse with a steep leading edge is applied to the driver through

THIS PAGE IS DECLASSIFIED IAW EO 13526

coupling capacitor C1 and isolating diode V1. The positive trigger pulse causes the thyratron V2 to ionize. The current which flows through V2 must come from the discharge of the artificial line because R5 is too large to allow the flow of current sufficient to maintain ionization. The discharge of the artificial line through V2 and R6 produces a —300-volt pulse across R6 during the discharge.

Tube V3 is a double beam-power tube but for convenience it is shown in Figure 1-25 as a single tube. The tube normally is cut off, since its cathode is connected to the —1,100-volt tap and its grid is connected to the —1,250-volt tap on the power supply. The net bias on the tube is therefore —150 volts, which is ample to prevent conduction. When the artificial line discharges, the —300-volt pulse developed across R6 is coupled to the grid of V3 through C10, causing the tube to conduct strongly. The cathode of V3 rises from 1,100 volts below ground to a positive potential with respect to ground because of the voltage drop across R9.

The life of thyraton V2 is shortened by positive ion bombardment of the cathode if the grid is driven sufficiently negative to cause acceleration of the ions toward the cathode. This condition is avoided by using diode V1 and capacitor C3. The trigger pulse is coupled to the grid of V2 through capacitor C1 and diode V1. The positive swing of the pulse causes diode V1 to conduct and produce a signal voltage across R2 and R3. The drop across R2 is applied directly between grid and cathode of V2 and C3. When the pulse is removed capacitor C1 discharges, but, since the diode cannot conduct, the negative voltage resulting does not appear at the grid of V2. The pulse developed in the cathode of V2 is coupled back into the grid through C3, causing the grid to rise with the cathode, and thus prevents a negative voltage on the grid from this source. Resistor R4 is used to limit grid current through V2. Since gain is essential in the operation of this driver, a bootstrap amplifier is used. The bootstrap circuit includes elements which cause the voltage on the grid of the amplifier tube to rise with the cathode voltage, maintaining a constant signal voltage from grid to cathode. These elements include a source of plate voltage for the preceding tube which is not tied directly to ground, and a means of coupling the rise in potential of the cathode to this plate supply.

The artificial line is the source of plate voltage for tube V2 during the pulse, and is isolated from ground by resistor R5. The only other path to ground is through resistor R9 in the cathode of tube V3. Therefore, as the cathode of V3 arises during the pulse, the entire circuit of V2 is raised the same amount above ground. The drop across R6 is maintained by the discharge of the line, and is applied directly between the grid and cathode of V3. This is the bootstrap action, so-called because the amplifier raises its grid-circuit voltage in order to maintain a constant grid signal. When the artificial line is completely discharged, the voltage difference across R6 disappears, and the potential of the grid of V3 at once becomes —150 volts with respect to the cathode, and the tube is made nonconducting. The modulator tubes normally are cut off by the —1,100 volts applied to their grids through R9. The positive pulse produced across R9 drives V4 and V5 into heavy conduction, so that C16 is permitted to discharge through the magnetron to ground and through V4 and V5 in parallel. Since these tubes are in parallel, the resistors R10, R11, R12, and R13 are necessary to prevent parasitic oscillations. The charge that is lost from C16 during the generation of the r-f pulse is restored to the capacitor during the resting time by a charging current which flows from ground through diode V6, capacitor C16, and resistor R14 to the —13,000-volt supply. The diode is used as a one-way resistor which permits current to flow to charge C16, but which prevents loss of energy during the pulse, since none of the discharge current can flow in the diode. The use of the diode permits more efficient use of the energy stored in the capacitor because a resistance used as a charging element may dissipate as much as 20 per cent of the available energy during the discharge.

Line-controlled Blocking-oscillator Driver

A modification of the circuit of the single-swing blocking oscillator may be used to produce a pulse of accurately-controlled duration

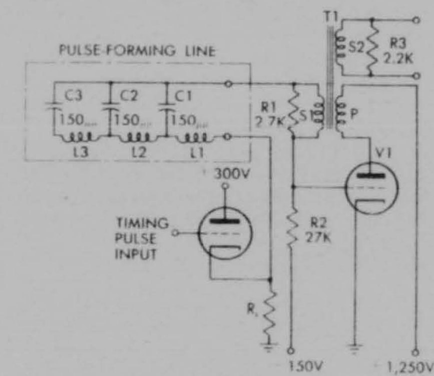

Figure 1—26. Line-Controlled Blocking Oscillator: Schematic Circuit Diagram.

for the operation of a modulator tube (Figure 1-26). An artificial transmission line is used to control the duration of the pulse, since the blocking oscillator itself is unable to produce a square output of controllable duration. One advantage of this type of driver is that it requires only one tube, which makes the driver circuit and the associated power supply simple.

The blocking-oscillator tube V1 is normally cut off because its grid is connected through R2 to the —150-volt bias supply. A positive timing pulse of approximately 110 volts is applied to the circuit through a cathode follower to start the operation. This pulse is coupled across the capacitance of the artificial transmission line and through winding S1 on the pulse transformer to the grid of V1. Although the pulse suffers considerable attenuation in passing through this network, it is of sufficient amplitude at the grid to start conduction in the blocking-oscillator tube.

The plate current of V1 flows through the transformer primary, P, which produces a voltage across this winding. A voltage in secondary S1 is also induced that reinforces the trigger pulse, so that the grid is rapidly driven very positive as soon as conduction is started. If 1,000 volts appears across P, a voltage of 500 volts is induced in S1 because of the 2-to-1 turns ratio of the transformer. Since the voltage induced in S1 is relatively constant during the pulse, it may be represented as a 500-volt battery with polarity as indicated in Figure 1-27.

The artificial transmission line normally is charged to -150 volts through Rk, S1, and R2 from the bias supply for V1. In the equivalent circuit, the line is shown as a resistor in series with a 150-volt battery. Since the two batteries oppose, only 350 volts is available to drive a current through the circuit. The sum of the grid-to-cathode resistance of V1 and the output resistance of the cathode follower is made equal to the characteristic impedance of the artificial transmission line. Therefore, a current i flowing in the circuit produces approximately 175 volts across the line and across the combination or Rk + Rgk with polarity as indicated in Figure 1-27. As long as the current i continues to flow, the voltage developed across Rgk will keep V1 in full conduction.

The additional voltage impressed on the line by the flow of current i in the circuit is of the same polarity as the initial charge. A traveling wave goes down the line, raising the voltage across it to 325 volts. When the wave strikes the open end of the line, it is reflected without change of sign. The wave then comes back toward the source, charging the line to 500 volts as it progresses. At the instant that the reflected wave reaches the input terminals of the line, the current i drops to zero, since the voltage across the transmission line equals the voltage induced in S1, at this instant making the net voltage in the circuit zero. Although the timing-pulse voltage may still

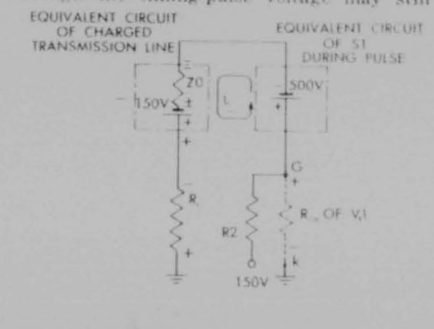

Figure 1—27. Equivalent Circuit of Line-Controlled Blocking Oscillator.

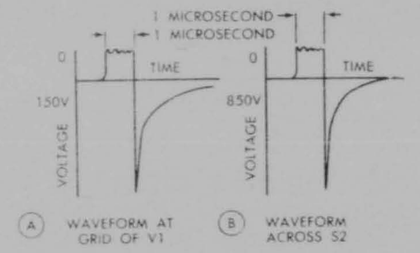

Figure 1—28. Waveforms in Line-Controlled Blocking Oscillator.

exist across Rk, the potential of the grid of V1 drops sharply because of the connection to the −150-volt bias supply, reducing the magnitude of the current flowing in the tube. The duration of conduction in V1, which is equal to the output-pulse length, is controlled by the artificial transmission line. Since the line is designed so that ½ microsecond is required for the wave to travel the length of the line, the output pulse is of 1-microsecond duration.

As the current in the tube starts to fall off, the voltage induced in S1 drops to zero and the artificial line begins to discharge through R2 and Rk. Both of these effects combine to drive the grid very sharply negative, which quickly cuts off the current in V1. The field set up by the primary winding must therefore collapse. In collapsing, a sharp negative surge of voltage is induced in S1 which drives the grid even farther negative. Resistor R1 is used to damp out the oscillations that are excited in the secondary by this negative surge. If no damping were provided, the positive swing of the oscillation might cause false triggering of the circuit.

The waveform of the voltage at the grid of V1 is shown in Figure 1-28A. The slight irregularities in the top of the pulse are due to the fact that the artificial line is only an approximation to a real line. The relatively slow recovery of the grid to its normal bias is caused by the discharge of the capacitors in the artificial line to their normal charge of −150 volts. The flow of current in the primary of T1 also induces a positive pulse in secondary S2. Since the turns ratio between windings P and S2 is 1 to 1, the output developed across this secondary is a pulse of approximately 1,000-volt amplitude (Figure 1-28B).

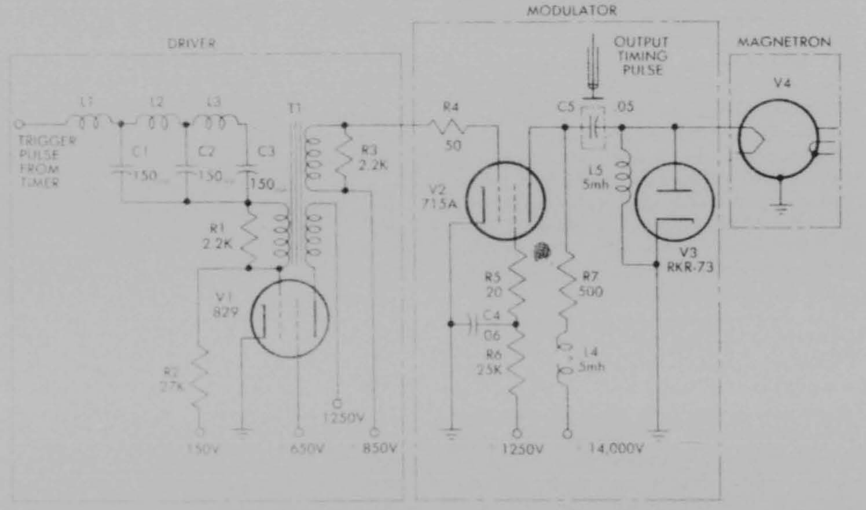

Figure 1—29. Transmitter with Line-Controlled Blocking Oscillator Driver.

The line-controlled blocking-oscillator driver is shown in Figure 1-29 as a component of a complete transmitter circuit. The input to the modulator tube V2 is the 1,000-volt pulse developed across winding S2 of the pulse transformer. V2 is normally nonconducting because of −850-volt bias supplied to its control grid. Capacitor C5 is charged from the 14,000-volt supply through V3, R7, and L4. When the positive pulse is applied to the modulator tube, C5 discharges through the magnetron and V2, generating an r-f pulse.

When the driver-output pulse falls, V2 is sharply cut off. Oscillations are set up in L5 and the distributed capacitance between the magnetron filament and ground by this sudden change. The inductance is put in the circuit purposely to cause oscillations, so that the pulse at the magnetron filament may have a steep trailing edge. For example, Figure 1-30A shows the effect of the distributed capacitance in prolonging the decay of voltage at the magnetron filament. Oscillations set up in the filament circuit by the addition of inductor L5 produce a voltage of the type shown in Figure 1-30B. Since the negative alternations of the oscillation, as at A and B, could cause the magnetron to oscillate, the negative portions must be removed. Damping is usually provided by a diode, so that a waveform of the type shown in Figure 1-30C is produced. The diode acts as a very low resistance across the resonant circuit during the positive alternation, and quickly damps out the oscillations by absorbing the energy in the oscillatory circuit. Therefore, no negative alternations occur to cause the magnetron to operate.

Because there is always a slight delay in starting the pulse in a blocking-oscillator driver, it is not desirable to use the trigger pulse for timing the rest of the radar system where short minimum ranges are important. To avoid the complexity that would be involved in attempting to match this delay by some form of delay circuit, a timing pulse is coupled out of the transmitter from the case of C5. Since the case of C5 is connected to one plate of the capacitor, it changes potential abruptly when the modulator is driven into conduction. Therefore, whenever the magnetron is pulsed, a negative timing pulse is coupled out to the rest of the circuit at exactly the same instant.

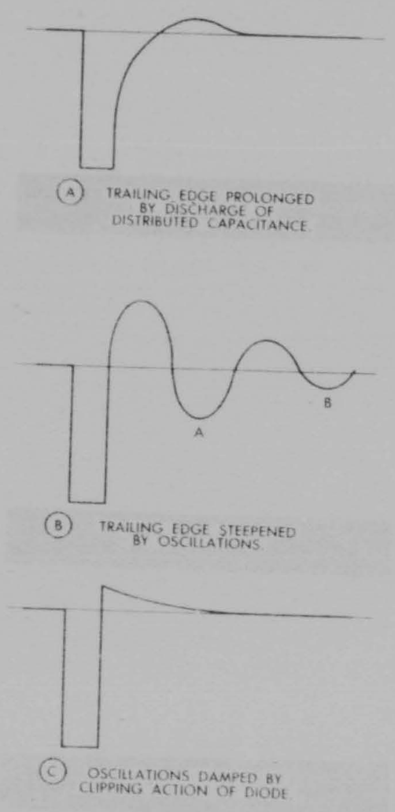

Figure 1—30. Modulation Pulses at Magnetron Filament.

Fixed Spark-gap Modulator

Instead of amplifying a modulating pulse in a series of vacuum tubes, a pulse may be generated at high-power level directly by discharging a pulse-forming line through the r-f generator and a switching device. The switching device in this type of system is usually a spark gap because of the limitations on the power-handling capacity or the break-down voltage of other devices. The obvious advan-

THIS PAGE IS DECLASSIFIED IAW EO 13526

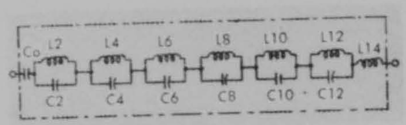

Figure 1–31. Guillemin Line.

tage of this system is that modulator tubes with their heady filament-power drain, are not required. The spark itself dissipates very little energy and the power consumed by the auxiliary controls is small, so that theoretical efficiencies of 80 or 90 per cent are possible.

One disadvantage of the high-level pulse-modulation system is the fact that there is no chance to improve the shape of the pulse after it is generated. In the vacuum-tube pulse modulator the pulse is generated at low voltage and thereafter is amplified in the non-linear amplifiers which saturate at the peak of the pulse. In this case, the artificial transmission line used to form the pulse may be a poor approximation of a real line because irregularities in the flat top of the pulse thus introduced may be clipped in succeeding amplifiers. In the high-level pulse modulator, on the other hand, no such opportunity for shape correction exists. The line employed must be a close approximation to a continuous transmission line.

If an artificial line is to meet this requirement, many sections must be used. Since all of the capacitors must withstand the high voltage, such a line would be very bulky. A means of reducing the physical size of the line is found in the use of the Guillemin line, shown in Figure 1-31. The series capacitor is the only one that need be insulated for high voltage since it is the only one charged. The other capacitors are paralleled by inductances and have voltage across them only during charge and discharge, where they divide the applied voltage.

When the Guillemin line is used in high-level pulse modulation, a very nearly rectangular pulse may be generated with steep rise and fall, and flat-top constant within ±5 per-cent. Modifications of the Guillemin line which use only a few sections have been developed. These networks are usually encased in a metal container filled with insulating compound, and are called "potted lines."

The basic circuit of the fixed spark-gap modulator is shown in Figure 1-32B. The pulse-forming line, which may be either the Guillemin line or the ordinary artificial transmission line, is charged from the power supply through L1 and V1. The inductance of L1 and the capacitance of the line form a resonant circuit so that the voltage across the line tends to oscillate. At the peak of the positive swing the line is charged to a voltage considerably higher than the DC supply. At this instant the trigger pulse is applied to the auxiliary electrode, and the spark gap conducts. The characteristic impedance of the pulse-forming line is made equal to the impedance of the magnetron so that one-half of the voltage on the line is impressed across the magnetron for the duration of the pulse.

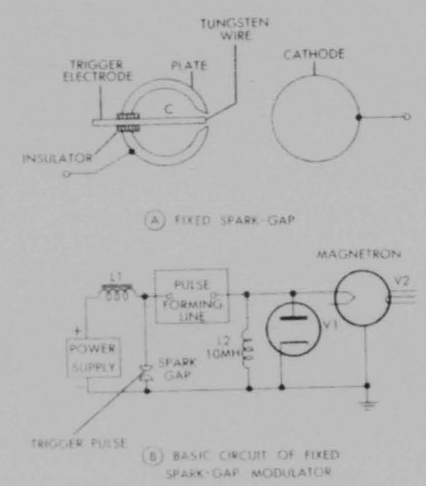

Figure 1–32. Fixed Spark-Gap Modulator.

The spark gap (Figure 1-32A) consists of two spherical electrodes, one of which is hollow. Inserted in the hollow sphere, and insulated from it, is a third electrode. The main gap AB is made large enough so that the voltage between A and B will not break it down.

If the gap between trigger wire C and electrode A is broken down by a trigger pulse, the resulting positive ions will be attracted toward the electrode B and will therefore cause break-down in the space between A and B. The instant of discharge can be controlled accurately in this way. Experience shows that the control of the timing of the discharge is more accurate when the hollow electrode serves as the anode, or plate, for the discharge. The spark stops when the network is almost completely discharged because the voltage across the gap is no longer sufficient to maintain ionization.

A thyratron tube may be used in place of the fixed spark gap in the same circuit. The limitation of the thyratron is that this type of tube cannot withstand a voltage in excess of 27,000 volts, while the spark gap can be used for practically any voltage.

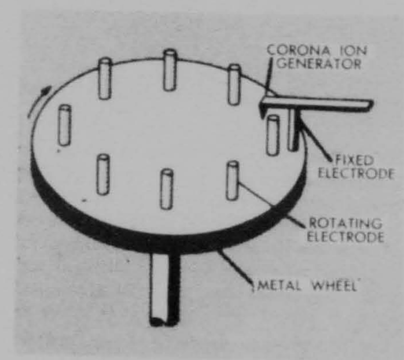

Figure 1–33. Rotary Spark-Gap.

Rotary Spark-gap Modulator

The spark gap is well suited for use in a modulator circuit because it can handle peak currents of 100 amperes or more at very high voltages. However, an arc that takes place in air produces ozone and nitrous oxide which corrode the metallic electrodes rapidly, especially in the presence of water vapor. The life of a fixed spark gap is usually less than 200 hours because of the rapid corrosion of the trigger electrode.

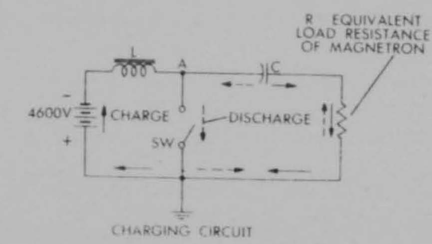

Figure 1–34. Equivalent Circuit of Spark-Gap Modulator.

Another way of breaking down a spark gap is to cause its electrodes to approach each other at the time the gap is to fire. This can be accomplished by rotating one side of the gap on a wheel in such a way that it regularly passes a fixed electrode, as shown in Figure 1-33. On the same bracket with the fixed electrode which serves as one terminal of the main discharge is mounted a small, sharply pointed electrode called a corona ion generator. Near the sharp point of the ion generator the voltage stress is much higher than elsewhere, so that the air is more easily ionized at the point. When the rotating electrode passes between the fixed electrode and the ion generator, the gap between the two main electrodes breaks down quickly because of the initial ionization provided by the ion generator.

Since the spacing of the electrodes which form the gap is not critical, and since the corrosion of the electrodes that takes place is distributed among the several rotating electrodes, the life of the rotary spark gap is much longer than that of the fixed spark gap. If the corrosive gases produced by the spark are removed either by a carbon absorber or blown away by a fan, the life of the rotary gap should be in excess of 1,000 hours.

Because radio-frequency energy is radiated from the spark it is necessary to inclose the mechanism within a metal container to prevent interference with other parts of the radar circuit. In addition, chokes and filters are inserted in all leads to and from the rotary-gap circuit to prevent transmission of r-f energy to other parts of the equipment. The spark gap should be kept at constant pressure to operate consistently. It is especially important that

THIS PAGE IS DECLASSIFIED IAW EO 13526

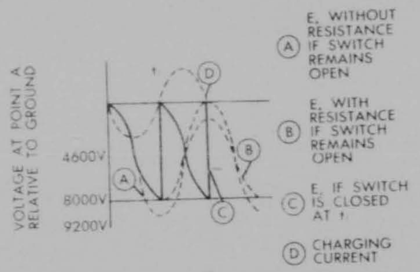

Figure 1–35. Capacitor Charge and Discharge.

the pressure be maintained in aircraft installations, because the breakdown voltage of air is considerably reduced at high altitudes where the air pressure is low.

The pulse-forming network used with a spark-gap modulator may be charged from either an AC or DC source. Since the charge is stored on the capacitors in the network, a capacitive reactance is offered by the network during the charging time. An inductor connected in series with this capacitance produces an oscillatory circuit (Figure 1-34). If switch SW is closed sometime before t_0 (Figure 1-35) the pulse-forming network, which is represented by C, will discharge through R and SW and the potential at A will be zero. If the switch is opened at t_0, a potential of –4,600 volts is suddenly applied to the RLC circuit. This sudden change of voltage sets up a train of damped oscillations. The initial surge of energy oscillates between the magnetic field around the inductor and the charge of the capacitor. If there were no resistance in the circuit, the current would be an undamped sine wave (Figure 1-35D), and the voltage at point A would vary between O and twice the applied voltage, curve (Figure 1-35A). However, with resistance in the circuit, the voltage at point A is a damped sine-wave curve (Figure 1-35B) which will ultimately die out, leaving the capacitor charged to the supply potential of –4,600 volts.

The damping caused by the resistance in the circuit limits the first swing of voltage at point A to about –8,000 volts. The inductance is adjusted to make the frequency of the oscillation equal to one-half the pulse-repetition frequency, so that the voltage at point A will be a maximum at time t_1. If the switch is closed at this instant, the voltage at point A falls to zero (curve Figure 1-35C), and the pulse-forming network discharges through R. Since R is equal to the characteristic impedance of the network, a pulse of 4,000 volt amplitude is produced across it by the discharge.

The exact instant of striking the arc in a rotary-spark gap is not easily controllable and the arc may not strike at exactly t_1 for every pulse. Although the voltage at point A does not change greatly within several micro-

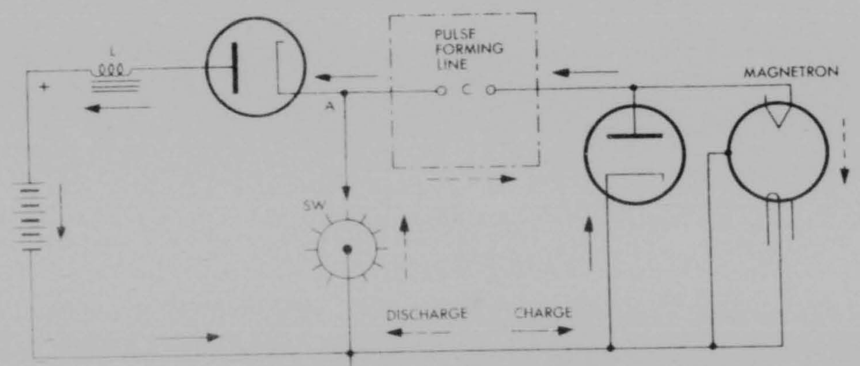

Figure 1–36. Charging Diode in Rotary Spark-Gap Modulator Circuit.

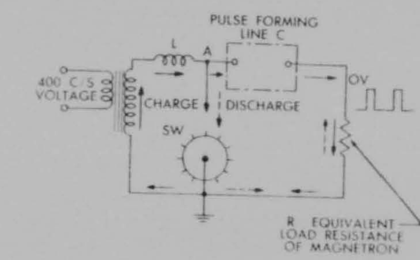

Figure 1–37. AC Charging Through Inductance.

seconds before or after t_1, it is sometimes desirable to connect a diode in the circuit to prevent this voltage from decreasing (Figure 1-36). The diode permits electrons to flow in the direction for charging the network, but at t_1 when the current attempts to reverse direction (Figure 1-35D), the diode becomes nonconducting and prevents any further change of charge on the network. By this means, the network can be charged to nearly twice the applied voltage, and as it will remain at this voltage there is no need of synchronizing the firing of the spark gap with the period of the charging oscillation.

The pulse-forming network may be charged directly from a transformer when connected in a circuit similar to that shown in Figure 1-37. In this case the circuit is not resonant, but the frequency of the applied power corresponds to the DC resonance charging of the type previously discussed. The same variations in the basic circuit can be made.

Improvement in the performance of spark-gap modulators can be had by using transformers which are specially designed to pass a pulse waveform without introducing substantial changes in its shape. Such transformers serve several important purposes in modulator equipment. In the first place they may be used to change the impedance level in pulse circuits, changing from a high-voltage, low-current source to a low-voltage, high-current output, or vice versa. In the second place, the transformer may be used as a polarity-reversing device, as in the blocking oscillator discussed above. In the third place, the transformer may serve to isolate DC sources.

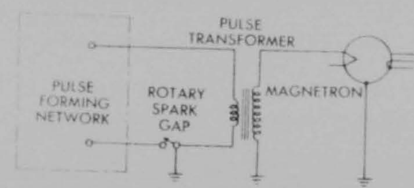

Figure 1–38. Pulse Transformer in Spark-Gap Modulator Circuit.

The most common use of the pulse transformer is illustrated by Figure 1-38. The pulse is formed by a rotary gap discharging an artificial line through the primary of the transformer. The turns ratio is such as to step up the primary voltage to a much higher value to be applied to the magnetron. Since the magnetron impedance as seen by the line is stepped down as well, the pulse-forming network need need not be built to withstand the high voltage of the pulse reaching the magnetron, and can have a lower characteristic impedance. The voltage of the power source for charging the pulse-forming line is correspondingly smaller.

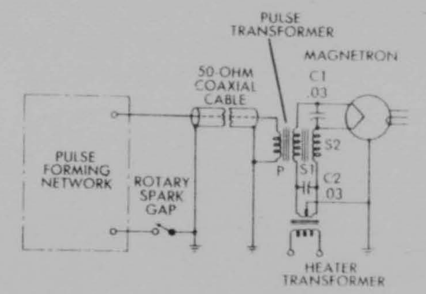

Figure 1–39. Separation of Magnetron and Modulator Circuits.

In many radar installations, particularly those in aircraft, it is desirable to separate the antenna and the bulky power units of the transmitter by a considerable distance. This can be accomplished by running a long coaxial line or waveguide from the magnetron to the antenna. However, long r-f lines tend to make the operation of the magnetron unstable and such long lines should be avoided if possible. An alternative to long r-f lines is to separate

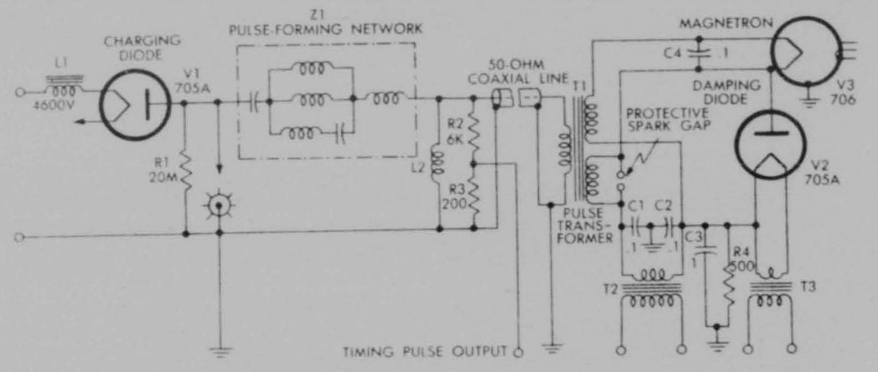

Figure 1—40. Schematic Circuit Diagram of Complete Rotary Spark-Gap Modulator and Transmitter.

the magnetron from the modulator and power supplies, and to connect them by a long cable (Figure 1-39). It is necessary to terminate the pulse cable in its characteristic impedance to prevent reflection of the pulse. Since it is impractical to build a coaxial line of which the characteristic impedance is equal to the static resistance of the magnetron (about 800 ohms), the coaxial line must be terminated in a pulse transformer. The pulse transformer and magnetron are not bulky, thus it is feasible to have them near the antenna.

Two secondary windings are wound on the pulse transformer. When a pulse is applied to the primary, the voltage induced in each winding is negative at the cathode end of the coils. The two secondary windings are effectively connected in parallel for the pulse voltage by capacitors C1 and C2, so that both windings aid in driving current through the magnetron. With two secondary windings connected in this way, the lower ends are nearly at ground potential. Therefore the heater transformer need not be insulated for high voltages. This connection permits the use of conventional heater transformer in this circuit instead of the special transformer, insulated for the full pulse voltage, that was required in the transmitter discussed in Section IV.

In Figure 1-40 is shown the circuit diagram of a complete rotary spark-gap modulator and transmitter. The pulse-forming network is charged to 8,000 volts from a voltage doubler through a resonant-charging circuit consisting of L1, V1, Z1, L2, R2, R3, and the primary winding of T1. Although most of the discharge current flows through the primary of the pulse transformer, some of the current flows through R2 and R3 and through L2. The output of the modulator is a positive-going 4,000-volt pulse. Therefore, a positive pulse of approximately 125-volt amplitude is developed across R3 to be used as the timing pulse for the rest of the system.

The 4,000-volt positive pulse in the primary of the pulse transformer induces a negative 18,000-volt pulse in the secondary windings. Should the load be removed by disconnecting the magnetron, a voltage much larger than 18,000 volts would be developed across the secondaries because of the poor regulation of the transformer. To prevent damage to the transformer from the possible high voltage, a protective spark gap, adjusted to first at 25,000 volts, is connected across one of the secondaries. Should the gap fire, the transformer would be heavily loaded, and the voltage could rise no higher.

The pulse voltage induced in the two secondary windings of the transformer is equalized by bypass capacitors C1, C2, and C4. Since it is desired to keep the lower ends of the two windings nearly at ground potential, capacitors C1 and C2 are connected to ground. The magnetron plate current passes through

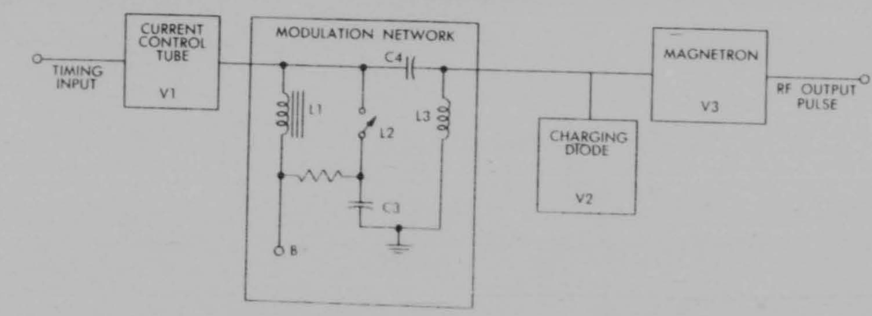

Figure 1—41. Block Diagram of Saturable Inductor Modulator.

the magnetron to ground. The magnetron plate current passes through the magnetron to ground, through R4 and C3 in parallel, and the pulse-transformer secondaries. The voltage developed across R4 is proportional to the average current flowing in the magnetron and the damping diode because C3 filters out the surges. If it is desired to have an approximate indication of the magnetron plate current, a meter may be connected across R4. If no meter is desired, the circuit may be simplified by the elimination of the bypass capacitors, and the center taps of the heater transformers may be grounded to provide a closed circuit for the plate current.

Saturable Inductor Modulator

Instead of producing a low-power pulse and amplifying it, or generating a high-power pulse from an artificial line, a saturable inductor can be used as a switch to control the charge and discharge of a network to produce an approximately square modulating pulse. The block diagram of such a system is shown in Figure 1-41.

The timing input to the current control tube is a square wave. During the positive portion of this square wave, V1 is conducting, and energy is stored in the field around inductor L1. When the tube is cut off, this field collapses, charging capacitor C4 through the charging diode. At the instant that the voltage across the capacitor is a maximum, the saturable inductor switch, L2, is closed and the capacitor voltage is applied across the magnetron through C3.

A saturable inductor can be used as a switch since it can be either a very high impedance or a very low impedance, depending the conditions under which it operates. This wide change of impedance is possible because the core of the saturable inductor, or nonlinear coil as it is sometimes called, is saturated by a relatively low current in the coil. A graph, called a **magnetization curve**, in which the flux density in the core is plotted against the current in the coil, is shown in Figure 1-42. The horizontal portions of the curve are called the saturated region because a current more positive than A or more negative than B cannot cause an increase in the flux density of the core. In the region between A and B the flux density in the core is directly proportional to the current flowing in the coil. Since the voltage across an inductor is proportional to the rate of change of the magnetic flux that links the coil, no voltage appears across it when the core is saturated, even though the current may be changing. With zero voltage across the inductor, it acts as a short circuit; with a voltage induced in the coil by a changing magnetic field, it acts as an impedance

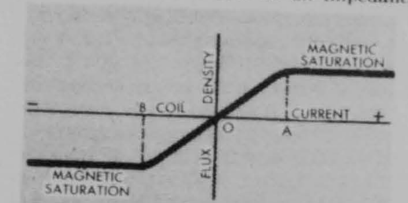

Figure 1—42. Magnetization Curve of Saturable Inductor.

THIS PAGE IS DECLASSIFIED IAW EO 13526

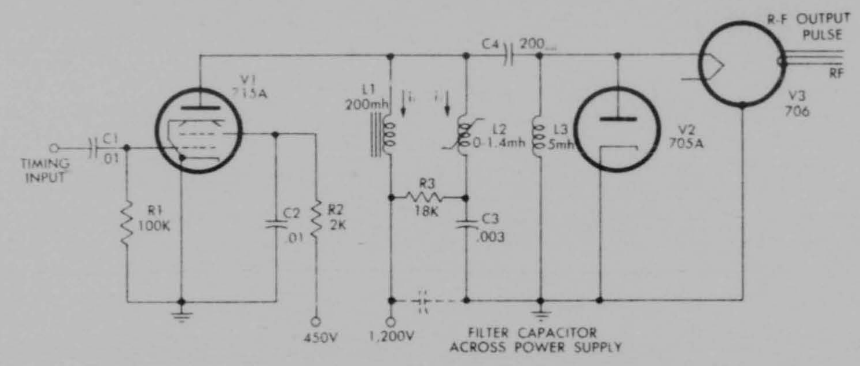

Figure 1—43. Schematic Circuit Diagram of Saturable Inductor Modulator.

which is made high by proper design of the coil. Therefore, when the current through a saturable inductor lies in the region between A and B, it may be considered as an open switch; when the current is beyond either A or B, the inductor is a closed switch.

A schematic circuit diagram of a modulator which uses a saturable inductor as a switching device is shown in Figure 1-43. It should be noted that the symbol for the saturable inductor, L2 is similar to the symbol for a conventional inductor with a line through it to represent its magnetization curve.

The current control tube V1 is normally cut off by grid-leak bias developed by C1 and R1. When the timing square wave swings the grid of V1 positive, current i_1 and i_2 begin to flow in plate-load inductors L1 and L2. Current i_2 quickly builds up to a value in excess of saturation value, so that L2 becomes a low impedance.

At this time, C3 quickly discharges through L2 to the voltage at the plate of V1. Although L2 offers very little impedance to a further change of current in this branch of the circuit the magnitude of i_2 is limited by resistor R3. Inductor L1 is shunted by a high impedance, whether L2 is saturated or not, so that most of the plate current of V1 must flow through L1. As the current i_1 continues to increase, energy is stored in the magnetic field around L1.

When the current-control tube is cut off by the negative swing of the timing square wave the field around L1 starts to collapse. A high voltage with polarity as shown on L1 is induced across L1 by the collapsing field. This voltage is momentarily short-circuited by the low impedance of L2, C3, and the filter capacitance across the 1,200-volt power supply, tending to reverse the direction of flow of i_2. When i_2 decreases to saturation value, L2 becomes a high impedance. At this instant, the energy of the collapsing magnetic field begins to be transferred to capacitor C4 in an oscillatory transient. As energy is transferred to C4, the voltage across it builds up along a sine curve. This voltage reaches a maximum of about 15,000 volts, with the polarity in approximately 10 microseconds, which is equal to a quarter of the period of the oscillation of the resonant circuit made up chiefly of L1 and C4. The path through which capacitor C4 is charged from L1 is through diode V2 and the filter capacitance across the 1,200-volt power supply.

While capacitor C4 is being charged, current i_2 in the saturable inductor decreases from saturation value A to zero and builds up toward saturation value B in the other direction. The time required for this reversal to take place is approximately 10 microseconds. When L2 again is saturated, it becomes a low impedance, grounding the positive side

of C4 through capacitor C3. Since the capacitance of C3 is about 15 times greater than that of C4, and since L2 is a low impedance, approximately 14,000 volts appears across the magnetron. The polarity of the voltage on C4 is such that the magnetron cathode is made negative with respect to the anode, causing oscillation.

Initially inductor L3 is a very high impedance to the discharge of capacitor C4, because the current in the inductor cannot change instantly. However, after about 0.3 microsecond, the current through this inductor has built up to an appreciable magnitude, and L3 effectively shunts the magnetron with a constantly-decreasing impedance. Since the impedance of L3 becomes low, the rate of discharge of C4 is increased, causing the magnetron to go out of oscillation quickly. Within the 0.3 microsecond period, oscillations of a single mode are produced by the magnetron in spite of the fact that the plate voltage decreases from 14,000 volts to approximately 8,000 volts during this time. Although it was pointed out that the voltage impressed on a magnetron should be constant to prevent oscillation in undesired modes, it is possible to operate improved magnetrons with the type of voltage provided by the saturable-inductor modulator without harmful loss of power.

SECTION V—ANTENNA SYSTEMS

1. INTRODUCTION

General

Previous sections of this manual have indicated that the electrical characteristics and physical appearance of radar antenna systems may vary widely. The approximate size of the antenna is determined by the selection of the carrier frequency and the type of installation. The actual design for a given equipment is based on several considerations which control the over-all efficiency and the angular accuracy of the data to be obtained.

Efficiency Considerations

Maximum efficiency of the antenna system demands that each link in the path from transmitter to antenna, and from antenna to receiver, waste as little of the r-f energy as possible. The transmission line used should, therefore, have the smallest possible losses, consistent with the physical types, which can be used for a reasonable size of unit.

In addition to protecting the receiver circuits from burnout and blocking, the T-R switch increases the energy transfer by guiding the signals to their proper destination. During the transmitted pulse the receiver path is closed, and during the resting time the transmitter path is closed. Thus, in each case, the energy is used to produce the desired result, without wasting power in inactive circuits.

Finally, the over-all efficiency can be raised if the particular application for which the system is to be used will permit concentration of the energy into a narrow beam.

Angular Accuracy

The ability of a radar unit to locate targets in azimuth or elevation depends on how well the antenna can select the direction of the return signal. It has been shown in section I that a narrow beam is better able to find the maximum return-signal direction than a wide one. Double-lobe systems still further increase the accuracy of angular measurement.

Back radiation and side lobes tend to confuse the operator, and therefore, decrease his ability to locate targets. Antenna construction which will reduce unwanted lobes in antenna patterns is usually employed to aid in this respect.

2. CONICAL SCANNING

General

The principle of lobe switching can be extended to give accurate azimuth and elevation

THIS PAGE IS DECLASSIFIED IAW EO 13526

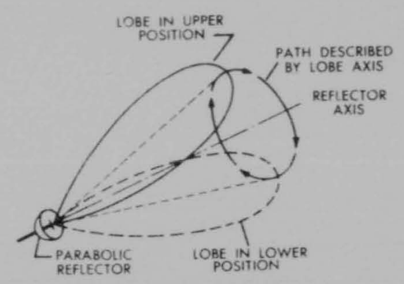

Figure 1—44. Conical Scanning.

simultaneously when applied to antenna systems using parabaloidal reflectors. The name given to this type of operation is **conical scanning** because an off-center lobe is produced which is rotated about the axis of the reflector (Figure 1-4). The lobe axis describes a cone in space around the axis of the reflector.

The echo signal received from a target which lies on the axis of the reflector has the same amplitude for all positions of the lobe. If the target moved away from the reflector axis the signal received varies approximately sinusoidally with the rotation of the lobe. As the axis of the lobe nears the target the signal increases, and as the axis of the lobe moves away the signal decreases. The relative phase of the signal variation therefore indicates the direction of the target from the reflector axis. The magnitude of the signal variation indicates the distance away from the reflector axis to the target.

Conical scanning is applied to micro-wave systems which are used for fire control against aircraft. The circuits which supply the indicator can be used simply to indicate the relative position of the target, or they can be made to track the target automatically as well as indicate its position. The discussion here will be confined to the methods for producing the conical scan.

Off-center Dipole

The simplest method to produce conical scanning is to use a coaxial line terminated in a dipole. The coaxial line is bent sufficiently to displace the electrical center of the dipole slightly away from the focal point of the reflector (Figure 1-45). The coaxial line and dipole are rotated by a scanning motor at a speed of 20 to 60 revolutions per minute.

The apparent source of energy for the parabaloidal reflector is the electrical center of the dipole assembly. Since it is off center with respect to the reflector, the lobe produced will be off center. As the center of the dipole rotates around the axis of the reflector, the lobe is rotated also.

The chief disadvantage of the method illustrated above is that the dipole assembly is not balanced mechanically about the axis of rotation. A second method has been used in which the dipole assembly closely resembles that of the system described previously. The coaxial line is at the center of the reflector, and is perfectly straight and properly balanced. Figure 1-46 shows a dipole; element A is fed in the normal manner by direct connection to the inner conductor. The path for energy flow to element B is made longer by causing the energy to flow from the inside of the outer conductor through hole C and around the outside of the coaxial lines to element B. This manner of feeding, plus the position of the bazooka and the fact that the dipole elements are of different shape, gives an uneven current distribution. The uneven distribution causes the electrical center of the dipole to move from the physical center. Therefore, the energy is reflected from the paraboloid at a slight angle

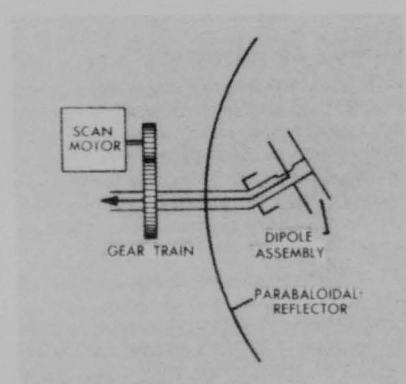

Figure 1—45. Off-Center Dipole.

to the axis. As the dipole is rotated, the point at which the energy is directed describes a circle around the center of the reflector and the reradiated energy describes a cone giving the desired conical scan. The bazooka or quarter-wave balancing section mounted on the outer conductor of the coaxial line also prevents standing waves on the transmission line.

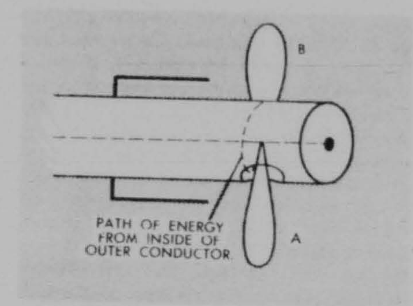

Figure 1—46. Construction of Balanced Conical-Span Dipole.

Waveguide Conical Scan

It is possible to produce a relatively simple system of conical scanning with a round waveguide which may easily be balanced mechanically. Figure 1-47 shows one type which is used. The r-f energy is supplied to a fixed round waveguide through a coaxial line. The inner conductor extends into the guide to act as the coupling probe, and a plunger in the end of the guide is used to adjust the degree

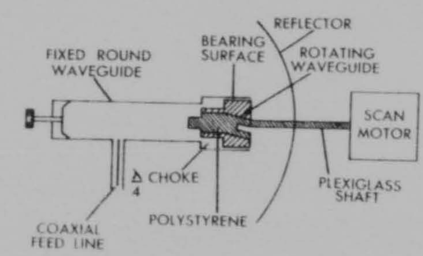

Figure 1—47. Conical Scanning with Waveguide.

of the coupling. A polystyrene-filled round waveguide is fitted in the other end of the waveguide.

The inner end of the polystyrene is of the proper size to match the impedance of the fixed waveguide to that of the rotating waveguide. The rotating waveguide is bent off the center line of the fixed guide in order to produce a beam shift by supplying energy off center to the paraboloidal reflector. The conical scan is produced by driving the offset rotating waveguide through a plexiglass shaft coupled to the scan motor. A small hole in the outer end of the polystyrene filling helps to match the rotating waveguide to the paraboloid and to free space.

The system can be balanced by properly distributing the weight of the metal plug in which the hole is bored to form the rotating waveguide. Radiation through the rotating joint between the fixed waveguide and the metal plug is prevented by a groove a quarter-wavelength deep, which acts as an r-f choke.

SECTION VI—RECEIVERS

1. GENERAL

Introduction

Improved receiver design can increase the usefulness of radar equipment, perhaps more than any other single factor. Only a small part of the energy radiated from the antenna strikes a distant target, in spite of efforts to limit the transmitted energy to a narrow beam. The reflections from the target are scattered in random directions, causing the echo which returns to the set to be extremely small. The receiver must accept signals of perhaps a microvolt or less in amplitude and amplify them to useful magnitudes. The effective range of a radar set is therefore proportional to the ability of its receiver to utilize weak reflected signals. The weaker the signal which the receiver can use, the greater the effective range of the set.

Signal-to-noise Ratio

Theoretically it is possible by using many stages of amplification to build any signal, no matter how weak, to any desired amplitude. However, there are present in all electrical circuits various random disturbances which produce small voltage variations known as noise. In particular, the input stage of the receiver generates such voltages. These are amplified along with the signal voltage in the following stages of the receiver. Noises are generated in the other stages, but these are less important since they are not amplified as much as those which are present in the first stage. If the signal is not at least as large in amplitude as the noise voltage at the input stage, it cannot be recognized at the receiver output and therefore is useless.

A primary consideration in receiver design is to keep the noise lever as low as possible so that, for a given signal, the signal-to-noise ratio is high. If the noise level is low, a weak signal from a distant target may be detected. If the noise level is high, the target has to be much closer before the echo from it is sufficiently strong to override the noise. Thus, the noise generated in the receiver is a factor which affects the useful range of the set. Reducing noise by improved design on a moderately good receiver may extend the range of the set much more effectively than increasing the output power of the transmitter.

The noises which are generated in an amplifier stage include three types. These are thermal agitation, shot effect, and induced noises. All of these include frequency components throughout the entire frequency spectrum, and the amount of noise therefore is affected by the choice of bandwidth for the receiver. In general, a reduction in bandwidth of the receiver reduces the noise voltage, but does so at the expense of pulse shape. The amount of distortion of the pulse shape which can be tolerated is the limiting factor in increasing signal-to-noise ratio by reduction in bandwidth.

Thermal-agitation noises are caused by random motion of free electrons in a conductor. At any instant there are likely to be more electrons moving in one direction than in the other, causing a voltage to develop across the conductor. If the temperature of the conductor rises, the agitation of the electrons increases in both directions so that the instantaneous current is greater. Since the noise voltage generated in a conductor is the IR drop from this current, the amplitude of the noise voltage increases with an increase of either temperature or conductor resistance.

Shot effect is caused by irregular emission from the cathode of a tube. The electron flow in the plate circuit varies slightly in the number of electrons reaching the plate from one instant to another, and in the velocities of the individual electrons. This very small current variation produces a small voltage variation across the load empedance of the tube which is known as noise, since the irregularities are entirely random. When a positive grid is placed in the electron path to divide the electron flow with the plate, the shot effect is magnified because the division of the electrons is also irregular. For this reason, multi-grid tubes are noisier than triodes. Shot effect can be minimized by using a high mutual-conductance tube, since the signal control of the electron stream is greater than in a low mutual-conductance tube for the same relative noise lever. An increase in the space charge by higher filament temperatures is sometimes helpful in smoothing out emission variations.

Stray electrostatic and electromagnetic fields may induce voltages and currents in resistors, leads, and even within the tubes themselves. In addition to the shot effect in the plate circuit, the irregular electron stream causes currents to flow in the grid circuit. The electrons moving past the grid induce charges on it which are dependent on the positions of the electrons. If the flow is constant in velocity and number of electrons, the net result of all electrons will be constant. Actually this is not true, so that a random variation in charge on the grid occurs, with a resulting movement of electrons to and from the grid circuit. This takes place without electrons from the cathode reaching the grid, but by merely passing by. The movement of electrons in the grid circuit produces a noise voltage across the grid circuit which is amplified by the tube. The magnitude of the noise voltage on the grid

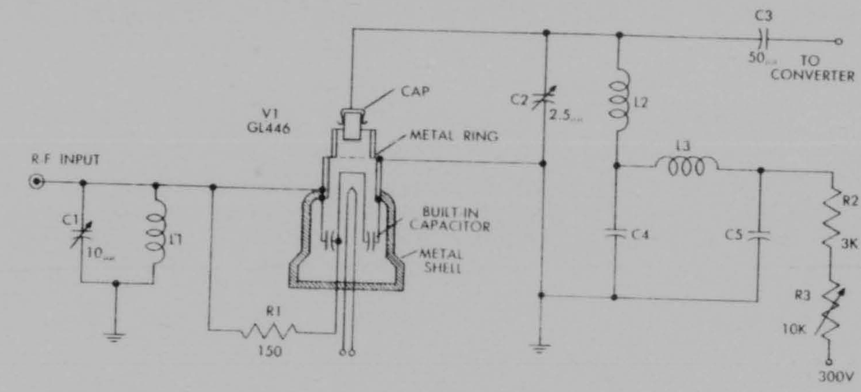

Figure 1—48. Grounded-Grid r-f Amplifier.

resulting from the electron stream increases with frequency, so that noise from this source depends both on bandwidth and the carrier frequency. Any other stray fields external to the tube may produce similar effects, in addition to voltages produced by insufficient filtering of the plate-voltage supply. Long feed lines are particularly susceptible to stray fields. Induced-noise voltages are minimized by low-impedance circuits, shielding, filtering, and short leads.

R-F Amplifiers

The difficulty of obtaining useful amplifications becomes greater as the carrier frequency becomes higher. Because of noise considerations, screen-grid tubes are in common use at the higher radar frequencies. The inductive reactance of the cathode leads at these frequencies causes appreciable degeneration. The signal voltage and part of the noise voltage are affected equally by this degeneration. The noise resulting from random division of current between the plate and screen grid, however, is not affected, because both of the currents flow in the cathode. The result is an over-all reduction of signal-to-noise ratio.

At extremely high frequencies, the capacitive reactance between tube elements becomes important. In triodes, the gridplate capacitance tends to cause instability which may set up oscillations. The grid-to-cathode capacitance tends also to shunt the signal voltage. The result is to limit the possible gain of the tube. The factors affecting the ability to produce amplification have been discussed in section III.

It was pointed out that the irregular emission of the cathode caused an apparent flow of current in the grid circuit without electrons reaching the grid from the cathode. This produces an input resistance to the tube which loads the grid circuit. The higher the carrier frequency, the lower is this input resistance. The electron stream is varied by the applied signal voltage as well, and this lowers the apparent input resistance. Thus the physical grid circuit constructed from inductance and capacitance is paralleled by the apparent input resistance and capacitance of the tube.

For the above reasons, r-f amplifiers have not been used extensively in the microwave region. At the lower radar frequencies, more or less satisfactory gain has been obtained by using tubes of small physical size to reduce interelectrode capacitance and the electron capacitance and the electron transit time. Multiple short leads to the cathode have been used in an attempt to reduce the inductance. A circuit with the grid grounded and the signal applied to the cathode is also useful in extending the high frequency limit of r-f amplifiers since the plate-to-grid capacitance then acts only as a load on the plate circuit,

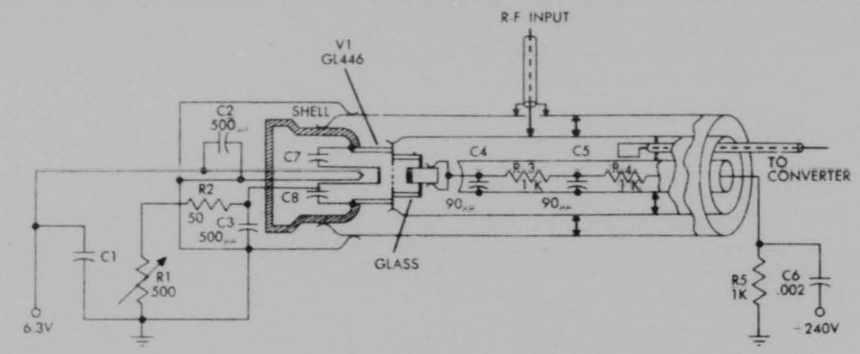

Figure 1—49. R-f Amplifier with Lighthouse Tube.

rather than as a feedback path as in a conventional circuit.

A tube which lends itself well to the grounded-grid type of circuit, or to circuits using tuned concentric lines, is the lighthouse triode. The heater and cathode connections are made to pins in a standard octal tube base. The plate connection is made to the cap, and the grid connection is made to a ring encircling the tube about halfway between the cap and the shell. This construction allows the tube to be made rugged with less interelectrode capacitance for the small spacing than in conventional triodes. A circuit using this tube as an r-f amplifier is shown in Figure 1-48. The coaxial cable carrying the signal is connected directly to the cathode shield. The signal voltage which appears across the tuned cathode circuit C1, L1, is coupled to the cathode by the capacitance between the cathode and a shield. Since the grid is grounded, the application of a signal to the cathode controls the plate current of the tube. Bias is developed across resistor R1. The plate coil L2 is tuned to resonance by capacitor C2. A filter network L3, C4, C5 bypasses to ground any r-f in the plate voltage lead. The resistors R2 and R3 permit the adjustment of the operating voltage to the proper value of from 200 to 250 volts.

Another r-f amplifier using a lighthouse triode and tuned by concentric lines is shown in Figure 1-49. The r-f input is tapped directly on the grid line. The cathode is coupled to the outer conductor of the grid-cathode line by the capacitors C7 and C8 which are built into the tube, and bypass radio frequency from the metal shell that forms the base of the tube to the cathode. Grid bias is furnished by the potentiometer R1 which is set to give the correct plate current. Plate voltage is supplied through the filter made up of C4, C5, and R3 located inside the plate line. Coupling to the next stage is made by means of a pickup coil positioned between the grid and plate lines. Because of the grid-plate line, some regenerative amplification may be realized. Oscillation is prevented by proper loading and location of the grid input tap.

Blocking and Recovery Time

The receiver, though partially protected by a T-R device, receives a strong signal directly from the transmitter. This signal may overdrive and block the receiver and render it insensitive to signals which follow shortly afterward. Thus, the minimum range may be seriously impaired by the receiver's inability to detect signals from nearby targets. The blocking results from excessive bias developed on one of the tubes by the signal, usually in a video stage which is resistance coupled. The blocking bias may be developed by grid current, or by excessive current through a cathode biasing resistor if it is bypassed by a capacitor. The stages preceding the second detector are not usually subject to blocking because the signal has not been amplified sufficiently to overdrive the tubes, since inductors rather than resistors are used in the grid leads, and because any cathode biasing resistors are unbypassed.

Blocking in the video stages can be prevented, or its effect minimized, in several ways. A gate pulse applied to one or more of the i-f stages may either bias the tubes to cut-off or remove the supply voltage for the duration of the transmitted pulse. When it is necessary to receive weak signals at the earliest possible moment after the transmitted pulse, as in AI equipment, gating is used. If the second detector produces negative pulses, the first video stage may be used as a limiter. Any signal of too great amplitude merely drives this tube to cut-off and its output is limited to a predetermined maximum amplitude. If the bias is supplied from the power supply through a voltage divider which draws a large current, any excess conduction by the tube produces only a negligible voltage change in the biasing resistor. When blocking does occur, its duration is determined by the time constants involved. The effect can be made less objectionable by making the time constants, and consequently the recovery time, as short as is practicable. By leaving the cathode resistor unbypassed, its time constant is made practically zero.

SECTION VII—INDICATORS

1. GENERAL

Types of Scan

The basic types of data presentation have been described briefly. The use of one or more types of scan in a radar set is governed by the application to which the set is to be put. As more and more uses are found for radar, the indicators are modified from the simple, basic types of scans to more complex scans which fulfill special needs by presenting all necessary data on one oscilloscope.

In search or early-warning sets it is desirable to view as large an area as possible and to track several targets simultaneously. For this application, the PPI-scan is very useful, and it is frequently supplemented with an A-scan so that the character of the echo may be carefully observed and both ranging and identification may be accomplished easily.

In fire-control or gun-laying sets it is usually desirable to concentrate on only one target, so that some form of gated A-scan or B-scan is often used. Where the target is an aircraft, the indicator must be designed to show the altitude as well as the range and bearing.

A third type of application is the use of radar in aircraft interception. In this case, the radar indicator must provide enough information for one airplane to be pointed at another, so that the type C-scan, or a modification of it, is used in conjunction with a type B-scan.

2. RANGE ESTIMATION

Methods of Estimation

A given range can be represented by the total length of the sweep on a cathode-ray tube screen. If the transmitted pulse occurs at the beginning of the sweep, the range of a target may be estimated by observing the fraction of the sweep length between the transmitted pulse and the echo. Estimations of this kind depend on the judgment of the operator, and are made less accurate by any nonlinearity of the sweep.

If the radar equipment is installed in a permanent location, there may be a number of fixed targets whose ranges are known. Thus, several points on the sweep may be accurately calibrated, and the ranges of other echoes can be estimated with reference to these known points.

Estimation of range is made somewhat more accurate by the use of range markers which divide the trace into equal time intervals. Markers which appear on the sweep it-

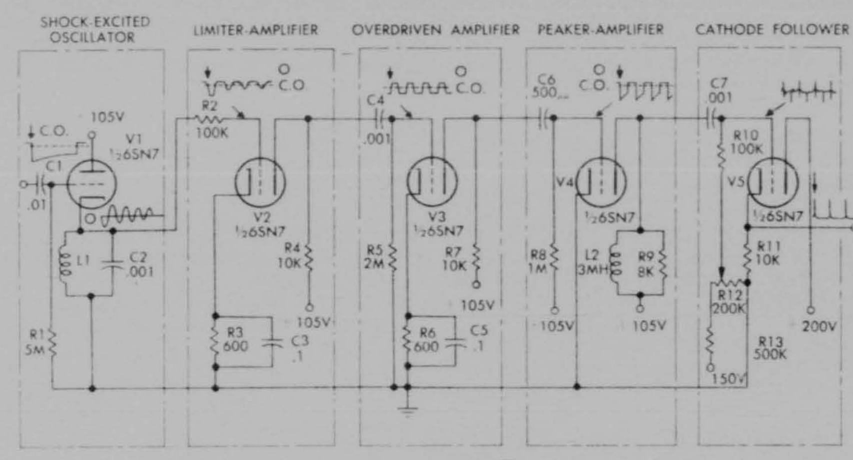

Figure 1—50. Shock-Excited Oscillator Used for Producing Range Markers.

self, rather than as marks on an overlaid scale, are preferable because they compensate for the effects of non-linearity.

Shock-excited Oscillator

A circuit, in which the plate current of a switch tube flows through the inductor of a tank circuit, may be used to produce a damped train of oscillations by cutting off the tube, as explained in section VII, TM 11-466 and Navships 900,016. The frequency stability of this type of oscillation is excellent because the tank circuit is very lightly loaded and the frequency depends in no way on the action of the tube.

One system that is used for generating range markers from the output of a shock-excited oscillator is shown in Figure 1-50. A negative-going square pulse drives the grid of V1 below cut-off at the instant that the sweep starts, thus setting up oscillation in the tank circuit made up of L1 and C2. Sharp, well-defined marker pulses are produced by feeding the output of the tank circuit through the remaining circuits of Figure 1-50. The damped oscillations are limited and amplified by V2 so that the output at the plate is a series of approximate square waves of the same amplitude. Resistor R2 in series with the grid limits the grid current and thus reduces any damping effect on the L-C circuit. The cathode bias developed across R3 and C3 prevents the grid from going extremely positive and thus aids in keeping the grid current low. A low-plate voltage is used to aid in the limiting action. The output of V2 is coupled to the grid of V3 which acts as an overdriven amplifier and produces a good square wave at its plate. The peaker-amplifier tube V4 has as its plate load inductor L2 shunted by resistor R9. The inductor resonates with its distributed capacitance at a frequency of the order of 2 megacycles per second. When the tube is cut off by the negative-going square wave, the coil is shocked into oscillation. The resistance damps the oscillation almost completely before one cycle is completed so that a positive pulse of approximately 0.25-microsecond duration is produced. When the grid swings positive, a negative pulse of smaller amplitude appears at the plate. This has no significance since the following tube is biased below cut-off so that only positive pulses affect its operation. The grid of V4 is returned to a positive potential rather than to ground to insure high conduction in the tube just before the grid swings negative. The large resistor, R8, in the grid circuit limits the grid current to a small value. The output of the pulse generator is fed to a cathode follower which is biased below cut-off. By adjusting this bias so that the positive

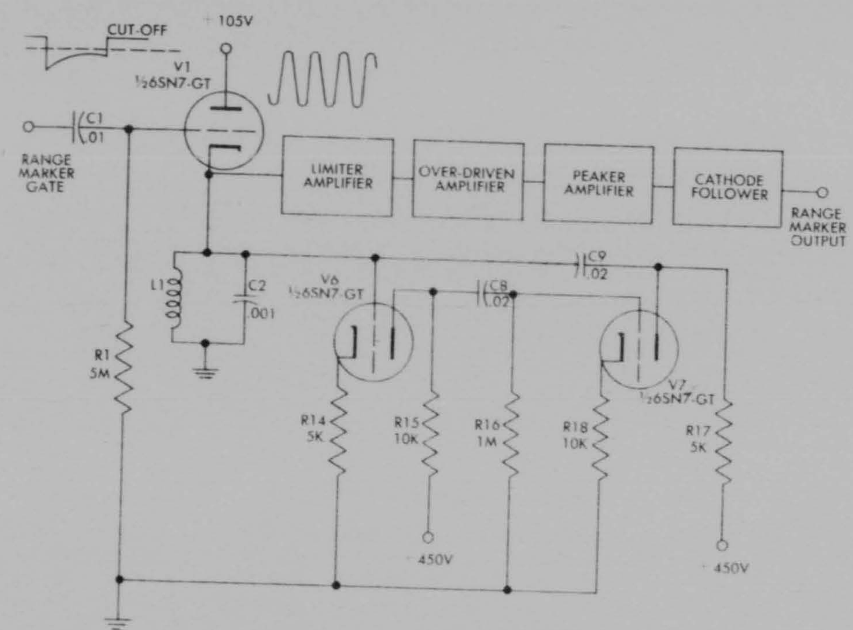

Figure 1—51. Sustaining Multivibrator.

peaks raise the grid above cut-off by the desired amount, the amplitude of the marker pulses can be controlled.

If the oscillations in the cathode circuit of V1 are damped too much to be useful over the entire sweep, a regenerative circuit (Figure 1-51) can be used to sustain their amplitude. The circuits are identical with those of Figure 1-50, with V6 and V7 added. The sustaining circuit is in the form of a multivibrator with a natural frequency of oscillation much lower than that of the input signal. The output of the L-C circuit is coupled directly to the grid of V6, is amplified in V6 and V7, and fed back to the input point in its original phase, having been inverted twice. The degeneration in the two unbypassed cathode resistors prevents excessive gain which would distort the sinusoidal wave generated in the L-C circuit. The frequency of oscillation is the resonant frequency of L1 C2, while the amplitude is held constant by the action of the multivibrator. When current flows in V1, the oscillations are damped out and start again when the current is cut off. The oscillations are used to generate positive marker pulses as discussed in connection with Figure 1-50.

Multivibrator

Range markers may be generated by the type of multivibrator circuit shown in Figure 1-52. The circuit is turned off and on by a signal applied through C1 to the grid of V1. A negative pulse of relatively short duration cuts off V1 and renders the circuit inoperative until the signal goes positive, at which time the sweep also starts. When V1 begins to conduct, its plate voltage drops, and causes the grid of V2 to swing in the negative direction. The current through V2 and consequently the voltage at its cathode decreases. This change, which takes place almost instantaneously, is coupled through C3 to the cathode of V1, driv-

THIS PAGE IS DECLASSIFIED IAW EO 13526

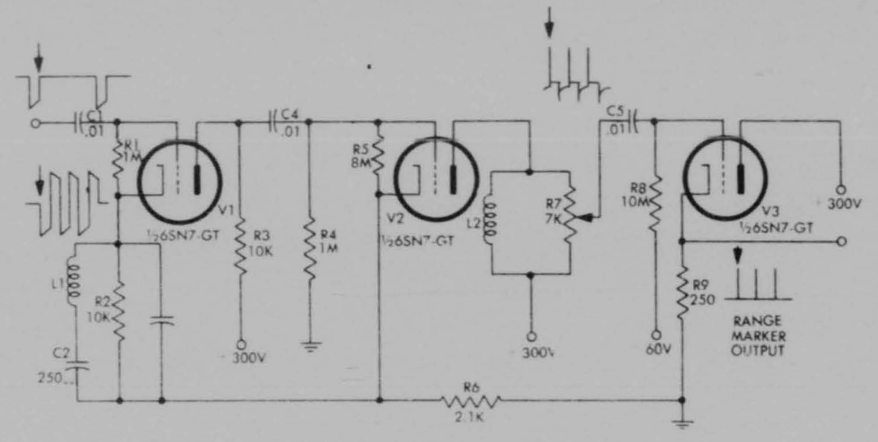

Figure 1—52. Range Marker Multivibrator.

ing it in the negative direction. Since the grid of V1 is held at a relatively constant voltage in respect to ground by the charge on C1, the effect of the voltage coupled through C3 is to increase further the conduction of the tube. This cumulative action cuts off V2 very quickly and drives V1 into saturation.

The plate current of V1 must flow through the three parallel branches in the cathode circuit of the tube. The current that flows in the branches in which there are capacitors causes a change in the charge of the capacitors by withdrawing electrons from one plate of each. This flow of current produces a voltage across the cathode impedance that drives that cathode positive relative to ground. Since the three branches are in parallel, the voltage across each branch must always be the same. The change of voltage that occurs across the branch containing L1 and C2 controls the cathode potential because the rate of change of voltage in this branch is slower than in the others.

As the voltage rises at the cathode of V1, its current becomes less and its plate voltage rises, causing the voltage at the grid of V2 to rise. When the point is reached at which V2 again conducts, a cumulative effect which is the reverse of that previously described, cuts off V1. The tube remains cut off only during the time of one-half oscillation of L1 and C2. At the end of this time, the voltage across the tank circuit has swung to its maximum negative value, causing the start of a second cycle of the circuit action. Thus, V1 and V2 are made conducting alternately at a frequency determined by the value of L1 and C2. Capacitor C3 is used principally as a means of causing the change from conduction to nonconduction to be abrupt. Resistor R2 is used to damp the oscillatory circuit so that the stopping of oscillation may be controlled by the gate voltage applied to the grid of V1.

Since V2 is cut on and off abruptly, sharp market pulses can readily be produced in the plate circuit. The action of the plate load impedance is similar to that described in the peaker-amplifier of Figure 1-50. Resistor R7 is a potentiometer which provides a means of controlling the amplitude of the markers. The cathode follower is biased beyond cut-off so that only positive pulses appear in the output.

3. RANGE MEASUREMENT

General

The difficult problem of firing a gun accurately can be simplified considerably if the exact distance between gun and target can be determined. Radar provides a means of find-

ing this distance by measuring the time required for r-f energy to travel out to a target, be reflected, and to return. Precise measurement of range requires the accurate measurement of extremely short time intervals. These intervals are measured by some means of introducing an accurately-calibrated variable delay between the transmitted pulse and the echo pulses on the indicator screen.

Several methods of producing a variable delay to measure range are in use in existing radar equipment. One commonly used method is to shift the phase of the sine wave, which times the indicator relative to the sine wave, which times the transmitter. The phase shift is used to delay the action of some circuit in the indicator by a measured number of electrical degrees, and therefore to measure the time in terms of the period of one cycle of the sine wave. The phase-shifting device usually is geared to a dial which is calibrated in yards or other suitable units of range.

The range of a target may also be measured by the use of a circuit which measures the magnitude of the sweep voltage at the position at which the echo pulse appears on the sweep. This method depends on the comparison of the sweep voltage with a calibrated variable DC voltage, and it is inherently not as accurate as most phase-shifting methods. However, it does find considerable use in search-radar sets in which it is desired to measure range to a fair degree of precision.

Other methods of measuring range include the use of a delay multivibrator, an acoustic tank employing a fixed and a movable crystal, and calibrated control of the position of the sweep relative to a fixed marker on the face of the indicator.

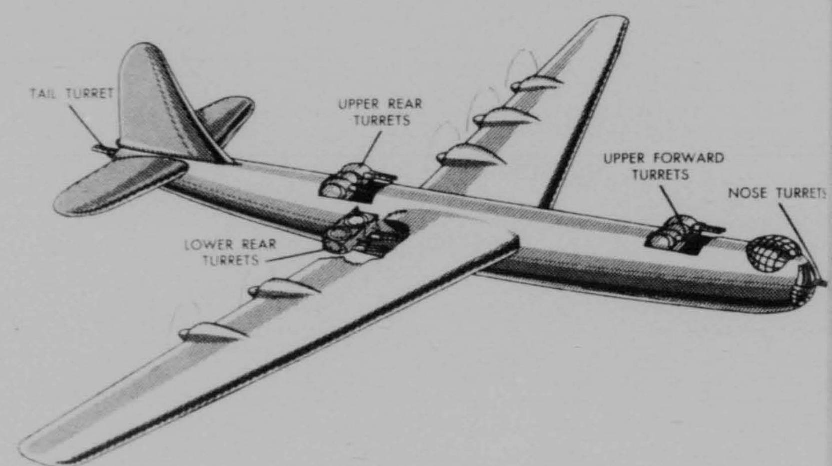

Figure 2—1. Location of Turrets on the B-36.

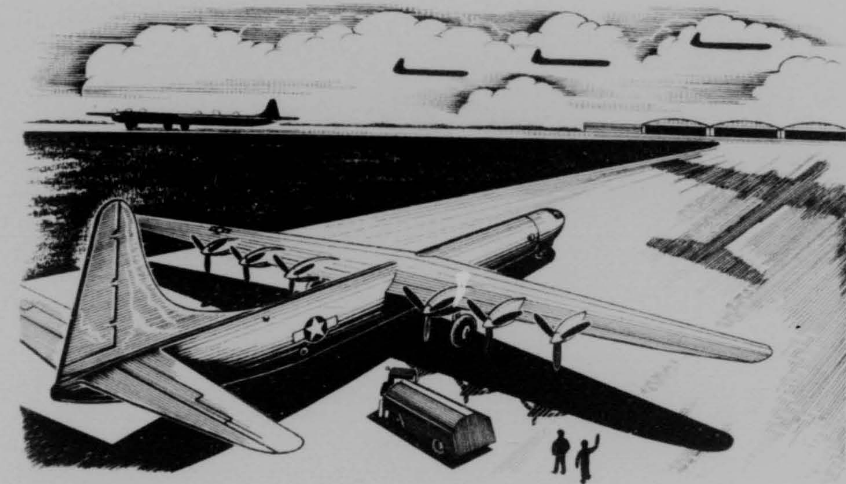
CHAPTER 2—FIRE CONTROL SYSTEM, THYRATRON



SECTION I—INTRODUCTION

1. GENERAL DESCRIPTION

This chapter contains information on the installation, operation, maintenance, and lubrication of the remote-control turret system used on the B-36 airplane. Information in this chapter pertains to Model 2CFR87 B1, manufactured by the General Electric Company.

The electrically operated remote-control turret system allows the gunners to be located at a distance from the guns which they control. It provides for concentration of heavy-fire power on a target approaching the airplane from any direction. The system is designed for operation between the altitudes of sea level and 40,000 feet above sea level, and within an ambient temperature range of —85° C (—121° F) to +52° C (+125.6° F).

There are eight electrically operated turrets; the upper-left forward turret, the upper-right forward turret, the upper-left aft turret, the upper-right aft turret, the lower-left aft turret, the lower-right aft turret, the nose turret, and the tail turret (See Fig. 2-1).

The turrets are remotely controlled and operated from seven sighting stations and one radar set. The seven sighting stations are the upper-left forward sighting station, the upper-right forward sighting station, the upper-left aft sighting station, the upper-right aft sighting station, the lower-left aft sighting station, the lower-right aft sighting station, and the nose sighting station. The GFE radar set is type AN/APG-3.

The B-36 remote-control turret system has seven gunners and the AN/APG-3 radar operator. Each of the seven gunners operates an optical sighting station which controls one turret. No interchange of control between

THIS PAGE IS DECLASSIFIED IAW EO 13526

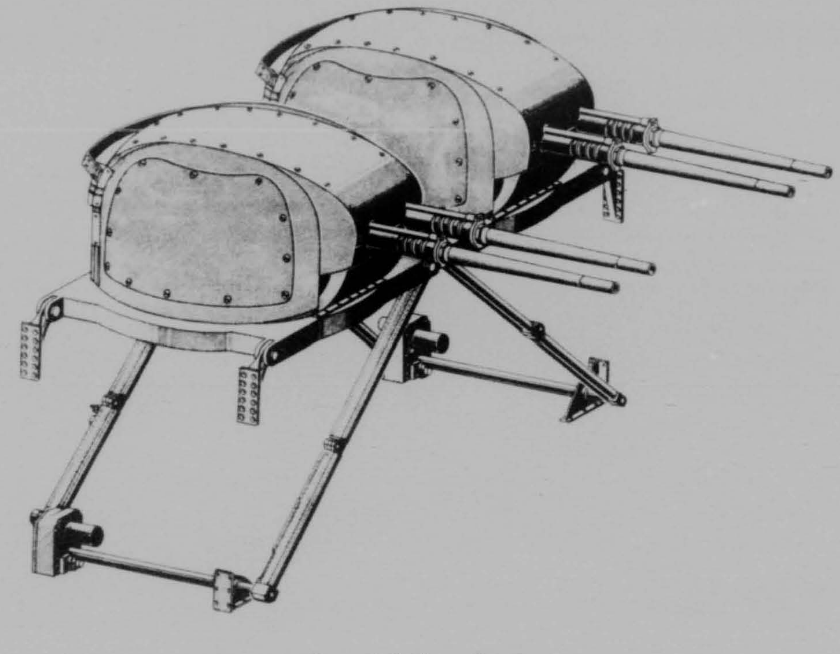


Figure 2—2. Upper Turrets.

gunners is provided. There are four upper-turret gunners, two lower-turret gunners, and a nose-turret gunner. The tail turret is controlled by the AN APG-3 radar operator.

Each turret is armed with two 20-mm guns. The guns move in elevation independently of turret rotation in azimuth. Automatic electric gun chargers and ammunition boosters are common to all eight turrets. The upper and lower turrets are retractable into the fuselage of the airplane. Each gun has a separate ammunition box with a capacity of 650 rounds. The ammunition boxes are furnished by the airplane manufacturer. There is no retraction mechanism, fire interrupter, or contour follower on the nose or tail turrets. All turrets contain Selsyn control transformers which are tandem mounted (Figures 2-2 and 2-3).

Upper Turrets

There are four upper turrets: upper-forward left and right and upper-aft left and right (Figures 2-2 and 2-3). All have approximately 26 degrees downfire and 90 degrees upfire. Rotation in azimuth is limited to 200 degrees, i.e., 100 degrees forward and 100 degrees aft from a position straight out to

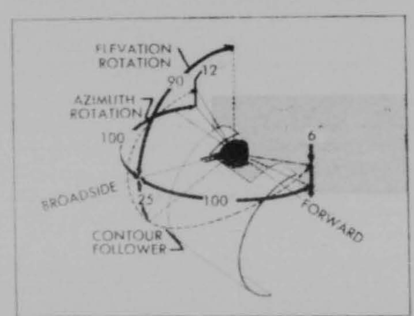

Figure 2—3. Schematic Showing Upper Turret Movement in Azimuth and Elevation.

the side. The contour follower raises the guns in both the forward and aft positions to prevent the guns striking the airplane structure. A fire interrupter prevents self-inflicted damage to the propellers, wing, and tail. The retraction mechanism extends the turret to the firing position and retracts it into the fuselage when desired. Other components of all upper turrets are: gun chargers, DC motors, and AC motors (Figures 2-4 and 2-5).

Lower Turrets

There are two lower turrets, lower-aft left and right (Figures 2-4 and 2-5). They have approximately 26 degrees upfire and 90 degrees downfire. Rotation in azimuth is limited to 200 degrees, i.e., 100 degrees forward and 100 degrees aft from a position straight out to the side. The contour follower lowers the guns in both the forward and aft positions to prevent the guns striking the airplane structure. A fire interrupter prevents self-inflicted

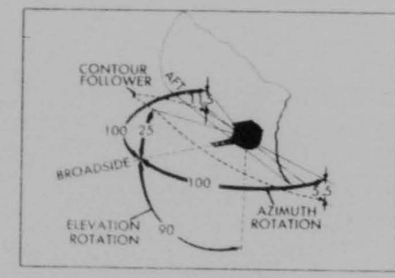

Figure 2—5. Schematic Showing Lower Turret Movement in Azimuth and Elevation.

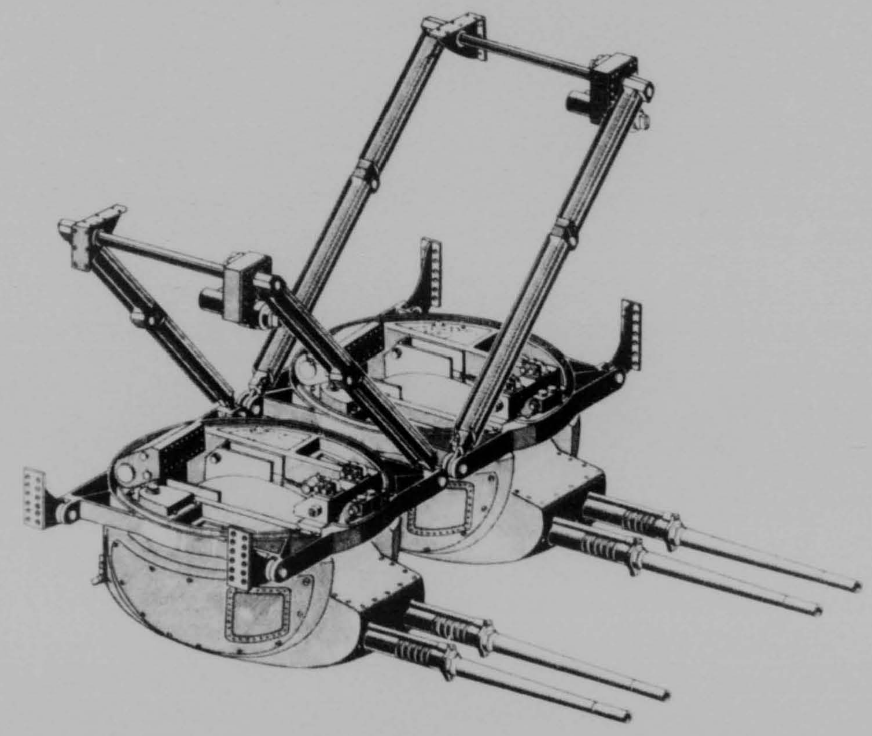

Figure 2—4. Lower Turrets.

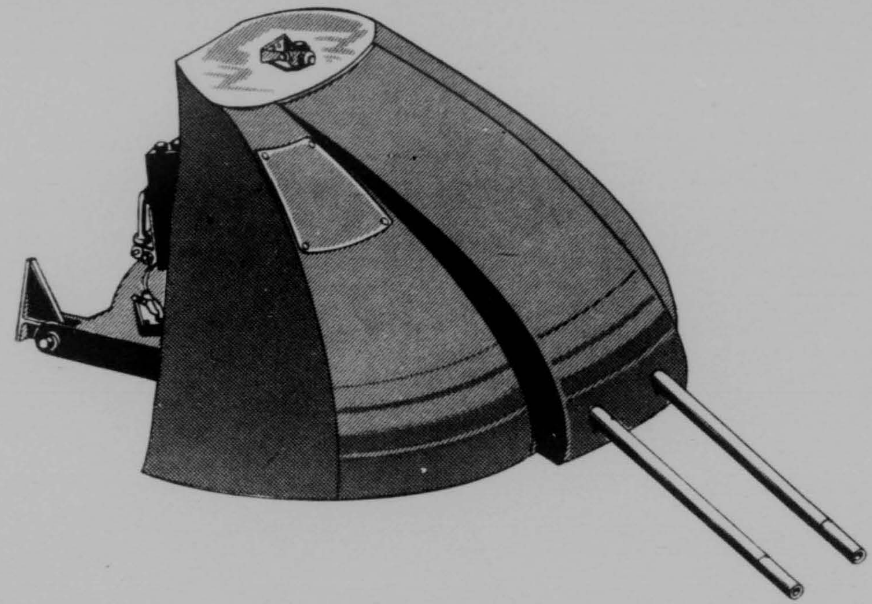

Figure 2—6. Nose Turret.

damage to the propellers, wings, and tail. The retraction mechanism extends the turret to the firing position and retracts it into the fuselage when desired. Lower turrets are essentially the same as upper turrets but, due to their location in the inverted position, minor adaptations are necessary. Used cartridges, for instance, are ejected into space. Other components of lower turrets are: gun chargers, DC motors, and AC motors.

Nose Turret

There is one nose turret (Figures 2-6 and 2-7). It is located in the upper part of the nose, above the gunner and bombardier. It has approximately 28½ degrees downfire and 30 degrees upfire. Azimuth travel is limited to 30 degrees to the left and right of straight forward. There is no contour follower, fire interrupter, or retraction mechanism. Other components are: gun chargers, DC motors and AC motors.

Tail Turret

There is one tail turret (Figures 2-8 and 2-9). It forms the rear end of the fuselage and has 40 degrees upfire and 40 degrees downfire. Azimuth travel is limited to 45 degrees to the right and left of straight aft. There is no contour follower, fire interrupter, or retraction mechanism. Other components are: gun chargers, DC motors, and AC motors.

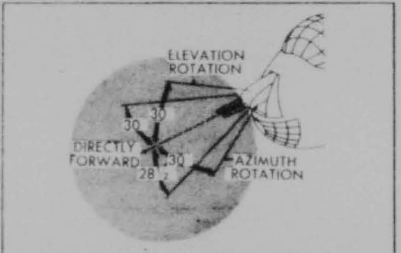

Figure 2—7. Schematic Showing Nose Turret Movement in Azimuth and Elevation.

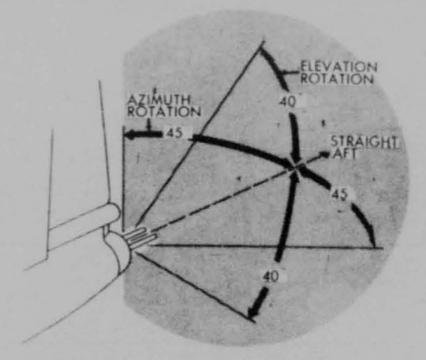

Figure 2—8. Schematic Showing Tail Turret Movement in Azimuth and Elevation.

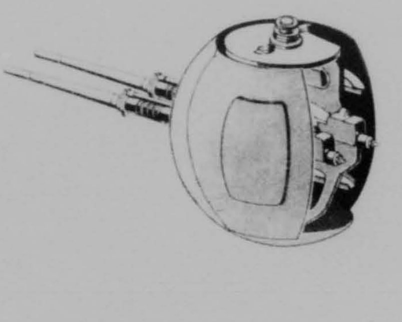

Figure 2—9. Tail Turret.

2. GENERAL DESCRIPTION OF SIGHTING STATIONS

A sighting station, used by a gunner in tracking and in operating a remotely controlled turret, consists of a retiflector sight and a means of indicating to a gun turret the precise direction in which the sight is pointing. The remote-control turret system contains seven sighting stations so designed that the gunners, protected from the slipstream of the airplane by fixed transparent enclosures, can scan the maximum area from their individual stations. There are three basic types of sighting stations: the yoke, pedestal, and the hemisphere. The yoke type is used in

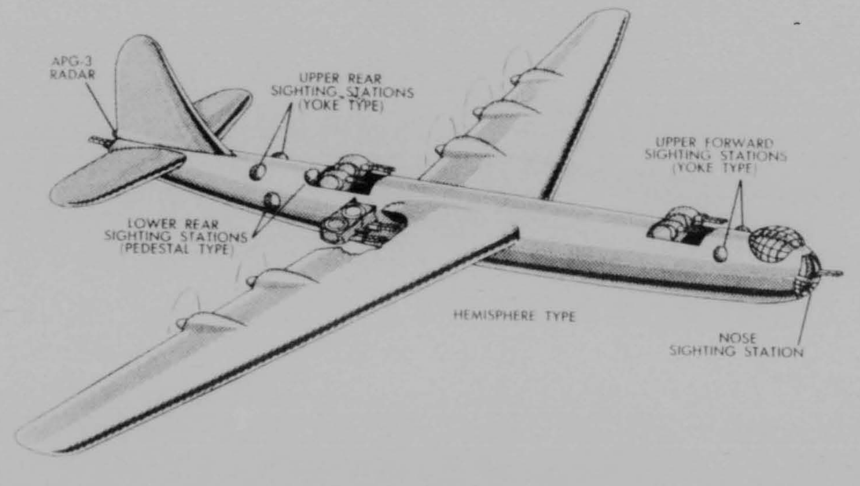

Figure 2—10. Location of Sighting Stations.

THIS PAGE IS DECLASSIFIED IAW EO 13526

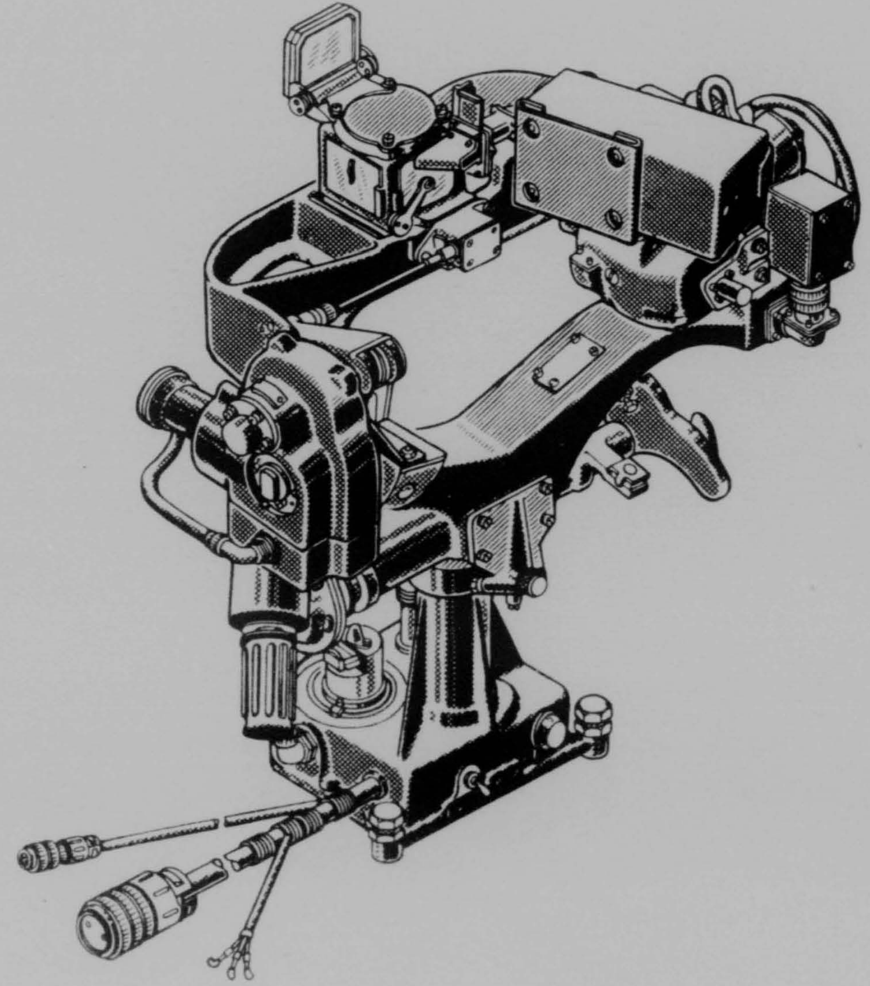

Figure 2—11. Yoke Sighting Station.

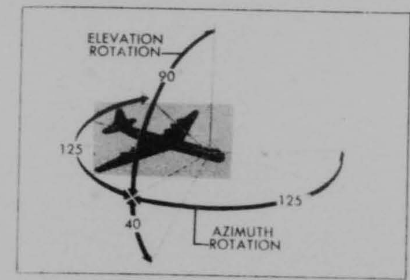

Figure 2—12. Schematic Showing Yoke Sighting Station Movement in Azimuth and Elevation.

the upper sighting stations. The pedestal type is used in the lower sighting stations. The hemisphere type is used in the nose position. Each sighting station contains a gyroscope which transmits lead data to the computer, and a camera which functions when the guns are firing. Selsyn generators are on yoke and pedestal sighting stations (Figure 2-10).

Yoke Sighting Station

The four upper yoke sighting stations are designed to provide the gunner with 90 degrees upfire and 30 degrees downfire, plus additional overtravel. Azimuth travel is 25 degrees greater in each direction than travel. Other components included are: a retiflector sight and a free gyroscope (Figures 2-11 and 2-12).

Pedestal Sighting Station

The two lower pedestal sighting stations can be elevated, depressed, or rotated by the gunner moving the sight handles. Elevation travel is limited to 60 degrees above and 90 degrees below horizontal. Azimuth travel is limited to an arc of 210 degrees. Other components are: a free gyroscope and a retiflector sight (Figures 2-13 and 2-14).

Hemisphere Sighting Station

The hemisphere sighting station, located approximately on the centerline and in the nose pressurized section of the airplane, is a horizontally mounted, double-prism periscopic sight so designed as to give the gunner a complete hemisphere of vision. The apex of this hemisphere is a horizontal line looking dead

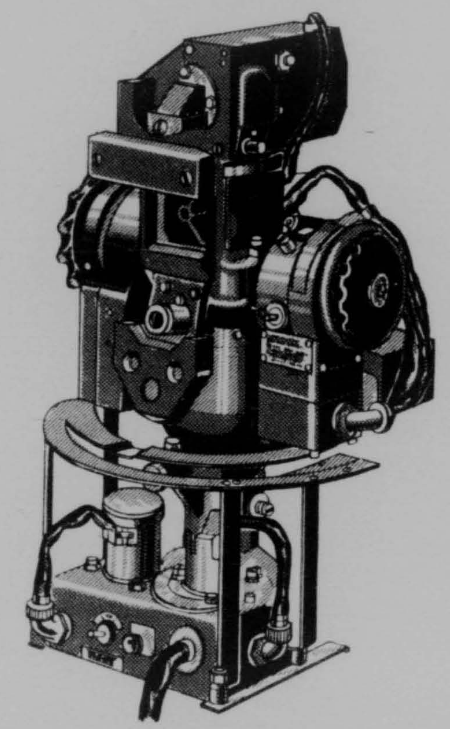

Figure 2—13. Pedestal Sighting Station.

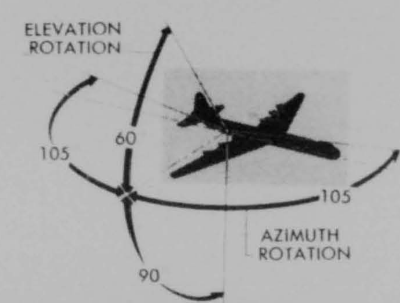

Figure 2—14. Schematic Showing Pedestal Sighting Station Movement in Azimuth and Elevation.

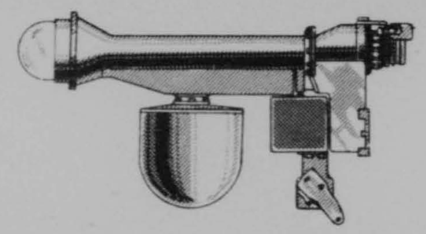

Figure 2—15. Hemisphere Sighting Station.

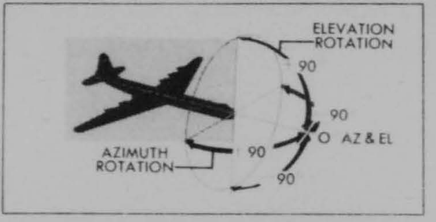

Figure 2—16. Schematic Showing Hemisphere Sighting Station Movement in Azimuth and Elevation.

ahead at zero degrees in azimuth. The gunner, without changing his position, can see 90 degrees to the right and left of zero degrees in azimuth as well as 90 degrees up or down of zero degrees in elevation. For tracking in azimuth, the gunner turns the handle assembly about a vertical axis approximately twelve inches forward of the eyepoint; in elevation, the gunner twists the handles about a horizontal axis which runs through the two handles. The gunner does not rotate his body as the eyepiece is fixed. The main assemblies of the hemisphere sight include the sight head, the main tube, the radarscope optical leg and tube, the rangefinder, and the main housing. The gear drive assembly contains the azimuth and elevation gear trains. This assembly also mounts the handles, interphone, and the action switches. The gyroscope is mounted below the main tube (Figures 2-15 and 2-16).

Computers

There is a remotely located computer for each sighting station. It is designed to allow the gunner to sight directly on a target and causes the gun axes to change from a position parallel to the line of sight to a position which will cause the projectile to hit the target. To accomplish this, each gunner's sighting station automatically supplies his computer with the relative velocity of his target (by means of gyroscopic measurement), and the azimuth and elevation gun position (by means of Selsyn signals). Each gunner introduces into his computer (by means of the handset located in his control panel) information on altitude, the airspeed of his own airplane, and the outside temperature. The computer then allows for windage and gravity (ballistics), the distance between the sighting station and the centerline of the guns (parallax), and the distance the target travels between the time that the projectile leaves the gun and the instant it strikes the target (prediction). Ballistics, parallax, and prediction corrections are computed and appear in the computer output as a single total correction which is then sent to the Selsyn control transformers on the turrets. Components of the computer include DC motors, differential Selsyns, and control-transformer Selsyns (Figure 2-17).

Thyratron Controllers

The thyratron controller is an electronic device which takes small AC error signals from the Selsyn control transformers and converts them to DC power for driving the turret motors. One controller is required for each turret-sight-computer combination (Figure 2-18).

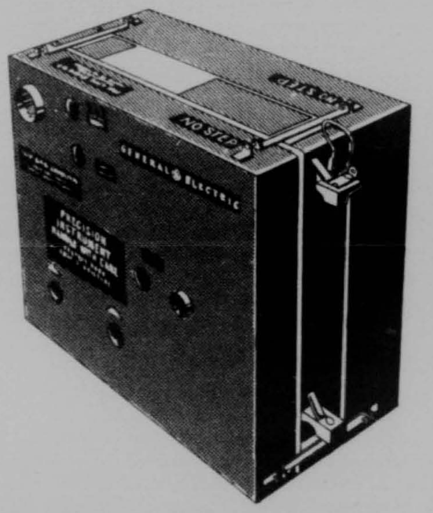

Figure 2—17. Free Gyro Computer.

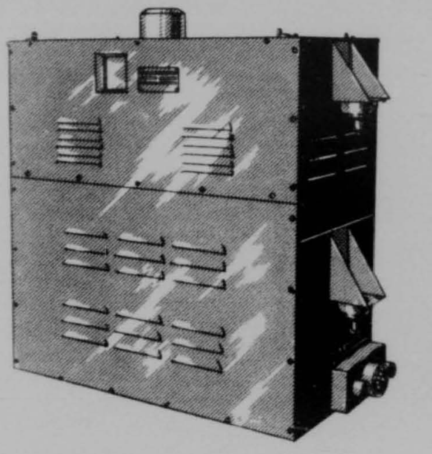

Figure 2—18. Thyratron Controller.

Control Panels

A control panel is provided for each gunner. A uni-switch, ammunition rounds counter, altitude and airspeed handset, circuit breakers, and indicator lights are provided on the control panels for the upper and lower retractable systems. The panels for the nose system and for the tail system omit the indicator lights and some of the uni-switch positions (Figure 2-19).

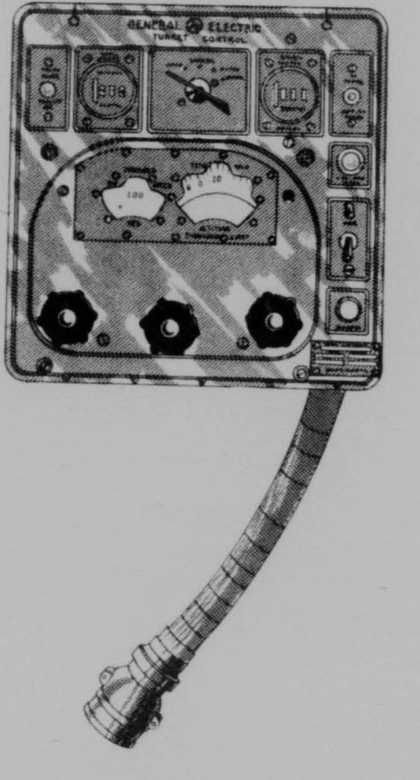

Figure 2—19. Typical Control Panel.

Junction Boxes

A junction box, located near each turret, contains a turret-stowing transformer, charger connectors, firing contactor, retraction-mechanism contractor, and a turret safety switch. In Model 9078151 G-1 junction box, the stowing transformer connections must be changed on a terminal board for each turret location. In model 9167170 G-1 junction box, the junction box is switched to its correct circuit for any particular turret system (Figure 2-20).

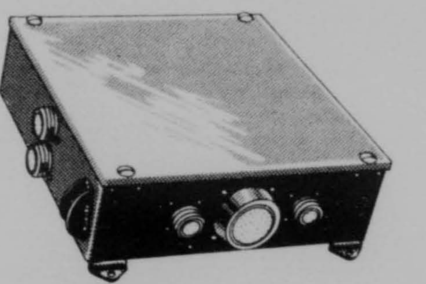

Figure 2—20. Junction Box.

THIS PAGE IS DECLASSIFIED IAW EO 13526

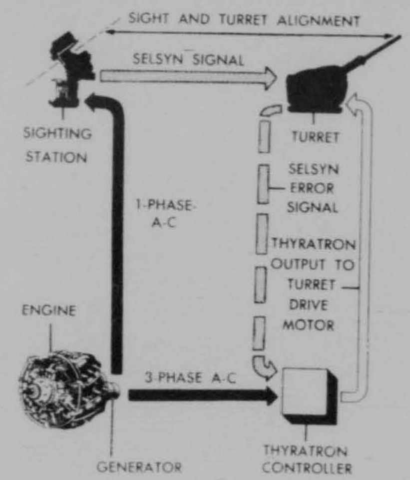

Figure 2—21. Sequence of Power Circulation.

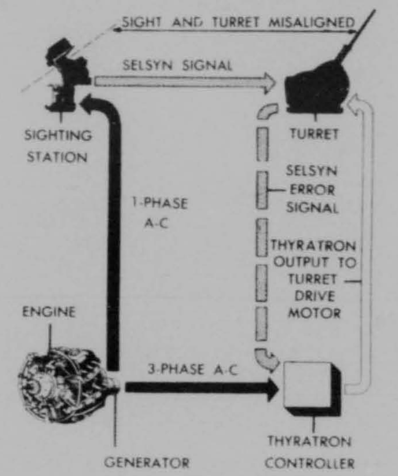

Figure 2—22. Sequence of Operation Steps Caused by Movement of Sighting Station.

Basic Electrical Connections

The electrical circuits for azimuth and elevation turret and gun movement are identical. Therefore, only elevation electrical connections and the elevation operation will be discussed.

Power Circuits. The airplane engine generator furnishes three-phase, AC power to the thyratron controller. Single-phase AC power is supplied to the sighting station. The sighting station is connected electrically to the turret and the turret, in turn, is electrically connected to the thyratron controller. The output of the thyratron controller is connected to the elevation side of the turret (Figures 2-21 and 2-22).

Operation Steps Caused by Movement of Sighting Station. When the gunner moves the sighting station in elevation and causes it to be out of alignment with the turret, the following electrical operations take place:

The sighting station sends an AC signal voltage to the turret, representing the direction of its line of sight.

The turret Selsyn transmits an electrical signal to the thyratron controller representing the difference between the sighting station's line of sight and the turret's line of fire.

The thyratron controller amplifies the error signal voltage and converts it into DC power which is sent to the turret-drive motor to move the turret's line of fire into alignment with the sighting station's line of sight.

When the alignment is complete, the signals from the turret Selsyn to the thyratron controller disappear and the turret is held in its new position.

3. PRINCIPLES OF OPERATION

In the remote-control turret system, the gunner aims the sight at the target and, through a series of electric control and drive units, the guns controlled by the sighting station are made to point at the same target at which the gunner points his sight. Corrections are introduced into the system when the computer operates. There are four basic units in the remote-control turret system: the turret, the sighting station, the thyratron controller, and the computer.

Remote-Control Turret System

Selsyn generators, located on the sighting station, send a signal corresponding to sight

position to the Selsyn control transformers located on the turret. The control transformers have an output voltage (called the "error signal") which is proportional to the difference in the directions in which the sighting station and turret are pointing. When they are pointing in the same direction the error signal is zero volts. The error signal goes to the thyratron controller which furnishes DC voltage to the turret motors proportional to the error signal. The turret motors are then driven in such a direction as to reduce the error signal to zero.

The computer contains Selsyn differential generators which are located electrically between the Selsyn generators and Selsyn control transformers. When no computer connection is necessary, the position signal from the sight is transmitted to the control transformer unchanged. Corrections result in the sight position signal being modified by the addition of the correct correction angles being turned into the differential generator. This new position signal is then sent on to the control transformers. The guns then point in the direction indicated by the sighting station plus or minus the correction angle determined by the computer.

External Power Requirements

The electrical power furnished to the system must meet the following specifications:

208 volts ± 14 volts line to line

120 volts ± 8 volts line to neutral phase, four wire

400 cycles per second ± 14 cycles

Generator must have 15 KW minimum capacity for operating one turret, fast recovery time, and good inherent regulation. Size is determined by peak power requirements.

Note: No DC power is required.

The Selsyn System

A Selsyn is a transformer in which one winding rotates with respect to the other. The voltage developed in the secondary winding is proportional to the cosine of the angle between the two windings.

A Selsyn generator has its primary wound

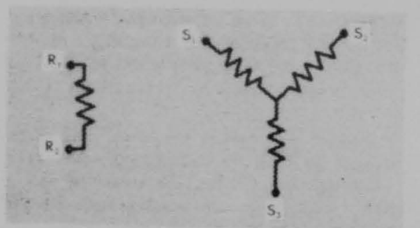

Figure 2—23. Selsyn System Diagram.

on the rotor while the three secondaries, located 120 degrees from each other, are wound on the stator. One end of each of the secondaries is connected together to form a Y-shaped winding (Figure 2-23). The power applied to the primary is 120 volt 400 cycle. When a secondary winding is lined up with the primary winding that secondary has 57.5 volts produced across it. As the rotor is rotated the voltages in the three secondaries vary in magnitude and phase. These voltages are a measure of the position of the Selsyn rotor.

In a Selsyn control-transformer, the three voltages corresponding to the rotor position of the generator are applied to the three winding, located 120 degrees from each other, on the stator. Note that the voltages developed across each of the three stator windings are in phase with each other, while the magnetic fluxes are displaced spatially by 120 degrees. For any combination of the three voltages, there are two positions of the control-transformer rotor which gives zero volts out of the single secondary winding on the rotor. When the rotor is not in the zero position, a voltage is developed which is proportional to the cosine of the angle between its present and zero positions. On one side of the zero position,

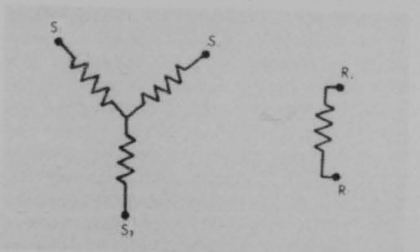

Figure 2—24. Selsyn Voltage Error Signal.

this voltage is in phase with the voltage applied to the rotor of the generator; on the other side, it is 180 degrees out of phase. This voltage is often called the "error signal" (Figure 2-24).

A Selsyn differential generator has three windings on both the stator and rotor, each winding located 120 degrees from the other. When the rotor windings are lined up with the stator windings (Figure 2-25) the three incoming voltages are transformed unchanged to the output side. A rotor rotation of x degrees produces the same change in the output voltages as an additional rotation of x degrees of the rotor of the generator would have caused.

The combination of a 1-speed and 31-speed Selsyn is used in azimuth tracking, and a similar combination is used in elevation tracking. The 1-speed Selsyn makes one revolution for each revolution of the turret, while the 31-speed Selsyn makes 31 revolutions for each revolution of the turret. Therefore, in a 31-speed Selsyn all errors are divided by 31. The turret, however, can line up at 31 different correspondence points; while in a 1-speed Selsyn there is only one correspondence point. Thus, the 1-speed signal insures that the turret follows the sight to within two to three degrees of the correct correspondence point. The 31-speed signal refines the 1-speed signal within these limits, and keeps the turret and the sight accurately aligned.

4. INTRODUCTION TO CIRCUIT DIAGRAMS

For installation and maintenance of the B-36 armament system, any or all of the following types of circuit diagrams can be used. The elementary diagram shows most clearly the electrical relationship between the various circuit components. The schematic diagram shows the approximate location of the devices shown in the elementary diagram and their corresponding interconnections. The wiring diagram shows the physical location of the devices shown in the elementary diagram and their corresponding interconnections. The interconnection or cable diagram shows all the cables running between different units. This diagram includes tables listing the

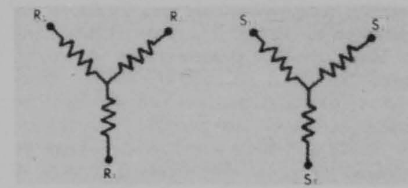

Figure 2—25. Rotor Windings Lined Up with Stator Windings.

wires in each cable and the units to which they are connected.

The Elementary Diagram

(Refer to Table I.) An elementary diagram is used to show in simple form the electrical relationship between components of the circuits in a system. On the elementary diagram different parts of the same device can be shown in different locations, wherever they fit most conveniently into the drawing of the circuit. Combination letter-numeral designations are used to identify the various devices. For example, a relay operating-coil may be designated at K209. Its corresponding contacts wherever they are located, also bear the K209 designation. The prefix "K" indicates that the device is a relay.

The Schematic Diagram

The schematic diagram is made up of the same symbols used in the elementary diagram but it shows the approximate location of the devices by system components.

The Wiring Diagram

The wiring diagram is of value to the maintenance man who may want to observe a voltage across two points on the elementary diagram. Reference to the wiring diagram will show where these actual points are located in the junction boxes and control panels. To aid in identifying circuits, a number system is provided which relates the circuit points on the elementary diagram to the corresponding points on the wiring diagram.

The Interconnection or Cable Diagram

This diagram shows the external connections between the different parts of the sys-

tem. All internal connections of the units themselves are omitted. The outgoing terminal or circuit numbers are indicated or listed in the tables giving the cable makeup. This type of diagram is very useful for installation and checking purposes.

5. TYPICAL REMOTE-CONTROL TURRET SYSTEM

A group of typical control circuits (representative of any turret system) will be developed in this section, using an upper-forward turret system as an example. A uni-switch controls the operation of these circuits in five steps, from an "off" position to readying the turret for "operation."

Circuits Controlled by Uni-switch

The first position in the uni-switch is the "warm-up" position. This furnishes single-phase AC power to the gun and computer heaters. The "stand-by" position; here AC power is supplied to the time-delay starting circuit of the thyratron controller. "Door open" position; energizes the door motor, opening the turret door. "Operation"; energizes the retraction mechanism motor, and extends the turret into position ready for use (Refer to table II).

First Position—"Off."

Second Position—"Warm-up". When the uni-switch is thrown to the second ("Warm-up") position, a switch is closed and supplies 120-volt, single-phase AC power to the gun and computer heaters.

Third Position—"Stand-by". When the uni-switch is thrown to the third ("Stand-by") position, a switch is closed and supplies 120-volt, single-phase AC power through a transformer to selenium a rectifier. The restifier supplies a DC voltage to contactor coil which closes its normally open contacts, furnishing DC power to the thyratron controller. AC power is also furnished to the Selsyn generators, stowing transformer, gyro, and altitude potentiometer.

Fourth Position—"Door Open". When the uni-switch is thrown to the fourth ("Door Open") position, the normally-open contacts of a switch are closed, sending DC power through a door limit switch to a contactor coil which closes normally open contacts. This furnishes three-phase AC power to the door motor. The door opens until it hits a limit switch, opening the normally closed contacts, de-energizing the contactor coil, and opening the contacts, stopping the door motor.

Fifth Position — "Operation". When the uni-switch is thrown to the fifth ("Operation") position, the normally open contacts of a switch are closed sending DC power through the switches to a contactor coil, closing the normally open contacts supplying three-phase AC power to the retraction motor. The turret extends until it hits a limit switch opening the normally closed contacts, de-energizing the contactor coil, and opening the contacts stopping the retraction mechanism motor. When the limit switch is actuated by the fully extended turret, it also connects DC power to the control power DC bus. The turret cannot operate until this circuit is energized.

Control Power. When the turret is fully extended, the line is energized with a 27-volt DC control power. The line carries the control power to the following components; gun chargers, drive-motor fields and brakes, contour relay, turret limit relays, computer, action switch, reticle light, range resistor, camera motor and heater, and gyroscope motor.

Automatic Stowing. The guns are held in stowed position when the action switch is not depressed. The stowing transformer supplies a fixed signal to the stators of the control transformers through the normally closed stowing relays.

Non-computing Operation. When the action switch is closed, the stowing relays are energized. This replaces the stowing transformer connections to the Selsyn control transformers with connections direct to the corresponding Selsyn generator stators through the normally closed computer by-pass relays. The system is now ready to operate with the computer cut out. The Selsyn control transformers are ready to transmit the intelligence they receive to the thyratron controller.

Computer In-out Switch. When the switch

is closed, the computer by-pass relays are energized. This action inserts the computer into the Selsyn system between the Selsyn generators and Selsyn transformers, allowing the computer to make all needed corrections to the Selsyn signal.

Turret Safety Switch. The manually operated turret safety switch is located on the system junction box. When this switch is open, no DC power is supplied to the system, thus preventing its operation. This is to protect anyone working on the turret.

Firing Circuits—Gun Safety Switch. When the gun safety switch is closed, 27 volts DC power will flow to the contacts of the firing contactor, provided the firing trigger is closed. When this safety switch is open, the firing circuits can not be energized.

Camera Circuit. The camera will operate whenever the firing trigger, the gun safety switch, and the camera switch are closed. Current flows from the DC control power line through the firing switch, to the camera, energizing a relay in the camera, and to ground through the camera switch. Twenty-seven volt DC power is furnished to the camera heater and camera motor from the DC control power line through a relay internal to the camera. The adjustable overrun control causes the camera to operate for a short time (zero to three seconds) after the trigger is released.

Guns Start Firing. If the normally open contacts of the turret limit relays are closed, 27-volt DC power will energize the firing relay coil. This closes the normally open contact and current flows through the gun safety switch, through the firing power circuit breaker, through the fire-interrupters, to the left- and right-hand firing solenoids and to the left- and right-hand charger relay coils. The normally open charger relay contacts close, sending three-phase, AC power to the left- and right-hand chargers. The booster motors are connected in parallel with the gun chargers and operate whenever the firing solenoid is energized. The fire-interrupter switches are located on the switch carriage of the fire-interrupter unit on the turret. If one or both of the fire-interrupter switches are open, the fire of one or both of the guns will be interrupted. The fire-interrupter automatically interrupts the fire of the guns whenever they are trained at some portion of the airplane structure.

Circuits Energized. With the uni-switch in the fifth position, all circuits previously energized in the second, third, and fourth positions are still energized.

Other Circuits Within the System. Out-of-Synchronism Fire Interruption. Whenever the turret is out of synchronism with the sight far enough to transfer from the 31-speed to the 1-speed Selsyn circuits, the firing circuits are interrupted. This prevents the guns from firing while they are slewing into alignment with the sight from an area over 3 degrees away from the line of sight.

Backout Circuit. Whenever the gunner tracks a target beyond the azimuth or elevation limits of the guns, the turret limit switches are actuated, de-energizing the limit relays in the thyratron controller and disconnecting plate voltage from the pulse thyratron in the channel that powered the turret in the direction in which it was moving, and opening the firing circuit. When the sight is moved back into the range of travel of the guns, the channel for the opposite direction supplies power to the turret motor.

Contour Follower Circuit. The downward travel of the upper turrets and the upward travel of the lower turrets is limited by the contour follower by an amount depending on the azimuth position of the guns. This action is necessary to prevent the guns from striking the airplane fuselage and to prevent the line of fire from pointing at gunners' sighting blisters. When the gunner tracks a target beyond the elevation travel of the guns toward the fuselage, a contour limit switch is actuated. This cuts off the power to the azimuth and elevation drive motors, the brakes are applied in both azimuth and elevation motors, and the firing circuit is interrupted. When the contour limit switch cuts off all these circuits, the limit switch cannot close until the turret is moved back off the contour. However, there is a backout circuit for both azimuth and elevation functions which pulls the guns back off the contour as soon as the sight returns to the area of fire. When the sight is moved from the point at which it left the guns on the contour, the guns will step-follow the contour;

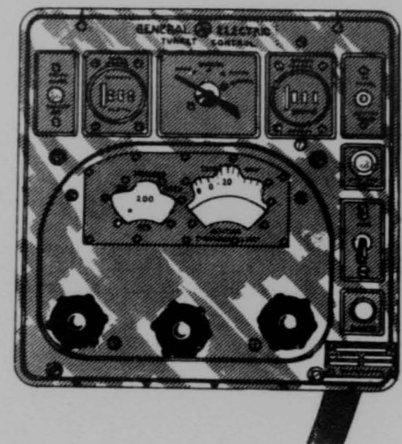

Figure 2–26. Typical Control Panel.

that is, they follow the contour in small increments, or steps, when going either up or down the contour.

Operation of the Contour Follow Circuits. The contour switch is actuated when the guns hit the contour. When normally closed the switch opens, it de-energizes the coils. This de-energizes the elevation and azimuth channels which powered the turret in the direction of travel of the guns. The elevation channel is cut off when the coil is de-energized. The azimuth channel to be cut off is determined by the position of the contour position switch, actuated by the passage of the turret into either the quadrant forward or aft of broadside. It permits the proper channel to be cut off, and maintains a closed limit circuit for the azimuth channel required for power to back the guns off the contour. The turret can then continue to follow the sight in normal operation.

DC Power Supply. A DC supply in the thyratron controller furnishes 27-volt DC control power to the turret system.

Operation Instructions

Starting the System (Figure 2-19). The remote-control turret system is turned on by turning a single uni-switch on the control panel adjacent to the sighting station which is to be operated. The sequence of the switch positions is as follows:

"Off." This is the first position of the uni-switch.

"Warm-up." This is the second position of the uni-switch. It energizes the gun and computer heaters.

"Stand-by." This is the third position of the uni-switch. It energizes the thyratron controller, Selsyn generators, stowing transformer, gyroscope, and altitude potentiometer.

"Door Open." This is the fourth position of the uni-switch. It energizes the door motor opening the turret door.

"Operation." This is the fifth and last position of the uni-switch. It energizes the retraction mechanism and extends the turret into position ready for use.

Warning: When the uni-switch is in the "operation" position the guns will fire, if loaded, when the action switch, gun safety switch, and firing trigger are closed.

Operating the Sighting Station (Figures 2-27 and 2-28). The rheostat (4) on the sighting station is turned on to adjust the reticle to proper brightness. The filament switch (3) on the reticle sight is flipped to make sure that both filaments of the reticle bulb work.

The "computer stand-by" switch (5) on the sighting station is turned to the "in" position. This connects the computer to your sight.

The warning light, which lights when the computer is at "stand-by," must be off.

The azimuth stow-pin (7) is released to permit azimuth movement of the sighting station. If the sighting station moves too easily or too hard, the azimuth friction adjustment (6) is used. The lock nut is loosened with a wrench and the screw turned with a screw driver. Turning the screw clockwise tightens the adjustment while counterclockwise loosens it.

The elevation stow-pin (9) is released to permit up-and-down movement of the sighting station. If necessary, the elevation friction adjustment (11) may be used.

10. INTERPHONE SWITCH
11. ELEVATION FRICTION SCREW

Figure 2–28. Location of Switches and Adjustments on Pedestal Sighting Station.

One or both of the sky filters are pulled down to avoid glare.

By moving the two handles on the yoke sighting station, the two handwheels on the pedestal sight, or the two control grips on the hemisphere sight, the sighting station is moved in elevation or azimuth. Unless the action switch (2) is held down, the turret guns will not follow the sight.

The guns are now ready for tracking and shooting. On the yoke sight, the target-size knob, the range grip, and a single trigger (operated by the right index finger) are used. On the pedestal sight, the target-size knob, the range wheel, and the triggers (pressed by the thumbs) are used. On the hemisphere sight, the target-size knob, the range grip, and the firing trigger are used. The sighting stations also have a push-to-talk button for the interphone.

Gunfire Interruptions. The following paragraphs list the fire interruptions designed to protect the airplane and its gunner from damage by its own guns.

Each upper and lower turret contains a fire-interrupter which automatically interrupts gunfire when the guns are trained at any portion of the airplane.

Each upper and lower turret contains a contour follower which automatically raises or lowers the guns to prevent their hitting any part of the airplane adjacent to the turret. When the guns are raised or lowered by the contour follower, the guns and controlling sight are not in alignment and gunfire is automatically interrupted.

Each turret is provided with an automatic stowing circuit. The turret guns automatically rise or descend to the horizontal position and rotate to the azimuth stow position 11.6 degrees outboard from forward position, when the gunner releases his action switch.

If the sight is raised on the lower turrets or depressed on the upper turrets beyond the limits of gun travel, the guns will remain seated against the stop in elevation and the firing circuit is opened by a limit switch. If the guns and line of sight are more than two or three degrees out of alignment, the firing circuit will be opened by the out-of-synchronism fire interrupter. The guns will follow the azimuth movement of the sight, where not limited by the contour follower, and when the sight and gun are again in alignment, the guns will resume movement in elevation.

Gunner's Preflight Duties

Gun Check. As the guns are not readily accessible during flight they must be in perfect operating condition when installed in the turret. (They should be checked personally by the gunner.)

After it has been determined that the guns have been serviced, the breechblock is removed, and the bore and chamber of the gun barrels are wiped out.

The adjusting screw must be tight against the buffer disks in the backplate.

The guns must be properly lubricated and all excess oil wiped off.

Caution: The bore and chamber should not be oiled before firing as dangerous pressures may develop.

The guns are then installed in the turret. (If the installation is made by others, it should be personally supervised by the gunner.)

The guns must be tight in their mounts.

The gun charges must be securely mounted on the gun.

Operation of the charger and guns should be checked; feeding must be correct; gun heaters should be secure and plugged in; all equipment must be properly safety-wired.

Ammunition and Ammunition Rounds-counter Check. Extreme care should be used in checking ammunition.

Inspection is performed to see that the links on the round are positioned correctly; that the rounds with respect to each other are positioned correctly; that there are no short rounds; that there are no bulges or burrs in the rounds.

All ammunition with too-thick or too-thin extraction rims is removed and replaced with perfect ammunition.

All rounds which have deepset or defective primers must be replaced; rounds should be checked for corrosion; all broken links or improper belting must be replaced; belts are checked by running them through the loading machine.

Ammunition boxes are inspected, and the boxes are loaded, making certain that the rounds point in the correct direction and do not bind.

The body of the cartridge case is oiled before inserting the round into the magazine, in order to prevent jamming. Extreme care should be taken to prevent oil from getting on the primer of the cartridge case.

Caution: Ammunition must not be fed into the feeder mechanism until the system has been checked.

The ammunition rounds-counter on the sighting station control panel should be checked to see that it is in proper working order; it must be set for the total number of rounds to be carried on next mission.

System Check. The remote-control turret system is given a preflight check, to see that everything is in readiness and operating prop-

THIS PAGE IS DECLASSIFIED IAW EO 13526

erly for the combat mission. (This inspection is virtually a duplication of that which is made by the ground maintenance crew.) The guns and sight should point in the same direction. If the computer does not operate properly in the ground operational preflight check, the computer should be replaced with one which is operating properly.

Miscellaneous Check. The interphone and suit-heater are checked.

Blisters of the yoke and pedestal sights, the window in the hemisphere sight, the sight reflector, mirror, and sky filters on the yoke and pedestal sights must be clean.

Both filaments of the reticle lamp should burn.

Ring-and-bead sight must function properly on the yoke and pedestal sights.

Friction adjustment on the sight is made and the sight stowed preparatory to take-off.

A check is made to see that the parachute is in good condition, and the harness adjusted so that it fits properly.

Spare fuses and tubes should be readily available.

All escape hatches must be cleared of obstructions and made ready for instant use.

A check is made to see that the cabin pressure valves are working properly, and that fire extinguishers, first-aid kit, hand axes, and flashlights are handy.

Ammunition Check. The total of the ammunition "rounds-counter" on the control panel is checked after every three or four bursts in order to gauge and conserve ammunition for the duration of time spent in the combat zone.

Gunner's Prelanding Instructions. The turret is stowed by releasing the action switch; the uni-switch is turned to "off" position.

The sight is stowed in azimuth and elevation, and covered.

All switches on the control panel are turned to "off" position before landing.

After Landing. No one should be allowed to pass in front of the guns until they are unloaded.

Warning: A check is made to see that the last round has been removed from the chamber.

The ammunition boxes are emptied, all ammunition is removed from the airplane, and taken to the armament section.

Any malfunction of the remote-control turret system should be reported to the R.C.T. specialist, who in turn will analyze and report all malfunctions to the ground maintenance crew. The R.C.T. specialist should keep a record of the status of the equipment including malfunctions, shortages of spare parts, etc., and will also note the time and kind of repairs and any other changes made. This log must be kept. Malfunctions of the airplane equipment, trouble lamps, etc., should be reported to flight engineer for repairs.

Gunner's General Information

How to Track an Enemy Plane. If the computer is supplied with the right information, it will come up with the right deflection. If the gunner makes a mistake, the computer will give the wrong answer and the target will be missed. Tracking and framing of the target must be absolutely accurate. Accuracy can be attained only through constant practice.

These rules should be followed closely.

The body, especially the upper arms from elbow to shoulder, must be well braced. A steady hand must be kept on the sight, yet there must be absolute freedom of movement for the wrists and fingers.

The friction adjustments are used to give the sight just the right "touch." The correct setting will vary with the individual gunner. If the adjustment is a little bit tighter or a little bit looser, he will have difficulty in tracking smoothly. If the gunner wears gloves in combat, he should wear them while making the adjustment. The feel of the sight is far different to a gloved hand.

For glare conditions, as little sky filter as possible should be used. The rheostat should be turned all the way with just enough filter to make the reticle clearly visible.

The eyes should be kept a few inches behind the optic head. As the gunner looks through

the glass with one eye, the other eye should be kept open to help in scanning.

The gunner should learn to recognize fighters at a glance and to recall their wing span quickly. When an enemy is sighted, the target-size knob is turned until the proper wing span figure is visible in the upper right corner of the reticle. The center dot of the reticle is placed on the target and the range wheel turned or gripped smoothly to keep the fighter's wingtips barely framed by the reticle circle. A smooth, steady, easy motion will keep the circle the right size at every instant. The range figure, in hundreds of feet, appears in the lower left corner of the reticle.

Note: If the target is viewed from the side, it should be remembered that on most fighters the fuselage is shorter than the wingspan. The target-size knob is set to the fuselage length, or, if the wingspan setting is used, the circle is kept a little beyond the ends of the fuselage.

The center dot of the reticle sight is kept on the middle of the fighter and tracking is smooth and continuous. Once the gunner has started tracking, his grip on the hand wheels or grips should not be changed until the fighter is hit or flies out of view. If the aim is wrong, if the dot is not moved along with the target or goes past him, the dot should be moved back slowly—not jerked. The guns should not be fired while the aim is incorrect.

Avoiding Overheated Guns. Since the opening range of machine guns on the B-36 is so great, there is always the danger that the gunner may fire so many rounds during a single attack that the guns will be overheated and will fire after the triggers are released. Special care must be taken to avoid such overheating which endangers the gunner's own bomber and all the other bombers in the formation. The guns should be cooled at every opportunity. Whenever as many as fifty rounds are fired within a short period, the first possible chance must be taken to cool the guns during a lull in the fighting. The best means for effective, even, cooling of the barrels is to move them right out into the slipstream, pointed fore and aft and at a 30-degree angle from horizontal. Care should be taken, however, not to point them at another bomber. They should be cooled, and the turret retracted for ten full minutes, if there is time.

Runaway Gun. A "runaway" gun should be pointed away from the gunner's own plane and all other bombers in the formation—a straight-up or down position is safest. The gun safety switch then is removed from the "fire" position. This should stop the gun unless it is overheated. If it doesn't, the switch should be thrown back to "fire" to keep the other gun ready for action and to let the bad gun run out.

Power Breaker Buttons. The power breaker buttons on the control panels operate somewhat like fuses. When a circuit is overloaded or overheated, the breaker opens and cuts off the current. A possible indication that circuit breaker CB-2, which is located on the control panel, has opened is to see the turret-extended light, also located on the control panel, and the sight reticle light go out while the system is operating. If the firing trigger is depressed for firing and neither one of the rounds counters operates, circuit breaker CB-3 may be open. To reset the breaker and start the circuit working again, the uni-switch on the control panel is turned off and the "breaker buttons pushed hard. The uni-switch is turned back to its former position and the sequence repeated, if necessary, until the turret properly follows the sight. After the uni-switch is back in its operation position, an interval of ninety seconds is required for the thyratron controller to restore DC power to the circuit.

Avoiding Self-inflicted Damage. Self-inflicted damage, which means bullet holes in one of our own planes from one of our guns, is always a possible danger when bombers fly in formation. Every precaution should be taken to avoid it.

Warning: If there is a choice between letting an enemy fighter go and running the risk of firing into a friendly bomber, the fighter should be allowed to escape.

There are no hard and fast rules for avoiding self-inflicted damage. The main consideration is to understand what happens to the guns when they are being sighted, and to exercise good judgment based on that knowledge.

As the sight is held on an attacking plane, the computer sets in deflections very similar to those used in position firing. The maximum deflection which the B-36 computers can set is about 200 mils, or more than 11 degrees. (A mil is the angle formed by two intersecting lines which are one foot apart at 1,000 feet.)

A very large deflection will also be obtained when firing at a beam attack. To avoid this, a safety zone is allowed for every bomber in the formation. As soon as the sight gets into this zone, the gunner should take his finger off the trigger.

SECTION II—TURRETS—UPPER, LOWER, AND NOSE

1. INTRODUCTION

This section contains instructions for the overhaul of the upper, the lower, and the nose turrets, of the remote-control turret system in the B-36 airplane.

The instructions for the overhaul of the tail turret are contained in a separate handbook. The instructions in both turret handbooks form a part of the complete instructions issued for the operation, service, and overhaul of the B-36 remote-control turret system.

The elevation and azimuth movement, the overall dimensions, and the weights of the different turrets used in the B-36 remote-control turret system are given in Table I.

2. GENERAL DESCRIPTION

There are eight turrets in the remote-control turret system of the B-36: four upper turrets, two lower turrets, one nose turret, and one tail turret. The tail-turret overhaul instructions are contained in a separate handbook.

All the upper and the lower turrets are retractable into the airplane's fuselage, a feature which reduces drag (Figures 2-2, 2-4, and 2-6). A fire interrupter which prevents the possibility of damage inflicted by the airplane's own guns, and a contour follower which prevents the possibility of the guns striking against the fuselage as the guns are swung along the contour, are installed in each of the upper and the lower turrets. The nose turret, because of its location in the airplane, is not retractable and is not equipped with a fire interrupter or a contour follower.

Each turret is equipped with two 20-mm machine guns which are mounted on a saddle assembly which is, in turn, mounted in the inner ring of the turret ring assembly. This mounting arrangement makes it possible to move the guns into any elevation and azimuth position within the limits imposed by the design of the armament system of the airplane.

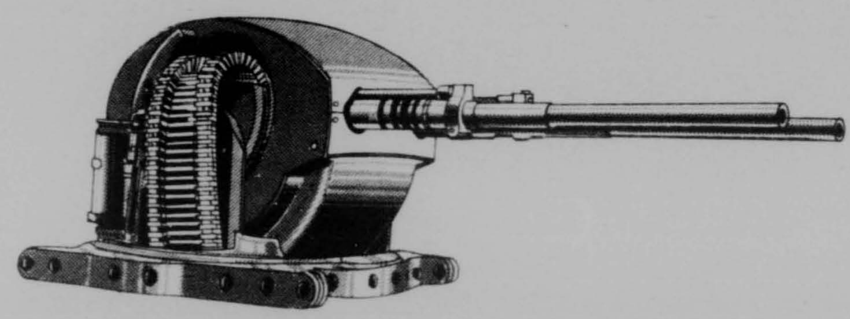

Figure 2–29. Front View of Upper Turret with Dome Removed.

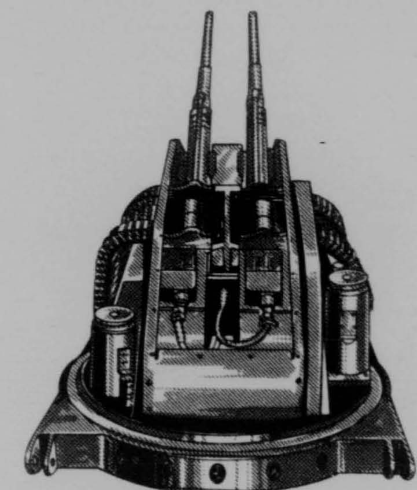

Figure 2–30. Rear View of Upper Turret with Dome and Top Panel of Gun Enclosure Removed.

The ammunition for all turret guns is carried in ammunition boxes which are attached to the airplane's structure. A separate ammunition box is provided for each gun and the rounds of ammunition, which are linked together to form a belt, are fed to the gun through flexible ammunition chutes. An ammunition booster on each box and a feed mechanism on each gun insure a positive feed of the ammunition to the gun. The ejected ammunition cases and links are collected from the guns of the upper turrets and the nose turret. The cases and links from the lower-turret guns are ejected through the lower dome assemblies into the slipstream of the airplane.

Upper Turrets

The four upper turrets are the same, except for their contour followers, their fire interrupters, their gun chargers, and their case-and-link ejection chutes (Figures 2-29 and 2-30). The basic assemblies which make up each upper turret are described in detail in the following paragraphs.

Inner and Outer Ring Assembly. This assembly is the basic framework of the turret. The outer ring is supported and positioned in the airplane by two fixed supports in the airplane's structure and by two movable supports of the retraction mechanism. The inner ring is positioned to the outer ring by ring bearings. It supports the saddle and the azimuth and elevation drives.

Outer Ring. The outer ring assembly consists of a single casting upon which the rest of the turret proper is supported (Figure 2-31). The azimuth ring gear (2), bolted to the outer ring, helps position the lower ring bearing, which in turn positions the inner ring (3).

Ring Bearings. The two ring bearings are located between the inner and outer rings. They support and position the inner ring in the outer ring.

Inner Ring and Saddle Supports. The inner ring (Figure 2-32) and saddle supports (1 and 2) are two magnesium castings bolted together. The base of the inner ring and saddle support assembly forms the inner ring or housing. It is held in place by the ring bearings. The two saddle supports extend upward from the inner ring. The azimuth drive assem-

5. LIMIT SWITCH CAM
6. ELEVATION GEAR SECTOR

Figure 2—33. Saddle, Sector, and Bracket Assembly.

bly is mounted on the left-hand saddle support. The elevation drive assembly and the contour follower are mounted on the right-hand saddle support.

Trunnions. Two steel trunnions, used to support the saddle, are bolted to the saddle supports. Needle bearings, pressed into the saddle, rotate with the saddle around the trunnion.

Azimuth Stops. The azimuth stops and limit-switch actuators are mounted on the outer ring. The azimuth limit-switches and buffer cartridge are mounted on the inner ring. These parts limit the azimuth travel of the turret to 200 degrees with 1½ degrees overtravel at each end.

Saddle, Sector, and Bracket Assembly. The saddle, sector, and bracket assembly (Figure 2-33) supported between the two saddle supports, mounts the two 20-mm guns. The guns are elevated or depressed by the elevation drive which engages the gear sector attached to the right-hand side of the saddle assembly.

Saddle. The saddle is a magnesium casting on which the other parts of the saddle, sector and bracket assembly are mounted.

Elevation Gear Sector. The gear sector (6) is bolted and doweled to the saddle. The elevation drive pinion meshes with the gear sector which moves the saddle and guns in elevation.

Gun Supports. The two 20-mm guns are mounted on the saddle by front and rear gun supports. Both front and rear gun supports are adjustable to provide for alignment of the gun bore. The two front gun supports (1) bolted to the saddle can be adjusted to move the guns laterally. The two rear gun supports (3) fastened to brackets which in turn are bolted to the rear of the saddle, can be adjusted to move the guns vertically.

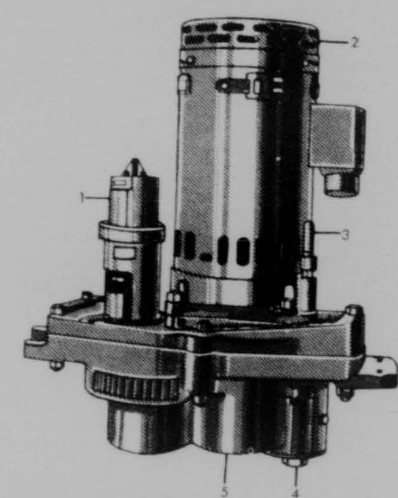
Elevation Stop and Limit-switch Cam. The elevation stop (4) and the limit-switch cam are mounted on the saddle. The limit-switch cam operates the elevation limit switch when the guns have reached their maximum elevation of approximately 90 degrees and an overtravel of 1½ degrees. The elevation stop mechanically restricts the travel of the guns at zenith after the limit-switch cam has been operated.

Azimuth Drive Assembly

The azimuth drive assembly (Figure 2-34)

which is located on the left saddle support of the inner ring assembly, performs two functions: it supplies the mechanical power required to drive the turret and guns in azimuth; and it contains the electrical equipment which assists in controlling the azimuth position of the guns. The drive assembly consists of three main sub-assemblies: the drive motor (2), the speed-reduction gear assembly (5), and the tandem Selsyn assembly (1).

Drive Motor. The azimuth drive motor (2), rated 1.1 horsepower, is a "separately excited" motor which rotates either clockwise or counterclockwise according to the signal from the thyratron controller. The input voltage from the thyratron controller regulates the motor speed. A solenoid-operated brake located at the base of the motor prevents rotation of the motor armature (and, consequently, the turret) when the motor is not energized. When the sight moves beyond the azimuth limit of the guns, the brake solenoid is de-energized and the brake is applied, holding the turret against the limit stop. When the sight is again moved within the limits of



1. TANDEM SELSYN ASSEMBLY
2. MOTOR
3. BRAKE RELEASE LEVER
4. CRANK ADAPTER
5. GEAR ASSEMBLY

Figure 2—34. Azimuth Drive Assembly.

gun travel, the solenoid becomes energized and releases the brake. The brake can be released manually by two spring-loaded levers, one located on each side of the motor.

Gear Assembly. The bear train of the azimuth drive assembly provides the speed reduction necessary to drive the turret in azimuth and to rotate the tandem Selsyn rotors. The gear assembly is driven through a friction clutch which protects the gear train from excessive shocks when the guns reach their maximum azimuth limit.

Power Gearing. Power to drive the turret in azimuth is transmitted from the motor through the gear train of the azimuth drive assembly as follows: The motor pinion (8) (Figure 2-35) meshes with the large gear of the clutch and gears assembly (5) which drives, through two speed-reduction gear stages (14 and 15) the azimuth drive gear (13) which in turn meshes with the azimuth ring gear (12) on the turret outer ring assembly. The turret is driven in either direction, clockwise or counterclockwise, depending upon the direction of rotation of the drive motor.

Selsyn Rotor Position Gearing. The tandem Selsyn control transformer assembly, which is mounted on the azimuth drive assembly, embodies both the 1-speed and the 31-speed Selsyn units with an internal planetary reduction gear system interposed between them. The Selsyn gear (11) on the end of the 31-speed rotor shaft meshes with the Selsyn drive gear (10) on the azimuth drive-gear shaft. As the name implies the 31-speed Selsyn rotor is geared to turn at a speed 31 times that of the turret. That is, if the turret were to turn one complete revolution, the 31-speed Selsyn rotor would turn 31 revolutions. The 1-speed Selsyn unit, which is in tandem with the 31-speed Selsyn unit, is driven through the interposed planetary gear system by the 31-speed Selsyn rotor shaft. The speed ratio of the planetary reduction gear system is 31 to 1. Thus the 1-speed Selsyn rotor turns at the same speed as the turret. The tandem Selsyn control transformer assembly indicates by means of an electric control signal, the azimuth position of the line of sight.

Figure 2–35. Schematic Mechanical Diagram of Upper Turret Gear System.

Manual Azimuth Movement. A handcrank is provided with each turret for manual rotation of the turret. A crank adapter (Figure 2-34) is provided on the bottom of the gear unit of the azimuth drive assembly for insertion of the handcrank. The crank engages the splined end of the clutch-and-gears-assembly shaft in the gear unit. Before the turret can be rotated, the brake in the drive motor must be released by means of the brake release levers (3). Approximately 70 revolutions of the handcrank are required to rotate the turret through its complete azimuth travel of 200 degrees.

Elevation Drive Assembly

The elevation drive assembly (Figure 2-36) which is located on the right saddle support of the inner ring assembly, performs three functions. It supplies the mechanical power required to drive the saddle and guns in elevation; it contains the electrical equipment which assists in controlling the elevation position of the guns; and it provides the gear drive for introducing the elevation position of the guns into the fire interrupter assembly. The drive assembly consists of three main sub-assemblies—the drive motor (1), the speed-reduction gear assembly (5), and the tandem Selsyn assembly (6).

Gear Assembly. The gear train of the elevation drive assembly provides the speed reduction necessary to drive the saddle and guns in elevation to rotate the tandem Selsyn rotors, and to drive the elevation functions of the fire interrupter assembly. The gear assembly is driven through a friction clutch which protects the gear train from excessive shocks when the guns reach their maximum position of elevation or depression.

Power Gearing. Power to drive the saddle and guns in elevation is transmitted from the motor through the gear train of the elevation drive assembly as follows: The motor pinion (25) (Figure 2-35) meshes with the large gear (26) on the clutch assembly shaft. The clutch assembly gear (24) meshes with the gear (27) on the end of the worm shaft (34). The worm meshes with the worm wheel (33) on the elevation drive shaft and drives the shaft gear (35) which meshes with the elevation gear sector (3) on the saddle. The saddle

and guns are driven either up or down, depending upon the direction of rotation of the drive motor.

Selsyn Rotor Position Gearing. The tandem Selsyn control transformer assembly used on the elevation drive assembly is the same as that used on the azimuth drive assembly (Figure 2-35). The Selsyn gear (36) on the end of the 31-speed rotor shaft meshes with a small gear on the end of the worm shaft (34).

Fire Interrupter Drive

An indication of both the azimuth and the elevation position of the guns is necessary in the operation of the fire interrupter assembly. The elevation indication is obtained from the elevation drive assembly and is transmitted by a flexible cable to the fire-interrupter assembly. The fire-interrupter take-off gearing in the elevation drive assembly consists of the gear and shaft assembly (28) whose gear meshes with and is driven by the wormshaft gear (27). One end of the gear-and-shaft-as-

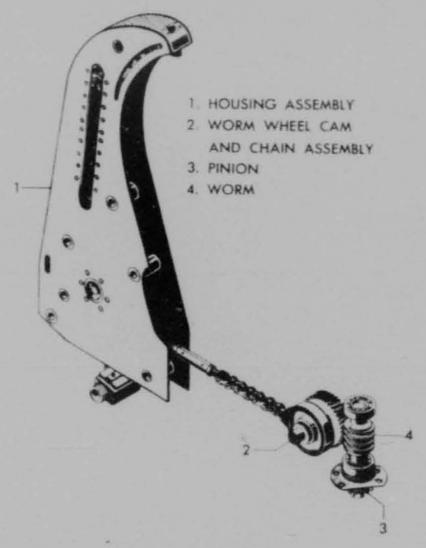

Figure 2–37. Contour Follower.

sembly shaft has external splines which mate with the splined fittings on the flexible cable (18) which drives the interrupter (16). The splined end of the shaft is enclosed by the coupling flange (Figure 2-36) which is externally threaded to receive the connector of the flexible cable. Since the gear and shaft assembly is geared to the power gear train in the elevation drive assembly, its position is relative to the elevation position of the saddle and guns. It is this position indication which is transmitted to the fire interrupter.

Manual Elevation Movement. A crank adapter (4) (Figure 2-36) is provided on the bottom of the gear unit of the elevation drive assembly for the insertion of the handcrank which is provided with each turret. The crank engages the splined end of the worm shaft in the gear unit. Before the saddle and guns can be raised or lowered, the brake in the drive motor must be released by means of the brake release levers. Approximately sixty-two revolutions of the handcrank are required to move the saddle and guns through their complete elevation travel.

Contour Follower

A contour follower (Figure 2-37) assembly is used on each of the upper and the lower retractable turrets. The only difference among the several turret contour followers is in their contour pattern. The contour pattern can be adjusted so that any contour-follower assembly can be used with any turret.

The function of the contour follower is to limit the downward travel of the guns (for upper turrets), or the upward travel (for lower turrets), for all azimuth positions of the turret, in order to prevent the guns from hitting the airplane fairing as the guns are swung along the fuselage contour, and to prevent the guns from pointing at the gunner's combat station.

The contour-follower assembly is mounted on the inner ring of the turret and consists of the following component parts and assemblies: housing assembly (1) (Figure 2-35), worm wheel cam and chain assembly (32), worm (31), and pinion (30).

The housing assembly is mounted on the right-hand saddle support in the path of the elevation-gear sector which travels between the two side plates of the housing. It consists of the link (2) and chain (22) assembly, roller and bracket assembly (21), spring (4), adjustment screw and spring (23), and two limit switches.

The upper end of the link rides in a curved track whose center of radius is that of the trunnion which supports the saddle. The lower end of the link rides in a straight track and is connected by a chain which passes over the roller of the roller-and-bracket assembly, to the worm wheel cam and chain assembly.

The roller-and-bracket assembly is pivoted at one end in the lower part of the housing. The other end of the roller-and-bracket assembly is held in position against the adjustment screw and spring by the chain which connects the link to the worm wheel cam and chain assembly. The chain is kept taut by the spring which pushes against the link to keep the whole contour follower linkage snug at all times.

The adjustment screw and spring is mounted between the two side plates in the lower

part of the housing and serves as a mechanical stop beyond which the upper turret guns can depress, or the lower turret guns can elevate, only as permitted by the stretch in the chain or the compression of the spring. The total movement of the roller and bracket assembly is limited to approximately 3/16 inch by the adjustment screw and spring before the spring bottoms.

There are two limit switches. One switch is attached to the upper end of the gear sector and the other is mounted under the adjustment screw and spring. The two switches are wired in series. When either switch is actuated, a relay in the turret junction box is energized which connects a plugging circuit (reverse current) into both turret-drive motors. The relay then cuts off both elevation and azimuth drive motors in the direction they are rotating, sets their brakes and cuts off the firing circuit. The upper switch acts to stop motion of the turret before a dangerous stress is brought upon the contour-follower chain. The upper switch is actuated by a cam and follower mechanism, located between the upper end of the gear sector and the link of the contour follower, to provide for stopping the motor 1½ degrees of elevation travel before contact is made with the contour-follower link. If the upper switch should fail to operate, the lower switch serves as a safeguard against damage to the equipment. The lower switch is actuated by an actuator arm assembly on the roller bracket when the adjustment screw and spring starts to compress.

Worm-wheel Cam-and-chain Assembly, Worm and Pinion. As the turret is rotated in azimuth, the pinion (30) which meshes with the azimuth ring gear (12) is rotated, turning the worm (31) which rotates the worm-wheel cam of the worm-wheel cam-and-chain assembly (32). As the worm-wheel cam is rotated, the chain is pulled in and around the cam, and in turn the link (2) is pulled down in its track. Thus the link moves up and down in its track as the turret moves in azimuth. The amount of up-and-down movement is determined by the diameter of the cam. If the motion of the link is plotted against the azimuth travel of the turret, measurement being taken in mils, the resulting curve represents the lower elevation limit for upper turrets, and upper elevation limit for lower turrets. The curve can be raised or lowered by setting the length of the chain by means of the turnbuckle. Since the diameter of the cam is fixed, the shape of the curve cannot be changed; the curve can be only raised or lowered by the chain setting.

Thus the different limits of gun elevation position are governed by the azimuth position of the turret as follows: As the turret is rotated in azimuth, the position of the link in its track is changed. When the guns are depressed (upper turrets) or elevated (lower turrets) to a position 1½ degrees before the gear sector engages the link, the upper limit switch is actuated. When the upper limit switch is actuated, the circuits to the azimuth and elevation-drive motors are plugged (reverse current is applied) in the direction they are rotating, the motor brakes are set, and the circuits to the guns are cut off. Although the limit switch cuts off all these circuits, there is a backout circuit for both the azimuth and the elevation drives which pulls the guns back off the contour as soon as the sight returns to the area of fire. The guns step-follow the contour when going either up or down the contour pattern. If the upper limit switch should fail to operate, the guns will continue to travel until the elevation-gear sector pushes against the link. This will cause the chain to tighten and force the roller and bracket assembly against the adjustment screw and spring. A small movement of the roller and bracket assembly will actuate the lower limit switch which has the same function as the upper limit switch.

Interrupter Assembly

The interrupter assembly prevents damage to the airplane by its own guns (Figure 2-38), indicates when the turret is stowed, and supplies an azimuth-position signal (forward or aft) to the thyratron controller. The interrupter assembly is mounted on the inner ring and consists of a housing (1) (Figure 2-39), a drum assembly (8), a switch carriage (13), and a position switch (10). Five bolts through the flange on the housing of the interrupter attach it to the inner ring.

THIS PAGE IS DECLASSIFIED IAW EO 13526

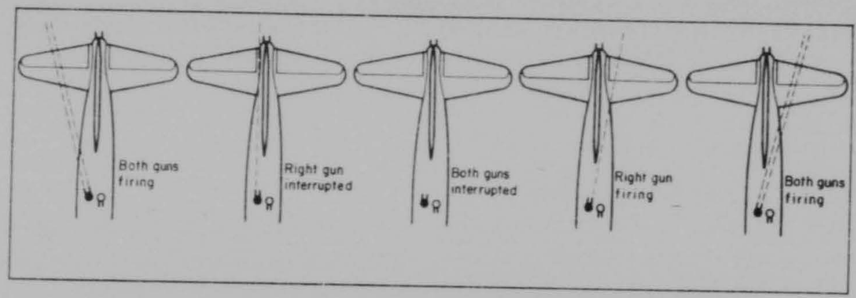

Figure 2—38. Fire Interrupter Protects Airplane from its Own Guns.

Housing. All parts of the interrupter are attached to or assembled inside of the housing (1). Bearings in the housing and in the cover plate (17), attached to the end of the housing, position the drum. There are two small gear assemblies on the cover plate for azimuth and elevation positioning.

Drum Assembly. The drum assembly consists of a cylindrical drum to which is fastened two sets of stainless-steel cam patterns (3 and 7) (Figure 2-39), a stow button (6), and two end plates (2 and 27). One end plate (27) serves as a cam for indicating the azimuth position. The drum assembly is geared to the azimuth gear assembly (19, Figure 2-35) on the housing cover. The azimuth gear assembly, in turn, meshes with the azimuth ring gear (12) on the outer ring of the turret. The stow button operates a switch which turns on a light in the control panel in the gunner's

compartment when the turret is stowed and ready for retraction. There is one set of cam patterns for each gun. This set of patterns represents such areas as propellers, wing tips, etc., for which fire must be interrupted. To insure greater interrupter accuracy, the drum assembly rotates 1.714286 times as fast as the inner ring on the turret.

Switch Carriage Assembly. The switch carriage (13, Figure 2-39) contains three snap-action switches (12, 14, and 15). Two of the switches, one for each gun, are normally closed; and one for the stowed position is normally open. The switch carriage is mounted on two rods (11) which guide the carriage back and forth across the drum assembly. The carriage is driven by a long lead screw (16), turned by the elevation gear assembly (17, Figure 2-35) on the housing cover. The gear assembly is driven by a flexible cable (18) whose other end is connected to the gear and shaft assembly (28) of the elevation drive assembly. Thus, elevation position of the guns is transmitted to the switch carriage with respect to the drum assembly. The switch carriage also contains a zeroing pin (24) (Figure 2-39) used to time the interrupter assembly (both in azimuth and elevation as regards the guns). The zeroing pin in the carriage should line up with the zeroing hole (5) in the drum when the guns are at zero degrees elevation and the turret is at zero degrees azimuth.

Position Switch. The position switch (10) (Figure 2-39), mounted on the housing and actuated by the drum end plate (27) nearest the housing cover, is a three-terminal, snap-action switch. It is closed either to one or to the other of two circuits, depending upon which side of broadside (forward or aft) the guns are pointing. This is necessary in order to have step-contouring of the guns in both up and down directions.

20-mm Guns and Accessories

The 20-mm automatic gun (Figure 2-40) is a combination blow-back and gas-operated aircraft weapon. The gun is air-cooled and has a cyclic rate of fire from 750 to 850 rounds per minute. The gun may be fired from either the left or right side, depending on the mounting of the feed mechanism (2). The breech block assembly is drawn back for injection of the first round by an automatic, electrically operated gun charger. The charger also ejects the duds. A rounds-counter actuator is included in the charger. Each gun contains a gun heater to prevent freezing of the gun. The gun accessories also include an electric trigger and a link chute.

Feed Mechanism. The 20-mm gun feed mechanism (2), mounted on top of the gun, is a complete unit designed for feeding belted ammunition into the 20-mm automatic gun. There are two feeders—one feeds ammunition from the right-hand side. Either the left hand or the right hand side feeder is used, depending upon the side from which the gun is fed. The main functions of this mechanism are to bring the ammunition from the ammunition chute into the gun, to strip the links from the ammunition belt, and to position the rounds, one at a time, into the mouth of the gun so that they can be carried forward into the chamber by the breechblock bolt.

Gun Accessories. The gun accessories in-

clude the following: gun charger, gun heater (Figure 2-41), electric trigger (7), link ejection chute (2), and gun-mounting brackets.

Gun Charger. The gun charger draws the bolt back to allow the first round to be positioned in the chamber. It also clears the gun of defective ammunition in case of misfire and cocks the gun after ejecting the duds.

Gun Heater. The gun heater (Figure 2-41) attached to each side of the gun receiver where the cases are ejected, consists of a resistance coil assembly. It furnishes heat to the working parts of the guns to prevent freezing at low temperatures. The gun heater is government-furnished equipment.

Electric Trigger. The electric trigger (7) operates the gun sear-actuating mechanism.

Link Chute. The link chute (2) is a metal fitting attached to the inboard side of the feed mechanism. It directs the ejected links from the feed mechanism down to an opening in the saddle assembly.

Upper Forward Turret Ejection Chutes

In the upper forward turrets, the case and link-chute adapter (stainless steel) is fastened to the bottom of the inner ring assembly. A rubber fabric chute, which funnels down to a rubber fabric tube, six inches in diameter, is fastened to the adapter. A spiral spring is sewn into the fabric tube to give it rigidity. The tube empties into a canvas bag, located in the airplane fuselage, which holds the ejected cases and links. The end of the tube is held at the top of the case-and-link container by an opening in the cover plate and by a flange and angles attached to the tube. By removing the four ring bolts and pulling away the ring, the case-and-link chute can be thrust through the opening in the plate and the ring reinstalled. The ring will prevent the case-and-link chute from moving up through the hole. After the tube is threaded through the plate, it will normally float in the opening in the plate, with the flange and angles acting

as a stop for its travel in the up or down directions. In retracting the turret from firing position, the rubber fabric chute and tube are deformed to allow full retraction. In bringing the turret into firing position again, the coil spring in the tube brings it back to its original shape and position. When cases and links are ejected from the gun and feeder, they fall through openings in the saddle casting, are deflected into the rubber fabric chute by the adapter, flow through the chute into the tube and then fall into a container in the airplane (Figure 2-42).

Upper-aft-turret Ejection Chutes. The upper-aft-turret ejection chute is similar to the upper-forward-turret ejection chute, described in the preceding paragraph, except for the method by which the end of the tube is held above the case-and-link container. The end of the tube is held above the container by tension coil springs which are fastened to the airplane and a flange on the tube end. In retracting the turret from firing position, the rubber fabric chute and tube travel downward between the ammunition boxes until the tension of the coil springs is relieved. Then the chute and tube are deformed to allow full retraction. In bringing the turret into firing position again, the coil spring in the tube brings it back to its original shape while the two external coil springs position it above the canvas bag.

Ammunition Boosters

The 20-mm automatic gun relies on a feeder, which is a component of the gun, to pull rounds of ammunition into the guns as it fires. The pull of the feeder is limited. Excessive retarding pull by a long ammunition belt results in failure of the feeder to supply a succeeding round of ammunition to the gun as it fires. Remote installations of ammunition boxes on the B-36 require boosters to assist the gun feeder and to assure continuous feeding of the ammunition belts. The boosters are installed on the ammunition boxes.

Construction. (Figure 2-43.) The booster consists of a gear unit and a guide bracket. The gear unit consists of the motor (3), gearing, clutch, and ammunition sprockets (1). The guide bracket is a sheet-metal support which serves both as a mount for the drive unit and as a means for directing the ammunition belt over the sprocket on the gear unit. The guide bracket also strips ammunition from the rotating sprocket to prevent jamming.

Gear Unit. (Figure 2-44.) The gear unit is powered by an aircraft electric motor (1) with a three-phase, 208-volt, AC power rating. Rotation of the motor armature is transmitted through a gear train, a clutch (2), and a shock-resisting drive (3) to the ammunition sprockets (4 and 5). The gear train and clutch are enclosed in a housing (2) (Figure 2-43) and a cover (4). The sprocket is supported in bearings between the housing proper and an

THIS PAGE IS DECLASSIFIED IAW EO 13526

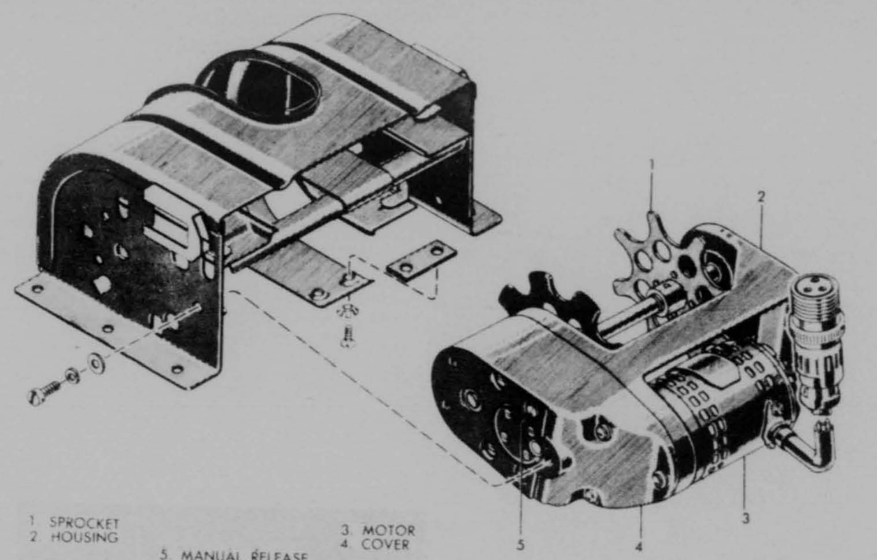

Figure 2–43. Ammunition Booster Assembly Partially Disassembled.

arm extending from the housing. The gear unit clutch has two unusual features: it unloads at a constant torque, and it has free wheeling, if the sprocket is rotated by hand in the direction that the sprocket is driven by the motor. The clutch (Figure 2-45) consists of a driver disk (3), and a clutch gear (6) mounting two rollers (5) in needle bearings (4), spring-loaded clutch arms (2) mounted on a spool (1), and a pinion-shaft assembly

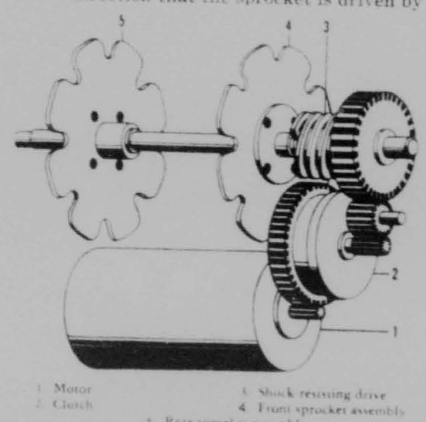

Figure 2–44. Schematic Diagram of Ammunition Booster Gear Train.

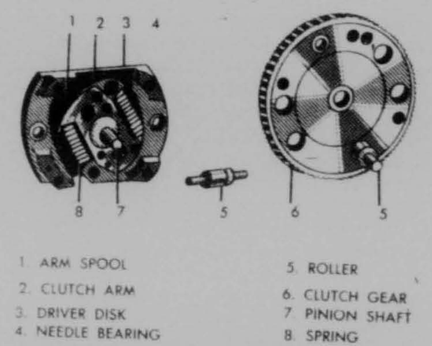

Figure 2–45. Ammunition Booster Clutch Partially Disassembled.

(7). The rollers engage the cams and drive the spool and pinion shaft until a torque is reached where the cams depress their tension spring. When the cams are depressed, the rollers overtravel the cams.

Function. (Figure 2-44.) The booster motor (1) is energized and the sprockets (4 and 5) rotated when the firing circuit is closed. Rotation of the sprockets move the ammunition belt forward until the portion of the belt between the booster and the gun is compressed to a point where torque on the cams and the compression springs in the clutch (2) depress the cams. The rollers then overrun the cams and the sprockets are not rotated. Overrunning of the cams continues until firing of the guns reduces the compression of the ammunition belt to a point where torque permits the rollers and cams to engage and rotate the sprockets. This engaging and disengaging action of the clutch is cushioned by a shock-resisting drive (3) connected between the drive gearing and the sprockets. Sudden loads on the motor and gearing or the sprockets are also cushioned by this spring. Since the normal driving speed of the sprockets is greater than the rate of fire, there will be a series of starts and stops of the sprockets during an extended burst of gunfire. Each time the sprockets stop, the ammunition belt is left in a partially compressed condition ready for the next firing. A ratchet-type brake in the housing of the gear unit maintains the compression during the period the firing circuit is not energized. A manual release (5) (Figure 2-43) on the exterior of the housing may be used to disengage this brake during unloading operations. A special feature of the torque-limiting clutch is that the clutch is disengaged during the periods of high torque. The motor is, therefore, unloaded and motor life is increased. The special clutch design (overrun of the clutch rollers) permits ammunition to be pulled through the booster by the gun in the event that the booster becomes inoperative.

Ammunition Feed Chutes. Ammunition is guided from the booster outlet mouth to the feed mouth by flexible feed chutes. The chute bends enough to allow for azimuth movement of the turret and elevation movement of the guns. In the lower turrets, the feed chutes travel from the booster mouth to the inner ring where guide brackets guide the ammunition belt to the feed mouth.

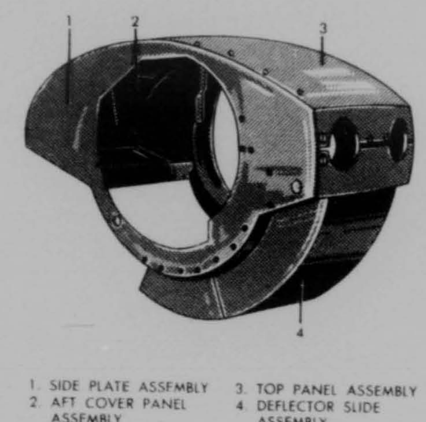

Figure 2–46. Upper Turret Gun Enclosure.

Gun Enclosure. The gun enclosure assembly (Figure 2-46) is made of magnesium alloy, specification No. AN-M-29. The assembly approximates the contour of the dome and is designed to enclose the moving parts of the gun. It consists of three sections: the side-plate assembly (1) which is secured to the sides and back of the saddle and is not readily removable; the aft-cover-panel assembly (2) which encloses the back end of the enclosure; and the top panel assembly (3) which encloses the top part. The aft cover and top panels are fastened to the side panel by quick-action fasteners.

Dome Assembly

The dome assembly is made of magnesium alloy, specification No. AN-M-29. The assembly is the enclosure for the turret assembly and is secured to a flange on the inner ring by screws. Two access doors, one located on the elevation-drive and the other on the azimuth-drive side of the turret, permit servicing of the turret without removing the dome. These doors are quickly removed by quick-action fasteners. The rear part of the dome is removable to facilitate servicing of the guns.

2. TORQUE TUBE
3. CRANK ARM
4. HAND CRANK
5. CLUTCH ASSEMBLY

Figure 2—47. Schematic Diagram of Retracting Gear Unit.

Retracting Mechanism

The retraction mechanism (Figure 2-47) is used to extend the turret into its firing position and to retract it inside the airplane's fuselage while flying to and from the combat zone. After the turret is retracted, a portion of the fairing slips over, covering and sealing the opening through which the turret projected. The only difference among these four assemblies is in the position of the retracting-gear unit with respect to the turret.

A crank arm is fastened on one end of the gear unit and a torque tube is fastened on the other end. On the opposite end of the torque tube, a second crank arm is fastened. The two crank arms are each connected to a pivot arm. The opposite ends of the pivot arms are pinned to the inboard side of the outer ring of the turret. The outboard side of the turret outer ring is hinged to the airplane. The gear housing and torque-tube bracket are mounted on the outboard side of the airplane. A connector bracket is fastened to one side of the gear housing from which an electric cable goes to the position switches on the crank arm nearest the gear housing.

Retracting Gear Unit

(Figure 2-47). The gear unit consists of ten gears (five sets). The first gear is on the electric motor shaft and has a ratio of 2426.66 to 1 of the crank arm. Between the fourth and fifth gears there is a clutch (5) which disengages the motor drive from the rest of the gear train when the hand crank (4) is pushed onto the shaft. In turn, the shaft forms a part of the fifth gear. The tenth gear is splined directly to the crank arm (35-tooth spline) (3) and the torque tube (34-tooth spline) (2).

Electric Drive Motor. The electric drive motor is a three-phase, 400 cycle, 208-volt motor, rated 10,200 rpm and 0.76 horsepower. The motor is equipped with a thermal-overload switch. Rotation of the motor is in either direction, depending upon the polarity of the

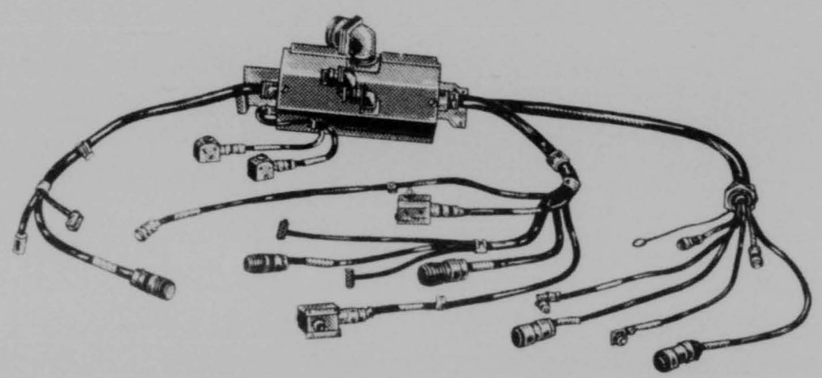

Figure 2—48. Turret Junction Box.

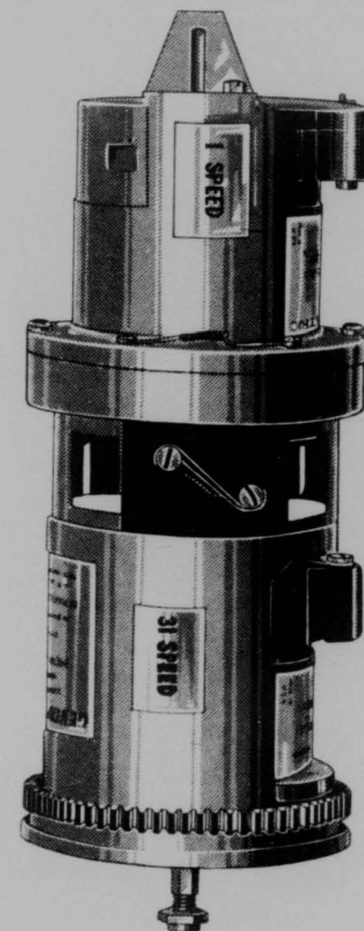

Figure 2—49. Selsyn Control Transformer.

control signal. A solenoid-operated brake prevents rotation of the motor armature and holds the turret in any position when the motor is not energized.

Torque Tube. The torque tube is made of seamless alloy steel and is supported through the 34-tooth spline by a needle bearing in the gear housing. The opposite end is supported by the bearing in the torque tube bracket. On this end, away from the gear housing, is a 35-tooth spline which supports the second crank arm. By means of the 34-tooth or 35-tooth spline on the torque tube, the second crank arm can be adjusted in 0.015-inch increments, as measured at the pin on the inboard side of the turret outer ring.

Crank Arms and Pivot Arms. The two pivot arms, controlled by the two crank arms, move the outer ring of the turret up to horizontal position for firing and down 67 degrees 15 minutes to the retracted position.

Retraction-mechanism Connector Bracket and Limit Switches. The connector bracket is a spot-welded sheet-metal assembly which supports the cable from the control box and the cable to the limit switches. The limit switches are so arranged on the crank arm that one switch cuts off the power to the drive motor when the turret reaches its firing position, and the other switch cuts off the power to the drive motor when the turret reaches its stowed position. An adjustable bracket on the upper arm actuates the plunger arm of this switch. The latter switch acts also as a holding circuit; it prevents the fairing cover from being closed over the turret opening until the turret is stowed and fully retracted.

Turret Junction Box

The turret junction box (Figure 2-48) is mounted on the inner ring. All electric power to the turret feeds into the junction box. Cables from the junction box take power to the firing solenoids, gun heater, drive motors, Selsyns, limit switches, and gun chargers. A relay, located in the junction box, controls the drive motors during the time the contour follower is in effect.

Selsyn Control Transformer Model 2JB15B1 (Tandem Unit)

The Selsyn control transformers (Figure 2-49) which are mounted on the turret-drive assemblies correspond to the Selsyn generators on the sighting station. One-speed and 31-speed Selsyn control transformers are provided for both the azimuth and the elevation Selsyn systems. For convenience the turret

THIS PAGE IS DECLASSIFIED IAW EO 13526

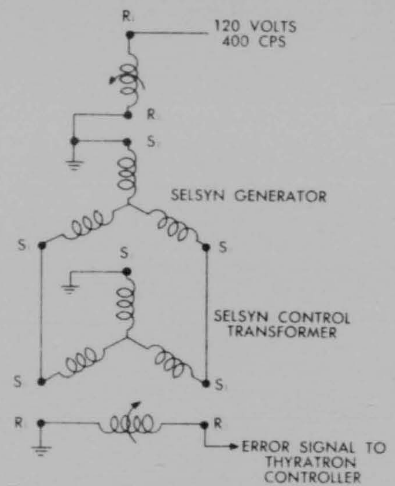

Figure 2—50. Selsyn Generator and Control Transformer Connection Diagram.

Selsyns are mounted in tandem. The 1-speed Selsyn control transformer is mechanically connected by gearing to the 31-speed Selsyn which, in turn, is geared to the turret.

A single Selsyn control transformer is a small electric device which consists of the following basic elements: a stator, a rotor, an end shield, and a connector. Actually, the electrical characteristics of the Selsyn control transformer differ considerably from those of the Selsyn generator so that these elements are not interchangeable in the system. One of the apparent differences is in the shape of the rotor. The Selsyn control transformer has laminated, round rotor punchings while the Selsyn generator has dumbbell-shaped punchings. It has a higher impedance than the Selsyn generator. The voltage on the rotor of the Selsyn control transformer is rated 120 while on the rotor of the Selsyn generator the maximum voltage is rated 57.5. Electric connections to the Selsyn control transformer are made through connector contacts identified by "R_1", "R_2", "S_1", "S_2", and "S_3".

The three stator windings of the control transformer are electrically connected through system wiring to the stator windings in the Selsyn generator so that the voltages appearing in the windings of the Selsyn generator are reproduced in magnitude and polarity in the stator windings of the Selsyn control transformer. (Figure 2-50). The resulting magneto flux in the control-transformer stator induces a voltage in the rotor by transformer action which is the signal voltage fed to the thyratron controller.

Non-interchangeable Items of Upper Turrets

The upper forward turrets are identical with the upper aft turrets except for the fire interrupter cams, azimuth stops, and case-and-link chute assembly. The fire interrupters have different cam patterns for each turret (refer to table II). Contour-follower assemblies are interchangeable but the contour patterns must be adjusted for each turret (refer to above paragraph).

Figure 2—52. Route of Incoming Ammunition and Ejected Cases and Links—Nose Turret.

Description of Lower Turret. The two lower turrets are essentially the same as the upper turrets, except for minor modifications which were necessary to adapt the turrets for operation in an inverted position.

Differences Between Lower Turrets and Upper Turrets. The lower turrets are identical to the upper turrets with the following exceptions: The sealing of the dome assembly to the gun enclosure; the lower dome access panels have blisters to allow greater clearance for the ammunition feed chutes; the ejected cases and links pass through the bottom of the gun enclosure; the feed chutes pass through, rather than over, the inner ring and saddle supports and saddle assembly (Figure 2-51); the lower-turret gun chargers are designed for installation on the lower side of the guns. The ammunition boosters are similar to those on the upper turrets except for the assembly of the housing and the gear unit. Also, one of the boosters has a horizontal inlet and outlet. The only difference between the upper and the lower contour followers is in the contour pattern. In the retraction mechanism the gear housings are mounted forward of the turret. The lower-turret interrupters differ from the upper-turret interrupters in their cam patterns and in the position in which the interrupter is mounted on the inner ring.

Gun Enclosure Assembly. The lower-turret enclosure is identical to the upper-turret enclosure except that it has four removable panels besides the side-plate assembly. The side-plate assembly is fastened to the sides of the saddle and is not readily removable. To the side plates are fastened the lower panel assembly, top panel assembly, front panel assembly, and rear panel assembly. These four panels are fastened to each other and to the side plates by quick-action fasteners, which facilitate the servicing of the guns, the gun chargers, and the feed mechanism.

Detailed Description of Nose Turret

The nose turret is essentially the same as the upper turrets, except that is has no contour follower, fire interrupter, or retraction mechanism.

Differences Between Nose Turret and Upper Turrets. The gun enclosure is similar to that of the upper turrets except that it is sealed to the turret enclosure, which, is sealed to the airplane fairing. The inner and outer ring assembly is designed differently to accommodate the azimuth stops and limit switches. These stops and switches are mounted on the top of the ring assembly. The junction box is mounted vertically between the two guns. The gun chargers are designed for installation on the lower side of the gun to avoid interference with the airplane structure. The ejected links and cases fall through the bottom of the saddle into a trough located in the airplane fuselage. (Figure 2-52).

Dome Assembly. The dome assembly (turret enclosure) made of magnesium alloy, specification No. AN-M-29, is secured to the inner-ring flange by screws and is pivoted at the top through a centering plate and support assembly which is fastened to the airplane fuselage. There are five access doors in the nose dome. Two access doors, one located on the elevation and the other on the azimuth side of the turret, permit a limited amount of servicing of the turret. The two lower access doors, when removed, permit the installation of the nose turret on the airplane with the dome mounted. The front access door, when removed, makes it possible to mount the dome on the turret after the turret is installed in the airplane.

SECTION III—PEDESTAL SIGHTING STATION

1. INTRODUCTION

This section contains instructions on the Models 2CSR4B5 and 2CSR4B6 pedestal sighting stations used with the remote-control turret systems for the B-36 airplane. The system is designed and manufactured by General Electric Company. (See Figure 2-53.)

2. DESCRIPTION

General

The term "sighting station" refers to the complete unit which mounts the retiflector sight, together with the controls used by a gunner in tracking and ranging a target. (Figure 2-53). A sighting station also includes the equipment which indicates to the computer the direction, angular velocity, and range of the target. The lower-right aft and the lower-left aft sighting stations are of the pedestal type. Fixed transparent enclosures protect the gunners from the slipstream of the airplane while they scan the maximum sky area from their individual stations.

Lower-right Aft Sighting Station

This blister is equipped with a pedestal sighting station. In operating this station, the gunner grasps both handwheels and moves the sight manually in elevation and azimuth. To enlarge the gunner's field of vision, the sighting station is bolted to a plate which is attached to the airplane structure so that the sight protrudes well into the transparent blister. Elevation travel is limited to 60 degrees above and 90 degrees below horizontal. Azimuth movement is 210 degrees. Because the pedestal-type sighting station is the same for both the left and right blisters, this description will cover both. The approximate overall height of the sighting station is twenty inches and the approximate weight thirty-six pounds.

The major assemblies (Figure 2-54) are the azimuth assembly (4), the elevation assembly (2), the retiflector sight (1), and the gyroscope (5) and camera.

3. AZIMUTH UNIT ASSEMBLY

The azimuth assembly (Figure 2-55) forms the base for the pedestal sighting station. It transmits signal voltages, which indicate the exact position of the line in azimuth, through the computer to the azimuth Selsyn-control transformers on the turret. The basic assemblies are the Selsyn-generators—a 1-speed unit (11) and a 31-speed unit (2)—an azimuth gear train, the inertia wheel (5), and a cast

aluminum-alloy gear housing (4). Also located on the gear housing are the computer stand by switch (8), the azimuth stow pin (10), the azimuth limit stops, the reticle adjustment rheostat (6), and the azimuth friction screw (12).

Selsyn-generator Units. The Selsyn units (2 and 11) (Figure 2-55) are mounted on the gear housing (4). So far as mechanical construction and electrical operation are concerned, these Selsyn units are identical to those used on the yoke sighting station. The 31-speed Selsyn unit is mounted in the following manner: its flanged end-shield, on the shaft end, has an adapter attached to it which permits the Selsyn to fit snugly into a rabbeted recess in the top of the gear housing. Three clamps hold it securely in place. The clamps, which fit over the edge of the Selsyn's flanged end-shield, are held by three screws and lock washers which fit into tapped holes in the gear housing. An adapter is attached to the top of the 31-speed Selsyn which permits connection with the lead checker. The 1-speed Selsyn is attached to a mounting plate in the same manner. A cover is placed over the 1-speed Selsyn for protection. Four screws hold the mounting plate in place on top of the gear housing.

Gear Train. (Figure 2-56). An input spur gear (2) on the end of the yoke shaft meshes with an identical spur gear (6) attached to the rotor of the 1-speed Selsyn generator (7). As the yoke is rotated in azimuth, the rotor of the 1-speed Selsyn unit makes one full revolution for every full revolution of the yoke. The spur gear (6), on the rotor shaft on the 1-speed Selsyn, drives the gear train (5) for the 31-speed Selsyn generator (3). The gear ratio of the train is such that the rotor of the 31-speed Selsyn-generator would (if the limit stop in the sighting station permitted) make 31 complete revolutions for each 360-degree rotation of the yoke.

Inertia Wheel Assembly. The inertia wheel (4) (Figure 2-56) is driven by a pinion meshing with the intermediate gear on the gear train. The flywheel action of the wheel tends to smooth out the movement of the sighting station as it is moved in azimuth.

Gear Housing. The housing consists of an aluminum-alloy casting containing two ball bearings which support the elevation assembly. (Figure 2-55). The azimuth gear train, inside the housing, transmits the azimuth motion of the elevation yoke to the 1- and 31-speed Selsyns (2 and 11).

Computer Standby Switch

This luminous toggle-switch (8), (Figure 2-55) is mounted on the front of the azimuth Selsyn-gear housing. The switch allows the Selsyn signal from the sight to by-pass the computer and go directly to the Selsyn control-transformers on the turret. This switch can be used to make the system noncomputing, if the computer is damaged by gunfire.

Azimuth Friction Screw. This device (12), (Figure 2-55) which is utilized by the gunner in adjusting the sighting station for freedom of movement in azimuth, is located on the side of the azimuth housing. Tightening or loosening the screw increases or decreases the pressure on the rotating drive shaft.

Azimuth Stow-pin. The stow-pin (10), (Figure 2-55), used to stow the sighting station in any one of three positions in azimuth, is located between the two Selsyn units on the front of the bearing support for the yoke. A ball, spring, and limit-screw assembly hold the pin in its "out" or "in" position.

Azimuth Limit Stops. These stops, which limit rotation of the sighting station in azimuth, are located near the stow-pin assembly. Two metal clamps, one for either side of the stow-pin assembly, carry rubber snubbers which engage ears on the yoke and stop rotation of the sight when it has reached the limits of travel in azimuth.

Reticle Adjustment Rheostat

A black composition knob (6), (Figure 2-55), extending from the left-hand side of the gear housing, is used to turn the rheostat to increase or decrease the brightness of the reticle image.

made through a cable and connector at the base of the azimuth assembly. Power is brought into the rotor and taken off the stator of each Selsyn-generator through a cable extending from the sides of the azimuth housing to each Selsyn.

4. ELEVATION UNIT ASSEMBLY

(Figure 2-57). The function of this assembly is to mount the retiflector sight and to permit movement of the sight in elevation. The elevation Selsyn-generators (1 and 2) transmit signal voltages from the sighting station through the computer to the elevation control-transformers on the turret(s). These signal voltages indicate the exact position of the line of sight in elevation. The major parts of the elevation Selsyn-generator assembly are: two Selsyn generators (a 1-speed unit and a 31-speed unit); two handwheels, by means of which the gunner moves the sight in elevation; two gear trains for connecting the rotors of the Selsyns with the handwheels; an elevation support yoke (5) which carries the entire elevation Selsyn-generator assembly; a sight yoke (6) for supporting the retiflector sight and a range handle (10); an elevation friction screw (9); and lock (8).

16. FIRING TRIGGERS

Figure 2–59. Location of Switches and Adjustments on Pedestal Sight.

Selsyn-generator Units

The elevation Selsyn-generators are identical in construction to those used on the yoke sighting station. The 31-speed Selsyn (2), (Figure 2-57) is mounted on the rear of the left-hand gear box (3). The shaft end of the 31-speed Selsyn has an adapter attached to it which permits the Selsyn to fit into a rabbeted recess in the gear-box housing (3). It is held in place by three clamps. The 1-speed Selsyn is attached to the right-hand gear box (7) in the same manner.

31-speed Selsyn Gear Train

(Figure 2-58). This assembly is housed in the left-hand gear box and connects the left handwheel with the rotor of the 31-speed Selsyn generator (4). The left handwheel is mounted on the end of a hollow sight-yoke shaft (3) which is supported at either end by ball-bearing assemblies which, in turn, fit into opposite sides of the gear box. As the gunner turns the left handwheel, the sight yoke (9) is raised or lowered. Inside the gear box a large spur gear (2), attached to the hollow drive shaft of the yoke (3), engages a pinion (8) on an intermediate shaft-and-gear assembly (7). Also mounted on this intermediate shaft is a large bevel gear (6) which meshes with a small bevel gear (5) on a short shaft which drives the rotor of the 31-speed Selsyn. As the gunner elevates or depresses the sight, the gear train turns the rotor of the 31-speed Selsyn. The gear ratio of this train is such that the rotor of the 31-speed Selsyn-generator would, if the limit stops of the sighting station permitted, make 31 complete revolutions for each single revolution of the handwheel. Ball-bearing assemblies provide freedom of rotation for the gear shafts.

1-speed Selsyn Gear Train

(Figure 2-58). As in the case of the left handwheel, the right handwheel is also mounted on a hollow shaft (11) supported by a ball-bearing assembly which fits into a recess in the side wall of the right-hand gear box. The shaft extends through the side wall of the gear housing and is part of the sight yoke (9). The gunner can rotate this handwheel and elevate or depress the retiflector sight. Inside the gear box ,the hollow shaft (11) mounts a bevel gear (10) which meshes with an identical bevel (12) mounted on one end of a shaft (13) whose other end carries a simple coupling. The coupling connects with a rotor of the 1-speed Selsyn. Because both bevel gears are identical, one complete revolution of the handwheel will cause one complete revolution of the rotor of the 1-speed Selsyn.

Elevation Support Yoke

(Figure 2-57). This yoke (5) is hollow and Y-shaped. The base of the "Y," which is also a hollow shaft, fits into the extended bearing support on the azimuth assembly. The spur gear (4), keyed to its lower end, engages the gear train of the azimuth Selsyn-generator assembly so that when the yoke is rotated, the azimuth gear train is set in motion. On the left-hand side of the front of the yoke is a leveling pad for use in mounting a level during harmonizing.

Action Switch

(Figure 2-59). This disc-like switch (15) is mounted on the left handwheel. It is held in a normally-open position by a spring assembly. When the gunner closes it, by pressing it with the palm of his hand, the turret guns will swing into alignment with the line of sight providing that the control-box switches are properly positioned and the computer switched to "out." Wiring for the action switch is brought into the elevation assembly through a hollow yoke and reaches the action switch through the hollow drive shaft carrying the left handwheel. A slot in this drive shaft permits the entry of the wiring and prevents undue twisting of the wiring when the sight is rotated through 150 degrees in elevation.

Right Handle

This handle (5) (Figure 2-59) is similar in contour to the left handwheel. It is mounted on the right handwheel. The range handle is mounted on a grooved shaft which extends through the hollow sight-yoke shaft and connects with the gear train of the retiflector

THIS PAGE IS DECLASSIFIED IAW EO 13526

sight. It is held in place by a spring-actuated pin that engages a groove in the shaft.

Sight Yoke

(Figure 2-60). A U-shaped yoke with supporting shaft is used to mount the sight. This yoke pivots between the arms of the main yoke and is supported by the two drive shafts from the right and left handwheels. Two pins on the sight mounting surface assure proper alignment of the retiflector sight. The front of the yoke is drilled and tapped to support a front bracket which supports one end of the gyroscope unit. The mounting surface for the front bracket has two pins to assure proper alignment of the bracket and hence the gyroscope.

Elevation Friction Screw

This is a device which provides for adjustment of the drag desired in the movement of the sighting station in elevation. The friction screw (3) (Figure 2-59) is located on the front of the right-hand gear box. Tightening or loosening of the screw increases or decreases pressure on a metal shoe which has a felt liner that rides on the drive shaft of the sight yoke. A lock nut holds the screw in position after the friction adjustment is made.

Elevation Stow-pin

(Figure 2-59). The elevation stow-pin (6) is used to lock the elevation assembly when stowing the sight station. It is located at the rear of the right-hand gear box and consists of a pin mounted in a flange on the gear box. It slides into a hole on the rear of the sight yoke to lock the sight yoke in the horizontal position.

Note: The proper spring tension is set at the factory and should not be changed.

Firing Triggers

(Figure 2-59). The two nonfiring triggers (16) are mounted on the front of the right- and left-hand gear boxes in a convenient position for the gunner to press them with his thumbs. Pressure on either trigger will actuate a relay which closes the firing circuit to

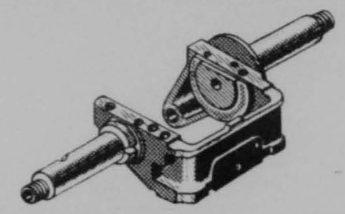

Figure 2—60. Sight Yoke.

the guns and, if the switch on the control box is in the "combat" position, the guns will immediately begin to fire.

Elevation Lock

The elevation lock (1) is located between the right elevation handwheel and the main yoke. Screws on the yoke lock are tightened to hold the sight in elevation during harmonizing.

Limit Stops

Mounted on the cover of the 31-speed gear housing are the stops which limit the travel of the sight in elevation.

Electrical Connections

The wiring for the Selsyns, retiflector sight, gyroscope, camera, and firing trigger is brought from the azimuth assembly into the elevation assembly through the hollow shaft and hollow arms of the elevation-support yoke.

Azimuth Scale

(Figure 2-59). The azimuth scale (9), located between the azimuth and elevation units, together with the indicator (8), indicates degrees of travel of the line of sight in a horizontal plane (azimuth). It is used for harmonization of the system, for checking computer operation and as a navigation drift scale. The scale is a semicircular piece, graduated clockwise from 0 degrees to 180 degrees in steps of 5 degrees and marked every 30 degrees. It is attached to two supports, one left and one right, which are bolted to the base of the azimuth unit and position the scale at a point level with the bottom of the great boxes on the elevation unit.

Indicator

(Figure 2-59). The indicator (8) is an index which, together with the azimuth scale, shows the degrees in azimuth of the line of sight. It is located to the bottom of the left and right gear boxes of the elevation unit. A pointer, located on the center of the indicator, overlaps onto the azimuth scale to indicate the degrees in azimuth.

Gyroscope

(Figure 2-61). The right blister sighting station has one free-gyroscope (9). It is mounted on the sighting station to furnish the computer with data onsight movement, both in elevation and azimuth, so the computer can calculate the correct predictions. For further information on computers, see AN 11-70AA-54. For information on the free-gyroscope, see AN 11-70AA-52.

Retiflector Sight

The retiflector sight (1) (Figure 2-54) is mounted on the sight yoke. It has a DC range output. The sight on the pedestal sighting station has the assembly containing the retiflector plate and the sky filters attached to the unit so that the line of sight is parallel to the long axis of the sight body. For further information refer to AN 11-70AA-42.

Camera (Gun Type, AN-N6)

This camera assembly (1), (Figure 2-59) with the exception of the camera adapter lens, is Government - furnished equipment U. S. Army Specification No. 75-366. It is mounted above the retiflector sight, and is used to make a permanent record of combat action.

Components

The camera is the 16mm type with a magazine containing fifty feet of film. The standard speed is sixteen frames per second although speeds of thirty-two and sixty-four frames per second are obtainable by setting the camera speed knob. Pictures are taken through the sight reflecting glass by means of a special periscope-type camera-adapter lens.

16. CAMERA

Figure 2—61. Gunner's Side of Pedestal Sight.

Operation

When the gunner presses his firing trigger the camera action starts. The camera records the target, reticle image, target size, and the range distance. An overrun control continues the picture-taking action, for a limited period, after the gunner has released the firing trigger.

Camera Adapters

(Figure 2-61). The sighting stations use camera adapters which enable cameras located adjacent to the retiflector sight to photograph the target as it appears on the sight reflector plate. The adapters, which are miniature periscopes, mount on the camera. On the yoke sighting station, the adapter extends

from the camera in a vertical plane to the retiflector sight. The adapter has an adjustable light opening which must be set for speeds and light conditions.

Detailed Description of Lower-left Aft Sighting Station

The lower-left aft sighting station is identical to the lower-right aft sighting station with the exception of the zero positioning of the azimuth with respect to the sighting station, the position of the nameplate on the main yoke which indicates the "forward" position, and the azimuth scale which is marked clockwise from 180 degrees to 360 degrees.

Detailed Description of Selsyns

A Selsyn is a small, self-synchronous instrument used as an electrical means of transmitting data concerning the relative angular positions between two or more remotely located devices. In the remote-control turret system, Selsyns are used to transmit the angular position of the sight and guns.

Selsyn Generator Model 2J15A1

The Selsyn generator is, mechanically, a miniature bipolar, rotating-field, three-phase alternator. The rotor is wound with a single-phase concentrated winding, and the stator with a three-phase, distributed "Y" connected winding.

Electrically the Selsyn acts as a transformer, and voltages and currents are single phase. The rotor is excited by an alternating voltage source, one phase of the aircraft's three-phase, 400-cycle power supply. By transformer action, voltages are induced into the three stator windings, the magnitude of the voltage in each depending upon the angular position of the rotor.

Mechanically the Selsyn generator consists of a stator carrying a three-coil winding, a rotor carrying a single winding which revolves inside the stator, an end shield forming part of the housing for the elements, and a connector for making electrical connections with the Selsyn.

The stator (3) (Figure 2-62) consists of three windings assembled within a slotted, laminated core which is fitted into the end shield (4). A lead from one end of each of the three windings extends to contacts (identified as "S_1", "S_2", and "S_3"), carried by the connector (8). The other ends of the three stator windings are connected internally in the Selsyn.

The rotor (6) of the Selsyn generator consists of a single coil wound on a laminated iron core. Opposite ends of the rotor are supported in ball bearings (5) carried by the two end shields. The ends of the rotor winding are brought out to spaced collector rings (7) mounted on the rotor shaft. Brushes (2), electrically connected to contacts on the connector, ride on the collector rings providing an electrical connection to the rotor. The contact pins connected to the brushes are identified as "R_1" and "R_2". (Figure 2-63.)

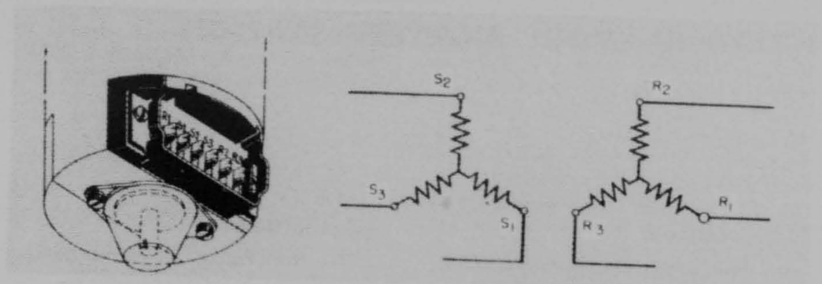

Figure 2–63. Connection Wiring Diagram for Selsyn-Generator, Model 2J15A1.

The rotor of the Selsyn generator is energized by 400-cycle alternating current from one phase of the aircraft's three-phase supply source. This produces a magnetic flux in the rotor winding which, in turn, and by transformer action, produces a voltage in each of the three windings of the stator. The rotor is geared to the sighting station so that as the sight is moved manually, the rotor is turned, varying the voltage induced into the stator coils.

5. OPERATION

Principles of Operation

General. A "sighting station," as the term is used in this handbook, refers to the actual sighting equipment, that is, the sight and accessory equipment used by a gunner in tracking a target and in operating remotely located gun turrets. Specifically, a sighting station comprises; a sight, a means of moving the sight in azimuth and elevation, a direction in which the sight is pointing, and a means of transmitting to the computing system variations in range and lead.

Pedestal Sighting Station

The pedestal sight is of the retiflector type and the gunner moves it manually in both azimuth and elevation. The Selsyn follow-up system provides the means of indicating the position of the sight to the turret. In operating the sight, the gunner grips both handwheels and moves the sight manually in elevation and in azimuth. To enlarge the gunner's field of vision, the sighting station is bolted to a plate which is, in turn, so attached to the airplane's structure that it allows the sighting station to protrude well out into the stationary, transparent blister.

The Selsyn System

The azimuth and elevation Selsyn generators located on the pedestal sighting station send a signal corresponding to the sight position to the Selsyn control transformers located on the turret. Located electrically between the Selsyn generators on the sighting station and the Selsyn control transformers on the turret are the computer differential Selsyns. When no computer correction is necessary, the position signal from the sight is transmitted unchanged electrically to the control transformer. Corrections result in the sight position signal that is being modified, by the addition of the required correction angle. This new position signal is then sent on to the control transformers and the guns then point in the direction indicated by the sightin station, plus or minus the correction angle determined by the computer.

SECTION IV—YOKE SIGHTING STATION

1. INTRODUCTION

This section covers the description and operation of the yoke sighting station, models 2CSR4D1 and 2CSR4D2, designed and manufactured by the General Electric Company for the B-36 Remote Control Turret System.

2. DESCRIPTION

Upper (Yoke) Sighting Station

The four upper gunners' positions are equipped with yoke-type (Figure 2-64) sighting stations models 2CSR4D1 and 2CSR4D2. The difference between the two models lies in the position of the switch cam on the yoke spur gear. The D2 models are mounted upper-left forward and aft. As a consequence, the switch cams are mounted on opposite sides of the yoke spur gear. These sighting stations consist of an azimuth unit on which the "Y" yoke (8) is mounted vertically so that it rotates freely in azimuth. The arm ends of the sight yoke (1), on which the gyroscope (4), camera (3), and retiflector sight (2) are mounted, are supported by bearings in the elevation unit on the arm ends of the "Y" yoke (8). This permits the sight yoke to rotate in elevation about a horizontal axis. The sighting station may be rotated in azimuth and elevation by hand grips attached to the "Y" yoke and connected by a link to the sight yoke. The action switch (Figure 2-64), trigger (Figure 2-65), interphone button (Figure 2-64), and range grip (12) are mounted on these handles. The sighting station may be rotated in elevation through an arc from 90 degrees above horizontal to 40 degrees below horizontal, and in azimuth from $117\frac{1}{2} \pm 5$ degrees forward to 101 ± 0 degrees aft of the broadside position.

Azimuth Unit

This unit (Figure 2-65) forms the base for the sighting station and transmits signal voltages to indicate the azimuth position of the sight. Its basic assemblies are the cast alloy gear housing (16), the azimuth gear train (Figure 2-66), the two Selsyn generators (15 and 17) (Figure 2-65) (1- and 31-speed), and the "Y" yoke (10).

Gear Housing. The gear housing (16) consists of an aluminum alloy casting which contains the azimuth gear train and bearings for supporting the hollow shaft forming the base of the "Y" yoke. Also located on the gear housing are the computer standby switch (11) (Figure 2-64), reticle adjustment rheostat (10), azimuth friction screw (14) (Figure 2-65), position-out switch (1) (Figure 2-67), and inertia wheel assembly (3).

Azimuth Gear Train

A spur gear (22), keyed to the end of the "Y" yoke shaft engages in identical spur gear (24) attached to the end of the 1-speed Selsyn generator rotor shaft. As the "Y" yoke (12) is rotated in azimuth, the 1-speed Selsyn (15) rotor makes one revolution for every revolution of the yoke. The spur gear (24) on the rotor shaft of the 1-speed Selsyn engages a pinion gear (16) on a shaft supported between bearings in the gear housing. Keyed to the opposite end of this shaft is a large spur gear (19) which engages a pinion gear (17) attached to the rotor shaft of the 31-speed Selsyn generator (15). The gear ratio of this gear train is such that the rotor of the 31-speed Selsyn makes 31 revolutions for each revolution of the "Y" yoke. (Figure 2-66.)

Inertia Wheel Assembly

The inertia wheel (20) is driven by a pinion gear (18) meshing with the same large intermediate spur gear (19) that drives the gear

on the 31-speed Selsyn rotor. The flywheel effect tends to smooth out the rate of motion of the sighting station as it is moved in azimuth.

Position-out Switch

This switch (23) (Figure 2-66) is located in the gear housing under the spur gear (22) on the end of the "Y" yoke shaft. It is operated by a cam (21), on the underside of the spur gear, when the sighting station is more than 100 degrees aft of the broadside position and cuts off control power to the turret. The D1 model switch cam is located on the opposite side of the spur gear from the D2 model. Thus, if the action switch is closed when the sighting station is in a position to cause the posi-

tion-out switch to be operated, the turret will not be brought under control of the sighting station and will not attempt to synchronize with the sighting station. The purpose is as follows: when the action switch is open, the turret automatically moves to its stowed position. If the action switch is closed when the position-out switch is not in its operated position, the turret will synchronize with the sighting station position. An inherent feature of the control system is that the turret will attempt to move through the shortest arc to align with the sighting station. If there were no position-out switch and the turret were more than 100 degrees aft of broadside when the action switch was closed, the turret would attempt to synchronize by moving forward until hitting the forward stops and would remain there until the sighting station were moved to a position less than 80 degrees aft of broadside. Under the above conditions, the position-out switch insures that the turret will remain in the stowed position until the sighting station is less than 100 degrees aft of broadside, instead of only 80 degrees, and

then will move into correspondence with the sighting station.

Selsyn Generators

These units (Figure 2-65) are mounted vertically on the gear housing (16) opposite the "Y" yoke shaft (10) from the gunner. A flange on the shaft end of each Selsyn fits snugly into a recess in the gear housing. Three clamps held by lock washers and screws, which fit into tapped holes in the gear housing, fit over the edge of the flange on each Selsyn. These clamps may be loosened to permit zeroing the Selsyns.

Computer Standby Switch

This toggle switch (11) (Figure 2-64) is mounted on the front of the azimuth unit gear housing. The switch allows the Selsyn signal from the sighting station to by-pass the computer and go directly to the control-transformers on the turret. Thus it can make the system noncomputing, if the computer is damaged by gunfire.

Azimuth Friction Screw

This assembly (14) (Figure 2-65), located on the neck of the gear housing opposite the gunner, adjusts the ease with which the sight may be rotated in azimuth. Tightening or loosening the screw increases or decreases the friction on the rotating shaft of the "Y" yoke.

Azimuth Stow-pin

The azimuth stow-pin assembly (9) (Figure 2-64), located in front of the gunner between the azimuth limit stops on the base of the "Y" yoke, fits into a recess in the neck of the azimuth unit gear housing. It stows the sight broadside in azimuth. A ball, spring, and limit screw assembly hold the pin in its "out" or "in" position.

Azimuth Limit Stops

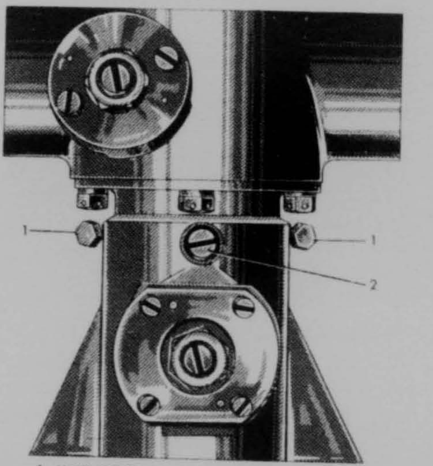
Two limit stops (1) (Figure 2-68), which consists of two adjustable screws with lock nuts, are installed in the stow pin bracket which is attached to the gunner's side of the "Y" yoke. The stops strike against a bumper (2), attached to the azimuth gear housing, when the azimuth travel limit is reached. To limit the azimuth travel of each sighting station more in the aft quadrant of operation than in the forward quadrant, a longer limit stop is provided in the forward side of the stow pin bracket. Minor adjustments of the travel limits are made by loosening the lock nut and turning the stop screws in or out, as required.

Electrical Connections

Electrical connections for incoming power and outgoing signals are made through a connector and cable entering the base of the azimuth unit on the left side. Power is brought into the rotor and taken off the stator of each azimuth Selsyn through cables extending from the sides of the gear housing to each Selsyn cap. Conections to those units mounted on the "Y" yoke and the sight yoke are made through the hollow shaft and arms of the "Y" yoke to connectors on the ends of the arms.

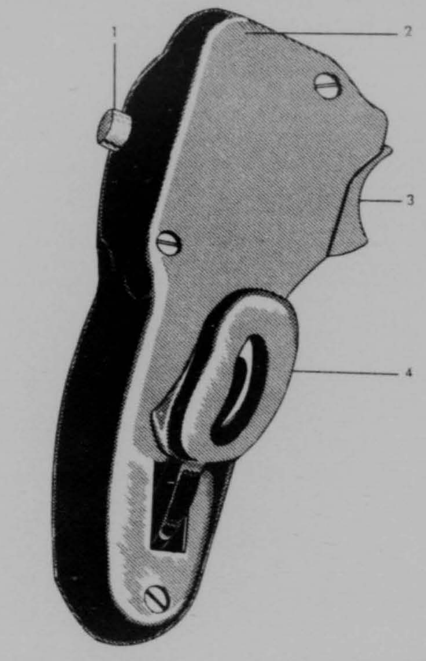
"Y" Yoke

This unit is a Y-shaped hollow, aluminum alloy casting (10) (Figure 2-65) which is supported by a hollow shaft mounted in bearings



1. LIMIT STOPS 2. BUMPER

Figure 2—68. Closeup View of Azimuth Bumpers and Stops.



1. INTERPHONE SWITCH
2. FIRING GRIP
3. FIRING TRIGGER
4. ACTION SWITCH

Figure 2–69. Closeup View of Firing Grip.

located in the neck of the azimuth gear housing (16). Mounted on the "Y" yoke are the firing grip (2), range grip (13), elevation 1-speed unit (5), elevation 31-speed unit (11), gyro-and-camera junction box (5) (Figure 2-64), elevation limit stops and stow pins (9) (Figure 2-64) and (1) (Figure 2-65).

Firing Grip

The right-hand grip (2) (Figure 2-69) is the firing grip and contains an action switch (4), the firing trigger (3), and an interphone switch (1). The action switch (4), which applies power to the turret, is held closed against a spring as the gunner depresses the switch lever with the side of his hand. The gunner's hand fits between the grip and the lever—not over the lever. The trigger (3), located at the top of the grip, is operated by the first, or index finger. The interphone switch (1) is a push button which is operated by the thumb.

Range Grip

The left-hand grip (25) (Figure 2-66) is the range-adjusting grip. Gearing connects the grip to a sheave cable (27) which, through additional gearing on the sight yoke (11), is connected to a flexible shaft (4). The flexible shaft, is, in turn, connected by gearing to the retiflector sight (6).

One-speed Elevation Unit

The 1-speed elevation unit (5) (Figure 2-65) is located on the end of the right-hand arm of the "Y" yoke. It contains the gearing connecting the sight yoke with the 1-speed elevation Selsyn generator, and a bearing supporting the end of one arm of the sight yoke. A bevel gear, pinned to the end of a shaft attached to the sight yoke (11) (Figure 2-66) and supported by a bearing in the 1-speed elevation unit, engages an intermediate spur gear. On the shaft with the spur gear is a bevel gear which engages a bevel gear pinned to a shaft which, in turn, is connected by an adjustable coupling (1) to the 31-speed elevation Selsyn generator rotor shaft. The gear ratio of this train is such that the rotor of the 31-speed Selsyn generator would, if the limit stops of the sighting station permitted, make 31 complete revolutions for each revolution of the hand grips.

Gyro and Junction Box

This assembly (5) (Figure 2-64) is mounted by a connector on the end of the right arm of the "Y" yoke (8). It serves as a central distributing and collecting point for the gyroscope and camera circuits. A camera "on-off" switch is mounted in the box.

Elevation Limit Stops

The elevation-stop bumpers located on the shaft of the firing grip, move with the grip as it is turned in elevation and bear against the stop assembly, located on the "Y" yoke, to limit the elevation motion of the sight. Minor

adjustments in elevation travel can be made by loosening the lock nuts and turning the stop screws in the face of the stop in or out.

Elevation Stow-pin

The elevation stow-pin (1) (Figure 2-65) located near the stop bumpers, fits into a machined recess in the "Y" yoke. It stows the sight in a horizontal position. A ball, spring, and limit screw assembly, hold the pin in its "out" or "in" position.

Elevation Clamp

This assembly, located on the 1-speed elevation unit, adjusts the ease with which the sighting station may be rotated in elevation. Tightening or loosening the screw increases or decreases the friction on the shaft of the right-hand arm of the sight yoke. The clamp can be used to lock the sight yoke in any elevation position during maintenance of the sighting station.

Sight Yoke

In order to minimize the amount of movement required by the gunner in tracking a target in elevation, that retiflector sight (2) (Figure 2-64) is mounted on the closed end of the sight yoke (1) which is, in turn, supported, at its open ends, between the elevation units on the open ends of the "Y" yoke (8). Shafts, pinned to the sight yoke, are mounted in bearings in the elevation units which permit the gunner to pivot the sight yoke, and thus the sighting station, in elevation. A camera (3) and gyroscope (4) are mounted on the right arm of the sight yoke. Model 2CSR4D1, serial No. 4291836 through 4291837, and 4314760 through 434785, inclusive, and model 2CSR4D2, serial No. 4291834 through 4291835, and 4414538 through 4414563, inclusive, are each equipped with a counterweight (33) (Figure 2-70) which is attached to the end of the left arm of the yoke. This counterweight, together with a counterspring which is attached to the sheave-and-gear assembly (14) (Figure 2-70) and which is supported by a bracket mounted on the "Y" yoke, counterbalances the weight load of the yoke and its attached equipment. All other yoke sights are not equipped with a counterweight; instead, a stronger counterspring is provided to counterbalance the weight load of the yoke and its attached equipment. The yoke is connected by a mechanical link (28) (Figure 2-66) to the right-hand grip which moves the sighting station in elevation as the hand grips are turned in elevation.

Gyroscope

Each upper sighting station has one free gyroscope (4). It is mounted on the sighting station to furnish the computers with sight movement in azimuth and elevation. (Figure 2-64)

Retiflector Sight

The retiflector sight (2), mounted on the closed end of the sight yoke, uses a DC range signal.

Camera

The camera assembly (3), with the exception of the camera adapter lens, is government furnished equipment, U. S. Army Specification No. 75-366. It is mounted on the sight yoke adjacent to the retiflector sight and is used to make a permanent record of combat action.

Camera Components

The camera is the 16-mm type with a magazine containing fifty feet of film. The standard speed is sixteen frames per second although speeds of thirty-two and sixty-four frames per second are obtainable by setting the camera speed knob. Pictures are taken through the sight reflecting glass by means of a special periscope-type camera adapter lens.

Camera Operation

When the gunner presses his firing trigger the camera action starts. The camera records the target, reticle image, retiflector target size, and the range distance. An overrun control continues the picture action, for a limited period, after the gunner has released his firing trigger.

THIS PAGE IS DECLASSIFIED IAW EO 13526

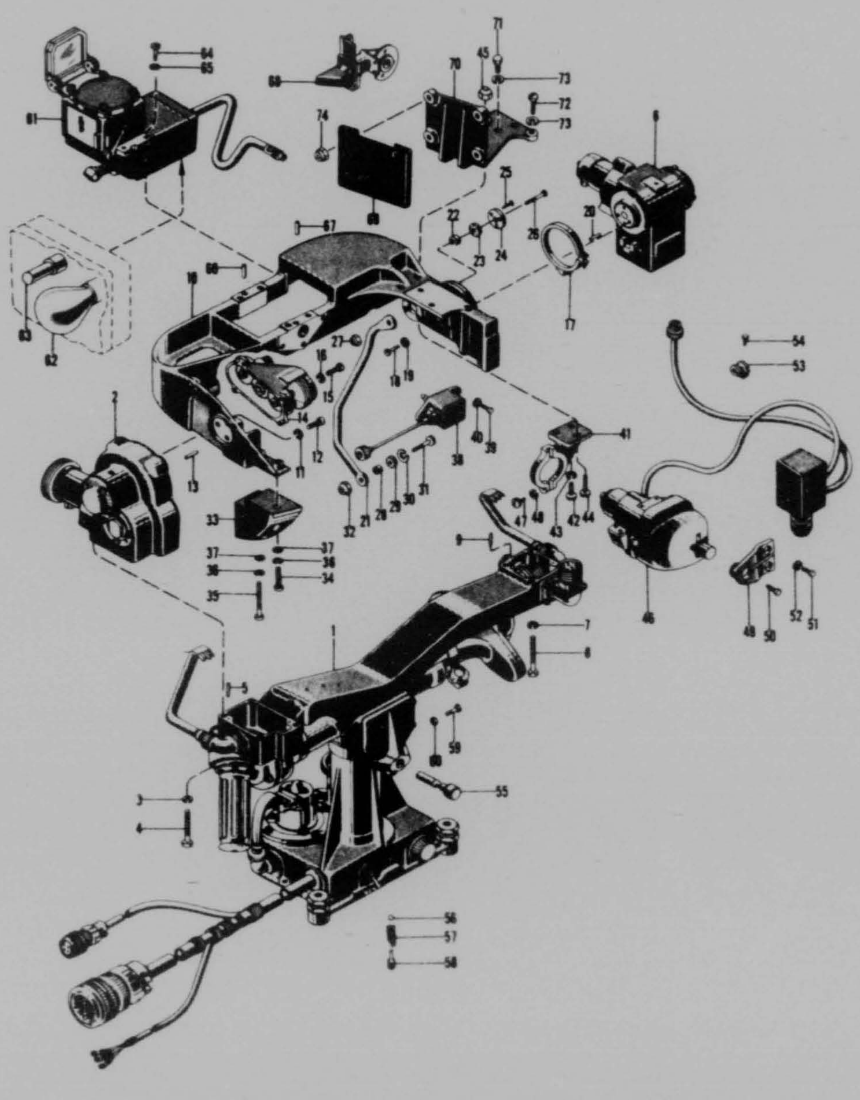


Figure 2—70. Exploded View of Yoke Sighting Station, Models 2CSR4D1 and 2CSR4D2.

Camera Adapters

The sighting stations use camera adapters which enable cameras located adjacent to the retiflector sight to photograph the target as it appears on the sight retiflector plate. The adapters, which are miniature periscopes, mount on the camera. On the yoke sighting station, the adapter extends from the camera in a vertical plane to the retiflector sight. The adapter has an adjustable light opening which must be set for speeds and for light conditions.

3. DETAILED DESCRIPTION OF SELSYNS

A Selsyn is a small self-synchronous instrument used as an electrical means of transmitting data concerning the relative angular positions between two or more remotely located devices. In the remote-control turret system, Selsyns are used to transmit the angular position of the sight and guns.

Selsyn Generator Model 2J15A1

The Selsyn generator is mechanically a miniature bipolar, rotating field, three-phase alternator. The rotor is wound with a single-phase, concentrated winding; the stator with a three-phase, distributed "Y"-connected winding.

Electrically the Selsyn acts as a transformer, and voltages and currents are single phase. The rotor is excited by an alternating voltage source, one phase of the aircraft's three-phase, 400-cycle supply. By transformer action, voltages are induced into the three stator windings, the magnitude of the voltage in each depending upon the angular position of the rotor.

Mechanically the Selsyn generator consists of a stator carrying a three-coil winding, a rotor carrying a single winding which revolves inside the stator, an end shield forming part of the housing for the elements, and a connector for making electrical connections with the Selsyn (Figure 2-64).

The stator (3) (Figure 2-71) consists of three windings assembled within a slotted, laminated core which is fitted into the end

shield (1). A lead from one end of each of the three windings extends to contacts (identified as "S_1", "S_2", and "S_3"), carried by the connector (8). The other ends of the three stator windings are connected internally in the Selsyn.

The rotor (6) of the Selsyn generator consists of a single coil wound on a laminated iron core. Opposite end of the rotor are supported in ball bearings (5) carried by the two end shields. The ends of the rotor winding are brought out to spaced collector rings (7) mounted on the rotor shaft. Brushes (2), electrically connected to contacts on the connector, ride on the collector rings providing an electrical connection to the rotor. The contact pins connected to the brushes are identified as "R_1" and "R_2".

THIS PAGE IS DECLASSIFIED IAW EO 13526

The rotor of the Selsyn generator is energized by 400-cycle AC from one phase of the aircraft's three-phase supply source. This produces a magnetic flux in the rotor winding which, in turn, and by transformer action, produces a voltage in each of the three windings of the stator. The rotor is geared to the sighting station so that as the sight is moved manually, the rotor likewise moves, varying the voltage induced into the stator coils.

4. PRINCIPLES OF OPERATION

The Yoke Sighting Station

The yoke sighting station is of the retiflector type and the gunner moves it manually in both azimuth and elevation. The Selsyn follow-up system provides the means of indicating the position of the sight to the turret. In operating the sighting station, the gunner grips both the range grip and the firing grip and moves the sighting station manually in elevation and in azimuth. To enlarge the gunner's field of vision, the sighting station is bolted to a plate which is, in turn, so attached to the airplane's structure that it allows the sighting station to protrude into the stationary, transparent blister.

The Selsyn System

The azimuth and elevation Selsyn generators located on the yoke sighting station send a signal corresponding to the sight position to the Selsyn control transformers located on the turret. Located electrically between the Selsyn generators on the sighting station and the Selsyn control transformers on the turret are the computer differential Selsyns. When no computer correction is necessary, the position signal from the sight is transmitted electrically to the control transformer unchanged. Corrections result in the sight position signal being modified by the addition of the correct correction angle. This new position signal is then sent on to the control transformers. The guns then point in the direction indicated by the sighting station plus or minus the correction angle determined by the computer.

The Free Gyro System

The gyro is used to indicate to each computer the angle traversed by the target during the prediction computing time interval. Specifically, the gyro is used in the computing circuit to predict the lead correction necessary for advancing the guns ahead of the target by an amount proportional to the range and relative speeds of the ownship and target. The gyro does this by very accurately measuring the angle traversed by the target during the prediction computing time interval. The free gyroscope is so named because it is free to move in any direction within approximately 15 degrees of the gyroscope axis. The motor shaft axis of the gyro is parallel to the line of sight. The caging mechanism end points toward the target. As the sight moves, the entire gyro moves with it so that the motor shaft always points along the line of sight. When the firing trigger on the sighting station is pressed, a solenoid in the gyro is energized and the caking cone is drawn away from the gyro motor frame. The housing will continue to move with the sighting station, but the motor shaft will stay pointing in the same direction it did at the instant it was uncaged.

The Retiflector Sight

The retiflector sight is a direct-vision type optical sight which is so constructed that when the gunner properly adjusts the circle of light to span his target, the sight through its accessory equipment transmits an indication of range, and because of its rigid mounting to the sighting station, indirectly transmits azimuth and elevation to the computer.

Camera and Camera Adapter

The camera is mounted adjacent to the retiflector sight and is used to make a permanent record of combat action. When the firing trigger on the sighting station is pressed, the camera action starts. The camera records the target, the reticle image, retiflector target size, and records the size of the reticle image so as to give an approximation of the range distance. An overrun control continues the picture action for a limited period after the gunner has released his firing trigger. In order to enable the camera, which is adjacent to the retiflector sight, to photograph the target as it appears on the sight retiflector plate, the

sighting station makes use of a camera adapter. The adapter is a miniature periscope and is mounted on the camera.

Installation of Elevation Selsyns

Installation of the elevation Selsyns is as follows: The coupling hub is installed on the shaft of the Selsyn-and-adapter assembly and secured with the lock nut. The tooth is positioned on the Selsyn coupling hub so that it will fit into the slot of the Selsyn nut and seat the Selsyn in the elevation unit housing.

The three Selsyn clamps, lock washers and screws are replaced.

The clamps are adjusted to engage the flange of the Selsyn casing and the clamps are tightened in position.

Installation of Retiflector Sight

The three Selsyn clamps, lock washers and (The sight or gyroscope should not be installed until the backlash tests and adjustments have been made. The sight should be tested in accordance with the instructions set forth in the instruction book AN 11-70AA-42 before installation.)

The sight assembly is mounted on the sight yoke. The sight is aligned on the yoke by two dowel pins and fastened to the yoke with the four screws and lock washers.

The electrical connector is attached to the rear receptacle on the 1-speed yoke arm.

Installation of Bevel Gear Support and Shaft

The bevel gear support and shaft are installed as follows:

The bevel gear support-and-shaft are mounted on the sight yoke and secured with four screws and lock washers.

The range grip is rotated until the cable clamps on the lower sheave are above the sheave shaft and in an approximately horizontal position. The nut is threaded and fastened on the end of the flexible cable to the hub inclosing the splined shaft of the sheave-and-gear assembly. Fastening the flexible cable to the splined shaft with the cable clamps in this position insures the widest possible range swing of the retiflector sight. Minor adjustments can be made after the retiflector sight is installed and the sighting station operated.

Installation of the Gyro

The gyro is installed on the sight yoke as follows:

The rear gyro bracket is fastened to the underside of the sight yoke with two screws and lock washers and the longer screw and nut, which also aids in securing the camera bracket.

The gyro is slipped into its rear bracket. Supporting the gyro with one hand the front bracket is fitted to the sight yoke with the two screws and lock washers.

The three screws which secure the front bracket to the gyro, and the clamping screw on the rear gyro bracket, are tightened.

The gyro junction box to the forward receptacle on the yoke arm.

Installation of Camera and Camera Adapter

The camera and camera adapter are installed as follows:

The camera mounting bracket is replaced on the top of the sight yoke and fastened with the screws and lock washers. The nut is threaded and tightened on the screw to fasten both the gyro bracket and the camera mounting bracket.

The camera and the camera guard are assembled to the side of the camera mounting bracket and the camera secured to the guard and bracket with four nuts.

The camera adapter lens assembly, if it has been removed, is replaced.

SECTION V—TAIL TURRET

1. GENERAL

The tail turret, model 2CGD20TRB1, is approximately spherical when the enclosure is mounted on it. Its diameter at mid-section is 40 inches and its overall height is 40⅞ inches. It travels 45 degrees each side of straight aft in azimuth and the two 20-mm guns travel 40 degrees above or below centerline. The guns move in elevation independently of movement in azimuth.

Basic assemblies comprising the tail turret are described in detail in the following paragraphs.

Gimbal Assembly

is the main framework of the tail turret on which all other parts of the turret proper are mounted. It rotates in azimuth on upper (1) and lower trunnions (12), located at the top and bottom of the gimbal. The azimuth stop (5) and azimuth limit switches (6), mounted on the gimbal, limit travel in azimuth of the turret. The elevation stop assemblies (7) and limit switches (4) (Figure 2-73), also mounted to the gimbal, limit travel in elevation of the saddle (10) (Figure 2-72) and the guns. The terminal board (4) and connector assembly (2) are also mounted on the gimbal assembly.

Plate and Sector Assembly

(6) (Figure 2-74) aided by two antirotation brackets (4 and 9). The azimuth drive unit (8) engages the gear sector (7), bolted to the plate (5), to drive the turret in azimuth. Azimuth stops and stop arms (3) (Figure 2-72) are fastened to the plate.

Saddle Assembly

The saddle assembly, supported on the gimbal by two steel shafts (5) (Figure 2-73), is a magnesium casting on which the two 20-mm guns are mounted by front and rear gun supports. The two front gun supports (6), bolted to the saddle, can be adjusted to move the guns horizontally. The two rear gun-slider mounts (9) (Figure 2-72), fastened to brackets which are bolted to the saddle, provide vertical adjustment of the guns. This adjusts the alignment of the gun bore. The elevation gear sector (8) (Figure 2-73) bolted to the side of the saddle is engaged by the elevation drive pinion to move the saddle and guns in elevation.

Azimuth and Elevation Drive Assemblies

The drive assemblies for movement of the tail turret in azimuth and in elevation are identical. For simplicity the following description will be of the azimuth-drive assembly as used for positioning the turret in azimuth.

Function. The azimuth drive (Figure 2-75) performs two functions. It supplies the mechanical power required to drive the turret and guns in azimuth and it provides electrical equipment which assists in controlling the position of the turret and guns in azimuth. The three main units of the azimuth assembly are the drive motor (1), the gear assembly (3), and the Selsyns (4).

12. SELSYN CONTROL TRANSFORMERS

Figure 2–76. Schematic of the Azimuth and Elevation Drives.

Drive Motor. The drive motor rated at ½ horsepower, is a separately-excited motor which rotates either clockwise or counter-clockwise according to the signal from the thyratron power supply. The input voltage from the thyratron power supply controls the motor speed. A solenoid-operated brake, located at the base of the motor, prevents rotation of the drive-motor armature when the motor is not energized. When the motor armature is locked by the brake, the turret cannot rotate in azimuth. The brake is applied automatically when the AN APG-3 radar antenna moves beyond the azimuth limit of the guns. This de-energizes the solenoid, thus engaging the brake and holding the turret against the limit stop. When the radar antenna is again moved back within the limits of gun travel, the brake is automatically released. The brake can be released manually by two spring-loaded levers (2), one located on each side of the motor.

Gear Assembly. (Figure 2-76.) Power is transmitted from the drive motor (1) through a power gear train to the azimuth gear sector as follows: The motor pinion (2) meshes with the large gear (3) of the clutch assembly (4).

A bevel pinion gear (5) on the clutch shaft meshes with a large bevel gear (6) which also serves as the drive gear of a planetary gear system.

The small spur gear (8), attached to the driven portion of the planetary gear system, is meshed with a large gear (10) on the main-drive-gear shaft. The main drive gear (9) meshes with the azimuth sector gear, driving the turret either clockwise or counterclockwise. The gears (11) connect the Selsyns (12) to the main drive shaft. The clutch assembly (4) protects the gear train from excessive shocks when the guns reach their maximum azimuth limits.

Selsyns. The Selsyn used on the drive assembly is the tandem model and is geared to the main-drive shaft. The tandem Selsyn embodies both the 1-speed and the 31-speed units in one case. The shaft of the 31-speed rotor extends outside the case and is geared to the main-drive shaft (Figure 2-76). As the name implies, the 31-speed unit would revolve 31 times if the turret were to make one complete revolution. An internal planetary gear system, located between the 31-speed and the 1-speed units, reduces the speed of the 1-speed rotor so that it would make one revolution if the turret were to revolve 360 degrees.

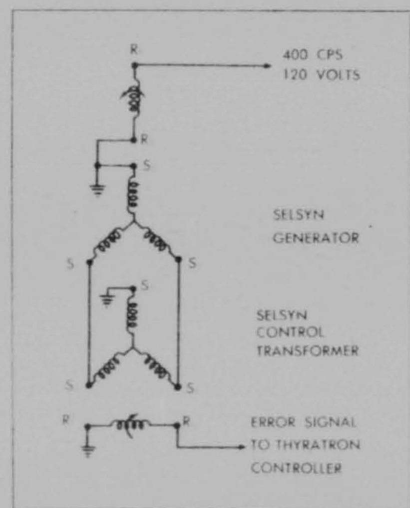

Figure 2–77. Elementary Wiring Diagram of the Selsyn Circuit.

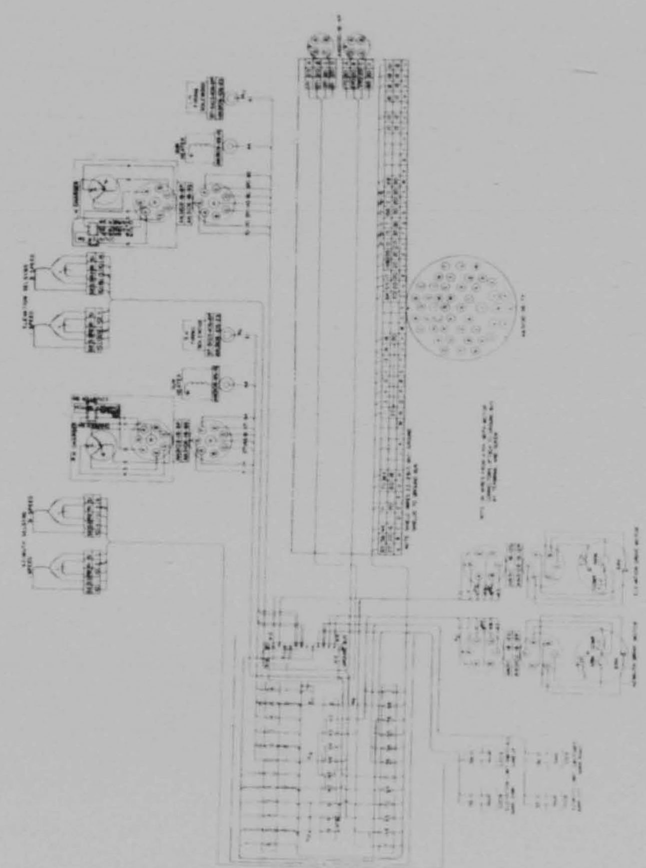

Figure 2–78. Wiring Diagram of the Tail Turret.

Each Selsyn control transformer consists of the following basic elements: a stator, a rotor, an end shield, and a connector. The voltage on the rotor of the Selsyn control transformer is rated at 120 volts. Electrical connections to the Selsyn control transformer are made through connector contacts identified by R1, R2, S1, S2, and S3. The three stator windings of the control transformer are electrically connected through system wiring to the stator windings in the Selsyn generator so that the voltages appearing in the windings of the Selsyn generator are reproduced in magnitude and polarity in the stator windings of the control transformer (Figure 2-77). The resulting magnetic flux in the control-transformer stator induces a voltage in the rotor by transformer action which is the signal voltage fed to the thyratron controller. This signal indicates the difference between the line of sight of the radar and the line of sight of the guns.

2. PRINCIPLES OF OPERATION

Electrically, the turret is made up of three major systems: the Selsyn system, the limit-switch, and drive-motor system, and the firing system. Each of these systems will be dealt with briefly (Figure 2-78).

The control transformers are connected directly to the Selsyn generators in the AN/APG-3 radar antenna unit. As long as the radar antenna is scanning, the Selsyns are inoperative. The Selsyn system is in operation, however, when the radar is tracking a target airplane. (Reference may be made to the handbook of operating instructions for the radar antenna unit for further information concerning the fire-control tie-in between the tail turret and the radar antenna unit.) Input voltage to the turret Selsyns is called the signal voltage from the radar antenna Selsyns. Output voltage from the turret Selsyns is called the error signal. The error signal is proportional to the difference in direction in which the radar antenna and the turret are pointing. The error signal from the turret Selsyns is fed to the thyratron controller where it is amplified and then returned as a DC voltage to the armature of the azimuth drive motor. The turret is then driven by the azimuth drive motor in such a direction as to realign the turret azimuth Selsyn rotor with the stator so that the error signal across the rotor is reduced to zero voltage.

The Limit-switch and Drive-motor System

The azimuth and elevation limit switches are protective devices which cut off DC power to the drive-motor circuits when the turret has reached the limits of movement in azimuth and in elevation. The 27-volt bus in the thyratron controller is connected to the turret safety switch in the junction box. From this switch the line is connected to circuit breaker CB-5 in the control panel. The circuit breaker in turn is connected to line 143 which is divided into two voltage paths. Line 143 is connected to the fields of both the elevation and the azimuth drive motors to ground. Line 143 is connected also to the turret limit relays in the thyratron controller, and through these relays emerges as lines 55, 56, 155, and 156 to the azimuth and elevation limit stops to ground. If, for instance, the turret reaches its elevation limit in one direction, one of the elevation limit switches opens. If it is switch S209 which opens, relay K108 in the thyratron controller becomes de-energized. Immediately, the brake coil in the elevation motor is de-energized, and the brake is momentarily applied. The backout relay K213 in the thyratron controller is de-energized and 27 volts is again applied to the brake coil in the motor, energizing the coil and releasing the brake. The motor is, therefore, prepared to rotate in the opposite direction should voltage from the thyratron controller of the proper polarity and value be supplied to the armature across lines 17 and 18. The azimuth drive circuit is identical to the elevation drive circuit and operates according to the same principles.

The Firing System

The gun heaters are supplied with 115 volts, 400 cycles through line 44 when the uni-switch on the control panel is in the warm-up position. The firing solenoids are energized by 27 volts DC through line 61. The gun-charger and booster motors are connected in parallel. These motors are energized when relays K26

and K27 in the junction box are energized. Lines 170, 270, 370, and lines 171, 271, and 371 supply 208 volts, 400 cycles to the chargers and the booster motors. Lines 80 and 81 are the thermal overload lines to ground on the charger motors.

SECTION VI—B-36 HEMISPHERE GUN SIGHT

1. INTRODUCTION

These preliminary engineering instructions contain technical information on the General Electric Model 2CSH4A2 hemisphere sighting station manufactured by the Farrand Optical Co., Inc. The sight is used with the General Electric Remote Control Turret System in both the YB-36 and B-36 airplanes.

The hemisphere sighting station enables the gunner to control the nose turret. Component parts of the system are (1) the hemisphere sight (2) the desiccator unit.

Function

The hemisphere sight is the controlling unit of a system that aims and fires the nose turret guns of the airplane in which it is mounted. The sight is operated by a gunner stationed beneath the turret. As the gunner moves the sight the turret guns are automatically positioned in aim to agree with the line of sight the gunner has selected through the eyepiece. This relation is accomplished by Selsyn circuits, which are regulated by the movement of the sight mechanism and control the aiming operations of the guns.

Description

The hemisphere sight is a stationary periscope, mounted horizontally in the nose of the airplane so that its spherical glass dome head projects through the nose structure. The sight is shock-mounted in its supports. At the head end the sight is supported in a cylindrical nose fitting, at the eyepiece end by means of vertical and lateral support rods. Rotation of the hand-control-grips serves to position the scanning prisms located in the prism head. The target is followed in azimuth by rotating the control grips about its horizontal axis. The guns are fired by actuating an action and trigger switch mounted on the left control grip. The ranging mechanism is controlled by a squeeze-grip lever located on the right control grip. A desiccator pump unit is mounted

Characteristics

The hemisphere sighting station has the following characteristics:

Dimensions:	Length: 48 inches Maximum Height: 22 inches Maximum Width: 23 inches
Weight:	150 lbs.
Sighting Limits:	Right Azimuth: 90 degrees Left Azimuth: 90 degrees Elevation: 90 degrees Depression: 90 degrees
Line of Sight-Stow Position:	Azimuth: 0 degrees Elevation: 0 degrees (+) 30 degrees
Ranging Limits:	250 yards to 1500 yards
Ranging Velocities:	30 feet per second to 1500 feet per second
Minimum Ranging Acceleration:	3000 feet per second
Wing Span Setting Limits:	15 feet to 100 feet
Required Voltages:	Sight & Selsyn power 115 v. 400 cycles Desiccator motor 208 v. 400 cycles Computer Potentiometer 27.5 v. DC (Filtered) Computer In-Out Lamp 27.5 v. DC
Telescope Field:	75 degrees
Magnification:	Unity
Desiccator Pump Capacity:	475 cubic feet per minute

separately on airplane adjacent to the sight. It dries and circulates the air from the dome and sight chambers. Static desiccators dehumidify the sealed optical compartments of the sight.

2. THEORY OF OPERATION

The Hemisphere (Nose) Sighting Station

The hemisphere sighting station is a stationary sighting instrument used by the nose gunner to track a target and to remotely-control the nose-gun turret. The sight optical system directs light rays from any chosen point in a hemispheric field into the eye of the operator. A Selsyn system, composed of azimuth and elevation Selsyns, transmits azimuth and elevation sight position information to the computer and to the gun turret. A gyro is used for lead prediction. A ranging device determines range, converts it to a voltage signal and transmits it to the system computer to aid in the calculation of gun correction angles.

The Optical System

The main optical system of the hemisphere sight images a target in the focal plane of the eyepiece. Auxiliary optical systems superimpose on the target image additional images such as a reticle, a range scale, a target size scale, a ranging ring and a computer "in-out" signal light. An auxiliary camera system deviates a portion of the light ray from the combined optical systems and directs them to the camera lens for recording purposes. A luminous ring, the diameter of which may be varied by the operator, is provided in the sight field for ranging purposes.

The Selsyn System

The azimuth and elevation Selsyn generators, located on the hemisphere sighting station, send signals corresponding to the sight position to the Selsyn differential generators, located in the computer. The sight position signal is modified at the computer by the addition of corrections, when necessary, and the resultant signal is sent to the control transformers in the gun turret.

The Free Gyro System

The gyro is used to indicate to the computer the angle traversed by the target during the prediction-computing time interval. Specifically, the gyro is used in the computing circuit to predict the lead correction necessary for advancing the guns ahead of the target. The gyro does this by very accurately measuring the angle traversed by the target during the prediction-computing time interval. The free gyroscope is so named because it is free to move in any direction within approximately 15 degrees of the gyroscope axis. Movement of the control grips positions the gyro unit so that the motor shaft is parallel to the line of sight as long as the gyro is caged. When the firing trigger on the sighting station is pressed, a solenoid in the gyro is energized and the caging cone is drawn away from the gyro motor frame, thus freeing the gyro. The housing will continue to be moved by the sight gearing, but the axis of the motor shaft and gyro flywheel will remain fixed in the same direction as it was at the instant it was uncaged.

The Camera

The camera is used to make a permanent record of combat action. When the firing trigger on the sighting station is pressed, the camera action starts. The camera records images of the target, the ranging ring, the reticle and the range-and-target scale readings. An overrun control continues the camera action for a limited period after the gunner has released his firing trigger.

The Ranging System

The ranging mechanism of the hemisphere sight determines the range of the target and transmits it electrically to the system computer. The mechanism is controlled manually by the ranging lever on the operator's right control grip.

The Desiccator System

With the exception of the gyro and Selsyn assembly section, the eyepiece lens cell, and the control-grip assembly section, the chambers of the sights are either statically or dynamically desiccated.

The eyepiece chamber and the objective-lens-cell assembly are hermetically sealed units. These chambers have charging and evacuating valves through which the air can be evacuated and the chamber charged with an inert gas such as nitrogen. The eyepiece lens cell, a completely sealed unit, is seal-mounted over the rear opening of the eyepiece chambers and is not desiccated.

The circulatory system dries and pumps air through the chambers of the sight not desiccated by other means. A pump forces air through desiccant-containing jars, through aluminum pipes to the dome space, outer space of the periscope tube, range compartment and back to the pump. This cycle is continued as long as the pump is turned on.

SECTION VII—MODELS "J" AND "K" RETIFLECTOR SIGHTS

1. INTRODUCTION

This section contains descriptive data, for the models "J" and "K" retiflector sights, designed and manufactured by the General Electric Company. (See Table I, Figure 2-79.)

The instructions contained in the section form a part of the complete instructions issued for the operation and service and the overhaul of the B-36 remote-control turret system.

General Description

The models "J" and "K" retiflector sights are standard equipment on the pedestal and the yoke sighting stations, respectively, which are used in the B-26 remote-control turret system. The two sight models are functionally the same; however, their main component parts are different and are not interchangeable. The model "J" retiflector sight has its reflector plate, filters, and ring-and-bead sight so arranged that its line of sight is parallel to the body of the sight; the model "K" has these component parts so arranged that its line of sight is at right angles to the body of the sight.

The model "J" retiflector sight is mounted on the sight yoke which is located in the center of the upper portion of the elevation assembly on the pedestal sighting station. The model "K" retiflector sight is mounted on the front, or closed end, of the yoke on the yoke sighting station.

Each sight model supplies a DC range input signal to the computer, through a range po-

Figure 2–79. Table 1—Sights and Their Location.

tentiometer. A reticle assembly, which is contained in the lamp housing of the sight, is used to establish the range of the target. The range potentiometer is co-ordinated with the reticle assembly so that as the range of the target varies, as indicated by the reticle image which is projected upon the reflector plate, the input signal from the sight to the computer is varied to correct for the change in range.

Detailed Description

Optical System. (Figure 2-80). The optical system produces the reticle image through the following components: the double-filament reticle lamp (8), the light source for the image; the condensing lens (10), which gathers and projects the light through the optical system; the orange-colored filter (11), which gives the reticle image its color; the reticle assembly, consisting of the range reticle (13), neutral reticle (14), and target-size reticle (15), each of which contains slots to break down the light from the reticle lamp (8) into a circular pattern of dots to form the reticle image; the 45-degree first-surface mirror (17), which reflects the reticle image upward through the cover glass (18) onto the Mangin mirror (2); the Mangin mirror, which

collimates the light rays that form the reticle image and reflects them onto the reflector plate (3); and the reflector plate, on which the reticle image is projected and through which the gunner sights his target.

Sky Filters. Hinged sky filters (1), (Figure 2-80) are provided to reduce the glare from brilliant sunlight and to increase the brightness of the reticle image. In night operation, the filters can be swung up, out of line of the sight.

Ring-and-bead (Peep) Sight. If the optical system should fail to work, the ring-and-bead sight (4 and 19), (Figure 2-80) can be moved into place for emergency sighting.

Electrical Elements. A potentiometer (7), controlled by the movements of the range-reticle assembly (13), provides the computer with an electrical signal which represents the range of the target. The reticle lamp (8) is built with two independent filaments to insure a replacement if the one in use should burn out. A filament-selector switch, for use of either filament, is located on the outside of the removable cover at the rear of the lamp housing. The intensity of the light from the filament lamp can be varied by turning the reticle-lamp rheostat on the sighting station.

2. OPERATION

Principles of Operation

Optical System. (Figure 2-81). The light from the reticle lamp passes through the or-

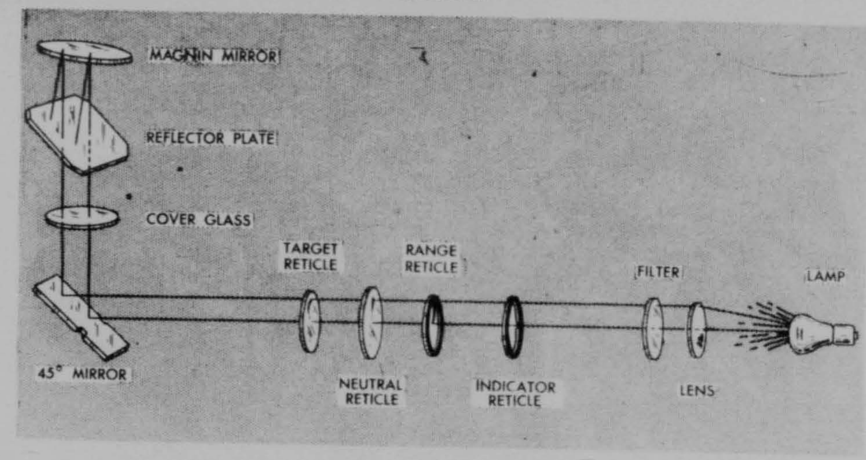

Figure 2–81. Schematic Diagram of Optical System of Retiflector Sight.

ange-colored filter, the condensing lens, and an indicator disc (mask) that has a circular opening the size of the maximum reticle image. The indicator disk contains an opening, cut into the inside diameter, which permits passage of light through the target-size and the range numerals. The light continues through the reticle assembly where it is broken up in dots which form the reticle image. In addition, the target-size and range numerals (illuminated index mark) are formed. The formed reticle image is reflected upward by the 45-degree mirror through the cover glass to the reflector plate. At this point, approximately 95 per cent of the light passes through the plate to the Mangin mirror. This mirror is so shaped and located, with respect to the reticle assembly, that the light rays from the reticle mirror are collimated, or made parallel, and reflected back to the reflector plate. Approximately 80 per cent of the remaining light is passed through the reflector plate, and the balance, 20 per cent, is reflected toward the eye of the gunner. These light rays form an image of the reticle at an infinite distance (infinity). Any object in line with the center of this reticle image will appear in the same position, irrespective of the distance of the gunner's eye from the reflector plate. A slight movement of the gunner's eye, up or down or from side to side, will not change the relative position of the target and the reticle image.

Reticle Assembly. (Figure 2-82). The target-size reticle (12) is located nearest to the body assembly; the neutral reticle (11) is in the middle; and the range reticle (10) is between the neutral reticle and the indicator reticle (9). The neutral reticle is connected to the other two reticles by a differential pinion gear. Thus, when either of the outside reticles is moved, the neutral reticle is moved proportionately. The three reticles ride on the inner surface, or circular bore, of the housing. When either of the outer reticles is turned, the teeth on the inside surface of the reticle flange turns the neutral pinion; the pinion, in turn, rotates the neutral reticle. The relationship of the slots of the range, neutral, and target-size reticles to each other determine the diameter of the image. The range of target-size adjustment is from 15 to 75 feet. The range scale indicates range in yards from "250" to "1500." The apertures of the target-size reticle and the range reticle are similar but curve in opposite directions. The apertures of the neutral reticle are radial and straight. Each of the three reticles contains a central hole to permit the passage of light to form the center dot of the reticle image when the angular relationship of the three reticles with respect to each other is changed. The gunner determines the

Figure 2–82. Partially Exploded View of Retiflector Sight Showing the Range and the Target-Size Input Gear Arrangement.

wing span of the target and varies the position of the target-reticle assembly by turning the target-size input knob (Figure 2-83). In normal operation the gunner sets the target size just before aiming at a target and allows the target reticle to remain in position. The gunner varies the size of the reticle image by changing the position of the range-reticle assembly (Figure 2-84). This is accomplished by turning the range-input grip on the sighting station. When the range-input gearing (Figure 2-82) turns the range reticle, it also turns the slider of the potentiometer which, in turn, sends the range correction to the computer. There are eighteen dots forming the reticle image at close range (largest circle), twelve dots at approximately eight-hundred yards range (medium circle), and six dots at approximately fifteen-hundred yards range (small circle).

The light from the lamp (4) (Figure 2-85) passes first through the indicator reticle (a disc whose inner diameter is slightly larger than the maximum reticle-image diameter), then the portion which comes through the center opening falls upon the range reticle (3). At this point, all light is blocked except that passing through the curved slots, the center dot, and the range and the target-size numerals. At the neutral reticle (2), the curved segments of light cross the straight reticle slot. Where they cross, light is permitted to pass through. This step forms dots of light. However, more dots are formed than are wanted; thus, as these dots fall on the target reticle (1), only those which intersect a slot in the

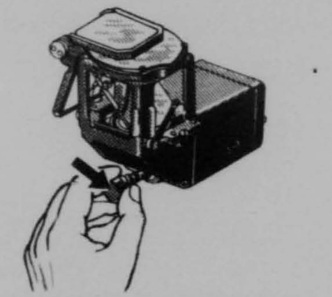

Figure 2–83. Target-Size Input Knob.

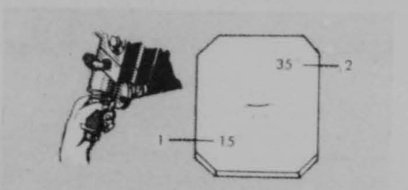

1. RANGE IN HUNDREDS OF YARDS
2. TARGET SIZE MEASURED IN FEET

Figure 2–84. Reticle Image Adjusted to Span Target at 1500 Yard Range.

target reticle get through to the first-surface mirror. In this way, the proper dots to form the reticle image are selected. Changing the position of any reticle changes the relationship of the slots and thus changes the selection of reticle-image dots. (Figure 2-82)

The two rectangular-shaped openings in the indicator reticle permit passage of light for the target-size and the range indications. The narrow slot above this opening passes light which becomes the index mark on the reflector plate. The wide, curved openings in the range and neutral reticles pass the light for the target-size reticle. Those for range are on the range reticle.

Use With Computer

When the system uses the computer, two adjustments must be made by the gunner:

Upon finding the target and identifying it, the gunner estimates, or knows, its wing span or length. If, for example, a target with a sixty-foot wing span is sighted, the gunner turns the target-size input knob, which is located on the left-hand side of the upper sight and in front of the gunner on the pedestal sight, until the figure "60" appears on the reflector plate. With the setting made, the gunner aims the sight, bringing the center dot of the reticle image to bear on the target.

The gunner adjusts the diameter of the reticle image (by turning the range grip or range wheel) so that the circle of dots just spans the target.

Use Without Computer

A small indicating lamp (6) (Figure 2-80) in the sight is turned on when the system is in operation without a computer. A small part of this light is passed through a glass rod (5) which projects into the lower right-hand corner of the first-surface-mirror housing. The gunner should adjust the reticle-image size to the intensity of light considered most suitable. The gunner must now make his own ballistic, parallax, and prediction corrections.

SECTION VIII—THYRATRON, CONTROL PANELS, JUNCTION BOXES, AND INDUCTION MOTOR

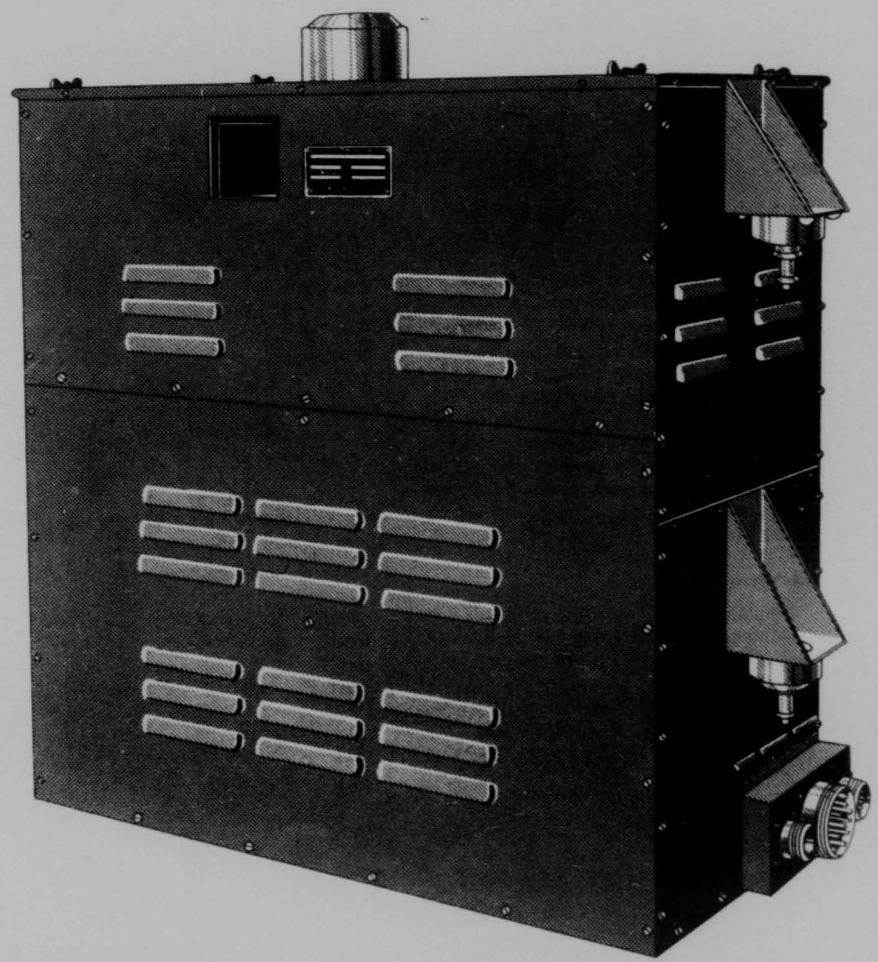

Figure 2–86. Overall View of Thyratron Controller.

1. INTRODUCTION TO THYRATRON

The thyratron controller (Figure 2-86), General Electric assemblies No. 8678508G1 and 8678508G2, is airborne equipment first designed for the remote-control turret system 2CFR87A1 installed in the B-36 airplane. Assembly No. 8678508G1 is used in the upper, lower, and nose systems and assembly No. 8678508G2 is used in the tail system. The thyratron controller is an electronic device which receives AC error signals from the Selsyn control transformers in the turrets and amplifies and converts these signals to DC power for driving the turret motors. It also supplies 27-volt DC auxiliary power for each system. One controller is required for each turret-and-sight combination in the B-36 turret system.

Data pertinent to the thyratron controller may be found in the following publication:

AN 11-70AA-31 Operations and Service Instructions for the Model 2CFR87A1 Remote-Control Turret System.

2. DESCRIPTION OF THYRATRON

This section contains general information pertaining to the thyratron controller and covers, in detail, the description of the various components thereof.

Test Equipment Required

The test equipment listed in Figure 2-87 is required to adjust, align, check and repair the thyratron controller.

Detailed Description

Eight thyratron controllers are used in the B-36 remote-control turret system, one for each turret. Input power to each thyratron controller is three-phase system is wye connected. Selsyn signals created by movement of the sights are fed into the controller and are then amplified and used as signals to the power thyratron tubes. The thyratron controller contains a frame, tube shelf, cover, base plate, and six panel assemblies.

Interchangeability

There are two types of thyratron controllers used on the B-36 remote-control turret system, assembly No. 8678508G1 which is used for the upper, lower and nose systems and assembly No. 8678508G2 which is used for the tail system. The amplifier panel contains different feedback resistors in the circuits for the one-horsepower motors in the upper, lower, and nose systems than the amplifier panels used in the circuits for the one-half-horsepower motors in the tail system.

3. OPERATION OF THYRATRON

Note: Before referring to this section it is important that the reader have a thorough

understanding of section IV, Theory of Operation in AN-11-70AA-31 (B-36 Operation and Service Handbook).

The thyratron controller is a device for supplying DC power to the turret motors so that they will drive the turret in such a manner as to always point in the same direction as the sight (computer is not operating in the circuit). This DC power is obtained by thyratron rectification of the AC power supplied to the thyratron controller. The DC voltage output can be varied by proper control of the grids of the thyratrons. The method of control is such that the DC voltage output is proportional to the error signal or voltage output of the Selsyn control transformers. Since the speed of a DC motor with constant applied field is directly proportional to the voltage applied, this means that the speed of the motors is proportional to the error signal.

The operation of the system can be stated as follows: (Figure 2-88). Assume that the sighting station and turret are aligned and are stationary. Moving the sight will cause error voltages to appear at the output of the Selsyn control transformers located in the turret. These voltages are fed into the thyratron controller. When the sighting station and turret are within 3 degrees of alignment, the 31-speed Selsyn signal is effective; otherwise, the 1-speed signal is effective. This signal is first amplified, converted into two voltages 180 degrees out of phase in the phase inverter, and then fed into the discriminator. The discriminator output is a DC voltage whose amplitude is directly proportional to the AC output voltage and whose polarity is determined by the relative phase of the AC input voltage.

This DC voltage is then filtered. In the filter section, a feed back voltage, which is a function of the rate of change of turret-motor armature voltage, is introduced. The connections of the feed-back depend on whether the 31- or 1-speed Selsyn signal is effective. The feed-back signal is used to keep the system from oscillating.

After being amplified in V116, the DC voltage is fed to twin-triode V113. The outputs of the cathode follower are used to control the trigger thyratrons. With zero Selsyn signal, the outputs of the cathode follower are both minus seven volts DC. With a Selsyn signal, the output of one of the cathode followers will go negative (with respect to minus seven volts) while the other one will go positive. The output that goes positive will cause the bank of trigger thyratrons (to which it is connected) to conduct. The output of the pulse transformers in the plate circuits of the trigger thyratrons will then be positive pulses which will cause one bank of power thyratrons to conduct. When the power thyratrons conduct, a voltage will be applied to the turret motor armature. One bank of power thyratrons (V101, V102, V103) have their plates connected to the AC lines. This bank, when conducting, delivers a positive voltage to the turret motor. The other bank has the cathodes connected to the AC line and therefore delivers a negative voltage. The direction in which the motor rotates depends on the polarity of the output voltage.

In order to explain how the thyratrons can deliver a variable DC voltage some explanation of how a thyratron works must be given. Thyratrons are gas-filled triodes or tetrodes. The grid can control the start of conduction, but it cannot stop conduction. The only way to stop conduction is to let the plate voltage become zero or negative or to make the plate current zero. When an AC voltage is applied to the plate the tube can conduct only during the positive half-cycle. Therefore, when the grid is made sufficiently positive during the positive half-cycle of the plate voltage the tube will start conducting and will conduct until the plate voltage becomes zero. By varying the point during the cycle at which the tube begins to conduct, the portion of the cycle during which the tube conducts can be controlled. The greater the portion of the cycle during which the tube conducts, the greater will be the DC voltage output. (Figure 2-89).

Current limiter V114 is used to limit the current passing through the motor armature to 60 amperes in the case of the one horsepower motors and 35 amperes for the one-half horsepower motors. Both of these currents are five times the normal rating of the motors.

Since torque is directly proportional to current, this limit is really a torque limit circuit.

Voltage limiter V115 limits the voltage and hence, the speed of the motor. This is done to protect both the motor and the controller.

4. CONTROL PANELS

There are eight control panels (Figures 2-90 and 2-91); one each for the upper-forward, upper-aft, and lower-aft turrets; one for the nose; and one for the tail. Because of the similarity in operations to be performed, several duplicate or similar devices are used in the eight control panels such as uniswitches, circuit breakers, handsets, and rounds counters. In addition, the tail control panel has a camera switch (Figure 2-91), on-the-target interlock relay, and radar and radar-computer position on the uniswitch (3), while the upper-forward, upper-aft and lower-aft turrets control panels have turret position indicating lights and "stand-by" and "door open" positions on the uniswitch. Each panel is connected to other parts of the system by a standard AN connector.

Location

The panels are conviently located so that each gunner can quickly and easily control and operate the equipment at his command. The control panels are mounted on bulkheads near each turret system's sight.

5. JUNCTION BOX

To eliminate long cable runs with their weight and voltage drop, system units are connected to a junction box located near the individual turret. Eight junction boxes are used in the remote control turret system; one for each turret. Junction boxes for the eight turrets are identical in size and method of mounting.

Location

All system junction boxes are located in close proximity to each turret's thyratron controller and computer. The nose-system junction box is located directly forward of the nose-turret computer on airplane station 89.

The upper-left and upper-right forward-system junction boxes are mounted directly aft of airplane station 283 above their respective turret computers. The lower-left aft-system junction box and the lower-right aft-system junction box are located aft of airplane station 1184, forward of the turrets. The upper-right aft-system junction box and the upper-left aft-system junction box are mounted above each turret's thyratron controller aft of airplane station 1184. The tail system junction box is located in the tail section of the airplane, aft of airplane station 1306 in the pressurized compartment.

Cables, jointed to the unit by means of standard AN connectors, serve as links between the junction box and its associated units. The turret connects to the junction box by means of three cables; the turret door mechanism by one cable; and the turret retraction mechanism by two cables. The computer, thyratron controller, and control panel lead into one cable which, in turn, leads into the junction box.

6. AC INDUCTION MOTORS

The turret motors consist of a stator, rotor, and end shields. Models 5K40BJ22, 5K40BJ29, 5K40JJ20, and 5K40JJ33 each are equipped with magnetic brakes and an overload switch. Models 5K25DJL9 and 5K25DJ20 are not so equipped. Ratings for the motors are given in table

The following description is applicable to all motor models except where differences are specifically mentioned. (Figures 2-92, 2-93, 2-94.)

Stator Assembly

The stator is a machined steel shell into which a stack of slotted punchings is pressed. A four-pole, three-phase, wye-connected winding is wound in the slots. All models, except models 5K25DJ19 and 5K25DJ20, have a thermal overload switch imbedded in and tied to the stator winding.

Note: Model 5K25DJ20 is a six-pole machine.

Operation of AC Induction Motor

The induction motor makes use of a constantly revolving magnetic field in the stator to turn the rotor. The copper bars of the rotor are cut by the revolving magnetic field. A starting torque in the motor is produced by the revolving field which cuts across the copper bars and generates an EMF in the closed circuit of the rotor. Since the EMF is induced in a closed circuit, current will flow in the rotor bars. The frequency of the EMF generated in the rotor at standstill is the same as the frequency of the applied voltage to the stator.

Starting Torque. The current in the rotor conductors at standstill is expressed by the ratio of the rotor voltage at standstill to the rotor impedance at standstill. The rotor impedance at standstill limits the current to about five times the full-load value. This large starting current produces a high starting torque.

Slip. When the motor is not carrying any load, the rotor will revolve at practically the speed of the revolving field, that is, at synchronous speed. It cannot turn at speed greater than that of the revolving field. When the motor is loaded, the rotor slows down, and as a result, it "slips" through the constantly revolving magnetic field of the stator. Slowing down results in the cutting of more lines of force, and the generating of more EMF. The resulting increased current will produce more torque. The rotor will continue to slow down until sufficient torque is produced to overcome the retarding torque of the load. The ratio of the difference between the synchronous rpm minus the motor rpm to the synchronous rpm times 100 is called the "per cent slip." If its value at full load is about four per cent, the revolving magnetic field will make one revolution while the rotor will make 0.96 revolution.

Load Characteristics. When the rotor is at standstill, the rotor frequency is the same as the line frequency. At full load, the rotor frequency is equal to per cent of slip times the line frequency. As the load on the motor increases, the motor slows down and slips more rapidly through the revolving field, causing the rotor current and the frequency of the

rotor current to increase. The characteristics of an induction motor is such that up to a certain point, called the "breakdown point," or "point of maximum torque," the greater the rotor current, the greater the torque. Beyond this point, the torque decreases as the rotor current increases. The relation between speed, torque and current is shown in Figure 2-95.

Direction of Rotation. A reversal in rotor rotation may be accomplished by changing the relative sequence of magnetic flow cutting the rotor. This can be accomplished by interchanging the connections of any two of the three leads of a three-phase induction motor.

Motor Brakes. Magnetic brakes are used in some types of fractional-horsepower induction rotors to aid in bringing the rotor to a quick stop after the energizing current to the

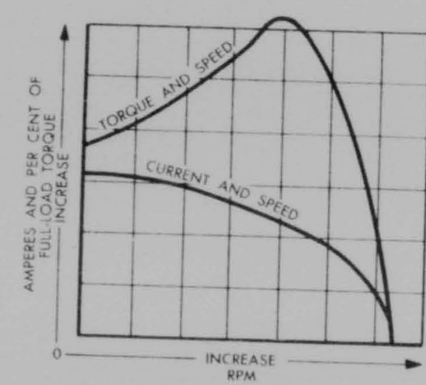

Figure 2–95. Curves Showing Relationship of Speed, Current, and Torque in an Induction Motor.

stator has been cut off. The brake consists essentially of a brake drum mounted on the shaft extension. The brake drum fits over the brake-coil assembly. Brake shoes are held against the inner side of the drum by spring pressure. The brake-coil assembly is connected in parallel with the field windings. When current is supplied to the field, the brake shoes pull away from the drum. Rotation is free until current is cut off. Upon cutoff of the current, the brake-coil assembly becomes de-energized and spring pressure pushes the brake shoe against the drum, bringing the rotor to a quick stop.

Overload Protector. Overload thermal protectors are used on some motors to prevent the motor from overheating when a greater load than normal is applied. The overload protector consists of a thermally controlled switch connected in series with the coil of the power contactor in a junction box. When the switch opens, the contactor is de-energized, thereby opening contacts in each of three lines to the motor. This protector is so adjusted that if the motor current becomes higher than normal, a movable diaphragm opens a pair of contacts and cuts off the power. Upon cooling of the motor, the contacts close and power can again be applied.

SECTION IX—FREE GYRO AND COMPUTER

1. FREE GYRO

General Description

Each sighting station has one fully gimbaled gyroscope mounted so that it moves, in azimuth and elevation, with the line of sight. A gyroscope, located in the tail of the B-36 airplane, is provided for the AN APG-3 antenna.

The different gyroscopes which are covered by this Handbook are located as shown in table 2-1.

Function. The gyro is used in the computing circuit to predict the lead correction necessary for advancing the guns ahead of the target by an amount proportional to the range and relative speeds of the bomber aircraft and the target. The gyro does this by very accurately measuring the angle traversed by the target during the prediction-computing-time interval. The free gyroscope is so named because it is free to move in any direction within approximately 15 degrees from the caged position of the gyroscope axis.

The gyroscope assembly (Figure 2-96) consists of the following basic component assemblies; the motor and flywheel assembly (5); the gimbal system which consists of three parts: the bracket and pin assembly (11), the gimbal ring (22), and the housing (19), the solenoid assembly (15); the holding solenoid assembly (2); and the azimuth (10) and elevation (21) Selsyns. The other component assemblies consist of the cover (1) and the noise suppressors (12). A junction box, which houses the capacitors and resistors, and other electric equipment is a part of the gyroscope electric system. The junction box is mounted on the sighting station, except in the case of the gyro for the radar installation where the junction box is mounted on the gyroscope cover.

Motor and Flywheel Assembly. The gyroscopic action is provided by a flywheel (5) (Figure 2-96) mounted on the shaft of a small DC motor. The motor is rated 27.5 volts, 10,000 (plus or minus 25 per cent) revolutions per minute. The motor has a permanent-magnet field and a conventional armature which rotates in ball bearings. Since the performance of this type of gyro is not dependent upon accurately held speed, no form of speed control is provided. The motor and flywheel assembly (5) is mounted within a bracket and pin assembly, (11). The flywheel of the motor is enclosed by a cover (4) which is attached to one end of the bracket and pin assembly. The flywheel cover has a spherical surface against which the holding solenoid applies its breaking force when the solenoid is energized. The caging end of the bracket and pin assembly has a conical projection in which there is a ball-tipped caging pin. The motor

and bracket assembly is supported in the gimbal ring (22) by two bearing pins (7). Two adjustable counterweights for balancing the assembly are mounted on opposite sides of the bracket. The leads from the motor and Selsyn stator are brought to a clamp on top of the motor. Flexible leads connect from the motor clamp to an adjacent clamp on the gimbal ring.

Gimbal System

The gimbal system (Figure 2-97), in which the motor and flywheel assembly is supported to permit its movement in any direction, consists, essentially, of the bracket and pin assembly (11) (Figure 2-96), the gimbal ring (22) and the housing (19). The bracket and pin assembly which is fixed to the motor and flywheel assembly, is provided with a set of two ball bearings and two thrust-bearing disks seated in the sides of the bracket on its horizontal axis. The bracket-bearing axis is perpendicular to the gyro motor-shaft axis. The gimbal ring is provided with one set of two ball-pointed bearing pins along its horizontal axis, and one set of two ball bearings and two thrust-bearing disks along its vertical axis. The bracket and pin assembly is supported on its horizontal axis in the gimbal ring by the two ball-pointed bearing pins which engage the ball bearings and bearing discs seated in the bracket. This set of bearings on the horizontal axis permits the gyro motor-shaft axis to remain in the same space direction in which it was pointed, before the gyro was uncaged, as the housing is turned in elevation. The gimbal ring in turn, is supported on its vertical axis in the housing by two ball-pointed bearing pins which engage the ball bearings and bearing disks seated in the ring. This set of bearings on the vertical axis permits the gyro motor-shaft axis to remain in the same space direction in which it was pointed, before the gyro was uncaged, as the housing is turned in azimuth. The gimbal system does not permit free movement of the gyro through 360 degrees, but it does permit free movement through approximately 15 degrees in any direction from the caged position, which is ample latitude for computing the lead-prediction-correction angle.

The position of the motor and flywheel assembly within the housing is electrically transmitted to the computer in the remote-control turret system by means of the elevation and azimuth Selsyns. The rotor (8) (Figure 2-97) of the elevation Selsyn assembly is mounted on the gimbal ring, and the stator (4) is mounted on the bracket and pin assembly. The rotor (13) of the azimuth Selsyn assembly is mounted in the gyroscope housing, and the stator (10) is mounted on the gimbal ring.

Selsyns

The azimuth and elevation (lateral and vertical) deflection Selsyns are variable-voltage transformers in which the secondary stator voltage is a function of the relative positions of the stator and primary rotor voltage. The stator coil assembly consists of a toroidal (doughnut-shaped) winding on a build-up of magnetic ring laminations, which provide a low reluctance flux path for the stator flux. The coil is mounted in an aluminum case which protects the coil from mechanical damage and provides a means of mounting the stator. The rotor consists of a random-wound coil on a laminated magnetic core. The flux spreader furnishes an additional magnetic path and also provides a means of mounting the rotor.

Caging Mechanism

The gyro is spring-caged and electrically uncaged by means of a solenoid-controlled armature or plunger (18) (Figure 2-97). When the caging solenoid is energized, it pulls the magnetic plunger in, compressing the spring (16). This pulls the nonmagnetic caging cone (15) away from the ball-tipped caging pin (7). The motor shaft may then move approximately 15 degrees in any direction with respect to the housing before the caging pin hits the cone. When the solenoid coil is de-energized, the spring forces the caging cone over the caging pin, bringing the motor shaft into alignment with the plunger. At the end of the caging stroke the ball is held within a hollow cylinder at the apex of the cone. Thus, regardless of the displacement which occurs while the gyro is uncaged, the spring and cone bring it back to within a small fraction of a mil of the same position when it is recaged. The entire caging mechanism, except for the ball-tipped caging pin on the motor bracket, is a separate assembly held in place on the housing by an annular nut. The outside of the cylindrical coil case serves as the main support for the gyro in its mounting on the sight.

Housing. The aluminum housing (19) (Figure 2-96) serves as a part of the gimbal system, and as part of the enclosure of the gyroscope assembly which includes the motor and flywheel assembly, the gimbal system, the caging mechanism, and the noise suppressors. The caging mechanism is located in the end of the housing, and the noise suppressors are located in the housing, under the caging mechanism.

Cover. The cover (1) (Figure 2-96), which completes the enclosure of the gyroscope assembly, is of molded plastic compound. The outside surface and the mounting face is zinc-sprayed to a depth of approximately 0.015 inch; this acts as an electrical shield for radio noise that results from motor commutation. The cover contains an air filter which provides for ventilation of the gyroscope assembly. The holding solenoid assembly is mounted on the cover.

Holding Solenoid

The holding solenoid assembly (2) (Figure 2-96) is mounted on the cover along the normal gyroscope motor-shaft axis. Thus the solenoid plunger acts radially on the braking sphere of the flywheel cover when the motor and flywheel assembly is in any position within its range of movement.

Junction Box

The junction box is connected to the gyro by a flexible cable. It houses the capacitors and resistors used to adjust the phase angle and magnitude of the Selsyn stator voltages. Also located in the junction box is the additional DC line filtering, necessary to lower the gyro-conducted and radiated noise to within specifications. The gyro junction box serves as a connection for the camera mounted on the yoke and pedestal sighting stations. The camera is controlled by a switch on the box.

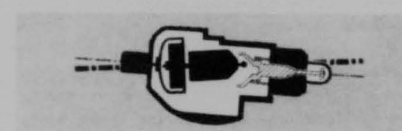

Figure 2–102. Gyro Uncaged and Locked.

Noise Suppressors. This information will be furnished as a revision at a later date.

Operation

The gyro is used to indicate to each computer the angle traversed by the target during the prediction-computing-time interval. The motor of the gyro is a 27-volt, DC type and is energized when the uniswitch located in the control panel is thrown to the "standby" position. The gyro remains energized when the uniswitch is in either the "door open" or the "operation" position.

Principles of Operation

The gyro is normally caged (Figure 2-98), and in this position its motor-shaft axis is parallel to the line of sight. The caging mechanism end points toward the target. As the sight or the radar antenna moves, the entire gyro moves with it so that the motor shaft always points along the line of sight. When the trigger is pressed, a solenoid in the gyro is energized and the caging cone is drawn away from the motor frame (Figure 2-99). The housing will continue to move with the sight or antenna but the motor shaft will stay pointing in the same direction it did at the instant it was uncaged (Figures 2-100 and 2-101).

As the housing turns, the relative position of one or both of the Selsyn rotors and stators is similarly changed and voltages are generated in the stator windings. These voltages energize the computer-output-unit motors by way of the gyro amplifier, and cause them to turn the computer's total-correction-unit Selsyns through the same lateral and vertical angles as the sighting station. The output unit motors are capable of making corrections much faster than the gyro housing moves in tracking a target. Consequently, the total-correction-unit Selsyns quickly catch up with the gyro Selsyn angles, reduce the net signal voltage to the drop-out point of the gyro-amplifier relays, and stop the computer-output-unit motors. As soon as the sight or antenna, which contains the housing, has again moved enough to provide the computer's gyro amplifier with a pick-up signal, the output-unit motors again run. The movement of the output units is, therefore, a series of rapidly repeated small steps following very closely the angular movement of the sight. At all times the lateral and vertical corrections are within a few mils of the displacement of the gyro Selsyns.

When the time interval of prediction computation has expired (one time-of-flight multiplied by the attack-factor correction), a relay operates in the computer. This relay energizes the holding solenoid in the gyro which locks the gyro in its subtended position (Figure 2-102), and starts the following chain of events: The output units are brought into agreement with the computed corrections; the gyro is unlocked and recaged; the timer unit in the computer is reset and the computation is started again after a predetermined time delay of 0.065 second. However, the output units or computer corrections remain in their previous position until the new time-of-flight problem has expired. At this time the out-put units are again allowed to drive into agreement with the newly computed gyro correction. This process is repeated as long as the trigger is depressed. (Reference should be made to the theory of operation for the computer in AN 11-70AA-54.)

When the trigger is released, the caging solenoid is reset and the caging cone realigns the gyro-motor shaft with the line of sight. At the same time, the power supply to the computer-output-unit motors is re-established and the prediction corrections in the computer are quickly brought back to zero.

When the trigger is pressed for a new attack problem, the entire cycle of prediction is repeated.

2. COMPUTER

The eight turret-sight systems of the B-36 airplane each are equipped with one computer. Each computer has been adjusted for the parallax between its sight and turret. Aside from the parallax adjustment, all computers are the same, except the nose turret-sight system computer, model 2CH2C1-N, which is equipped with a different timer-unit motor and a different total-correction unit assembly. This difference in the nose turret-sight system computer computes a faster lead-prediction correction cycle which is necessary to combat the faster moving attacks encountered in the nose hemisphere. Additional nomenclature is suffixed to the computer model-number designation, which is stamped on the computer nameplate, to identify that computer with the turret-sight system with which it belongs.

Each computer weighs approximately 100 pounds, and the four shock mounts together weigh one pound.

Description

Purpose of Computer. For short ranges, with a stationary gun and a stationary target, a gun can be aimed directly at the target by sighting along the gun barrel. However, in aerial combat this ideal condition is seldom met, and the direction of the gun's bore axis must be shifted with respect to the direction of the target. The amount that the gun must be shifted depends upon the forces acting upon the projectile after it leaves the muzzle of the gun, such as windage and gravity, and upon the movement of the target while the projectile is traveling toward it. If the sight of the radar antenna is not mounted on the gun, but is located at a distance from it, as is the case with the B-36 remote-control turret system, the gun's position must be further changed to compensate for this "parallax" distance.

There are two methods used at present for aiming the guns at the target, namely: noncomputing and computing systems. In the B-36 system, the computer can be switched "in" or "out" of the circuit instantly at the option of the gunner.

Noncomputing Systems. In a noncomputing system, the line of sight is maintained parallel with the gun's axis and the gunner advances the line of sight from the target position by an amount determined by him from his own experience and judgment.

Computing System. In a computing system, such as the remote-control turret system used on B-36 airplanes, the sight or the antenna is held on the target by the gunner, and the relative position of the guns is determined by a computer mechanism. The use of the computer eliminates the guesswork on the part of the gunner in estimating range, ballistic, parallax, and lead-prediction corrections and leaves him free to concentrate on accurately tracking the target and keeping the sight aligned with it.

When a noncomputing system is used, the same corrections must be taken into account in order that the projectile will strike the target.

Computer Corrections

All computer corrections can be classified into three groups, namely: ballistics, parallax, and lead prediction. These three corrections are added together and are electrically introduced into the remote-control turret system as a single total correction.

Ballistics. The ballistics correction compensates for the windage and gravity forces that cause a projectile to deviate from a straight line after leaving the muzzle of the gun.

Parallax. The parallax correction compensates for the distance along the longitudinal axis of the airplane between the turret and the sight that is controlling the turret.

Lead Prediction. The prediction correction compensates for the distance the target travels from the time the projectile leaves the gun until it strikes the target.

Basic Operation

The computer is essentially a mechanical computing device which receives all its input data in the form of electrical quantities. These input data, then are converted into mechanical shaft rotations for the mechanical portion of the computer. The output of the computing mechanism is a mechanical motion which is converted again into electrical quantities for introduction as corrections into the signal circuit between each sight and the turret it controls.

Design Characteristics—Correction Input Limits. The altitude-and-air speed handset and the range potentiometer at the sighting station are designed for computer inputs as follows:

Altitude: 0 to 45,000 feet

Air Temperature: −75° C (−103° F) to +50° C (122° F)

Indicated airspeed: 90 to 275 mph

Range: 250 to 1500 yards

Operating Limits. The computer is designed to operate continuously in any internal ambient rising temperature from 6.7° C (20° F) to +38° C (100° F), or falling temperature from +38° C (100° F) to 17.7° C (0° F), at any altitude between sea level and 40,000 feet. The computer may be operated at higher temperatures for short periods of time.

The computer will operate in any gun azimuth position and between ± 87 degrees gun elevation position.

The maximum correction that can be introduced between sight and gun is approximately 338 mils (19 degrees) in azimuth or elevation.

The 27-volt, DC supply voltage may vary from 26.1 to 28.9 volts; and the 115 volt, 400-cycle supply voltage may vary from 100 to 130 volts.

Limits of Accuracy. At zero degrees gun elevation, all static corrections are within four mils of the nominal value. The elevation correction remains within four mils or less at all gun elevations, but the azimuth correction varies as the reciprocal of the cosine of the gun elevation angle. At ± 60 degrees gun elevation for example, the error in azimuth correction may be ± 8 mils.

Mounting. The computer is mounted on four shock-absorbing brackets to absorb vibration. Internal parts are protected by removable, dust-resisting covers.

Operation

The B-36 remote-control turret system can be operated as a computing system or as a noncomputing system.

Noncomputing Remote Control. In the noncomputing remote-control system, electrical impulses are transmitted between the sight and the turret in such a manner that the turret automatically follows the exact position of the sighting station. Any movement of the sighting station or antenna causes a signal voltage to be applied to the thyratron controller until the turret assumes a corresponding position. The thyratron controller recognizes the polarity of the signal and delivers current in the proper direction to move the guns to the corresponding sight or antenna position.

The guns are, therefore, always in exact alignment with the sighting station, and all corrections must be estimated by the gunner. The sight or antenna must be aimed at the estimated position which the gunner believes, from experience, will cause the projectile to strike the target.

Computing Remote Control

The computing remote-control system is similar to the noncomputing system in all respects, except that a computing mechanism is connected in the electrical signal circuit between the sight and the gun turret. When not in use, this computer has no effect on the signals and the system continues to operate as a noncomputing system. However, when the computer is switched in, the computer automatically makes all computations for ballistics, parallax, and lead prediction; it displaces the distribution and changes the polarity of the signal voltage, as required, between the sighting station and the gun turret. The signal voltage is displaced by the necessary amount to aim the guns so that, when the sight or antenna is aimed directly at the target, the projectile will strike the target.

Computer Corrections. All the corrections can be classified into three groups; namely, ballistic, parallax, and prediction (lead). These corrections are expressed as angles, either in mils or degrees. An angular mil is 1/6400 part of a circle, and is approximately equal to the angle subtended by one yard at a range of one thousand yards. The ballistic, parallax, and prediction corrections are computed separately in the computer, and then added together to get the total correction.

Ballistic Correction. Ballistic correction compensates for the deviation of the projectile from the gun line. This deviation is caused by wind and gravity forces acting upon the projectile. The total ballistic correction consists of windage, gravity, and range corrections.

Affecting Factors. The factors affecting these corrections are air density (altitude, corrected for outside air temperature), true airspeed (indicated airspeed, corrected for altitude and outside air temperature), range, gun elevation, and gun azimuth positions. These factors may be regrouped as follows.

Windage. Windage is the term generally used to designate the effects of altitude, temperature, and airspeed on the path of the projectile (Figure 2-111).

A windage force is caused by the airspeed of the airplane. This windage has nothing to do with the actual wind on the surface of the earth; it is the apparent wind, as seen by the gunner, which is merely the airplane's speed relative to the air. This windage force is applied to the projectile in a direction parallel and opposite to the direction of flight.

In an airplane, the wind is always from the front to the rear, never deviating more than a few degrees from the fore-and-aft axis of the airplane. If the projectile is fired at zero degrees elevation (horizontal) and straight forward or straight aft, it is not deviated from the gun line by the windage force. However, for any other gun position, this force will deviate the projectile from the gun line toward the rear.

The windage deviations are symmetrical about the fore-and-aft center line of the airplane. Maximum deviation occurs when the target is broadside; and, for any given angle from the center line, it is greater in the two forward quadrants, since the energy of the projectile is lost at a faster rate in these quadrants because of greater resultant windage forces. The offsetting correction is always forward in the direction in which the airplane is moving.

The magnitude of the deviation, and hence the correction, depends upon the true airspeed, air density, and range. The windage correction increases with increase in airspeed and range and decreases with increase in altitude (reduced density). For the short ranges involved, the corection is nearly proportional to the range with other conditions constant.

Gravity. The effect of gravity upon the projectile is to cause it to curve toward the earth. (Figure 2-103). The angular drop of the projectile due to gravity is called "vertical gravity deflection." The offsetting gravity correction is greatest at zero degrees elevation of the gun (horizontal) and decreases with an increase in elevation or depression. Gravity acts upon the projectile throughout its time of flight, and the gravity correction varies almost directly as the time of flight of the projectile.

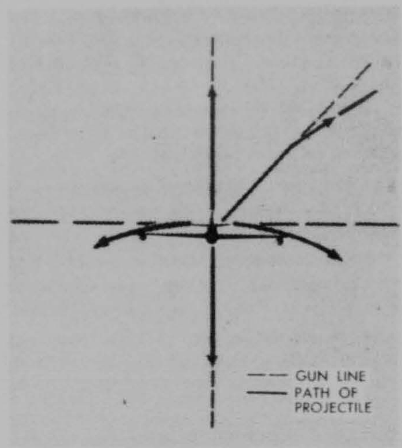

Figure 2—103. Effect of Gravity.

Range is the distance from the gun to the target. As the range is increased, the time of flight of the projectile is increased, which has an effect on all other corrections.

Gravity correction increases with range and is nearly proportional to it for the ranges encountered in computer operation.

Windage correction also increases with range and is nearly proportional to it for the ranges involved in computer operation.

Inputs Required. In order to calculate the ballistic correction, the computer must obtain the following information:

Azimuth and elevation gun position.

True airspeed.

Air density (a function of altitude and outside air temperature).

Range or distance of target from gun.

Parallax Correction. Parallax correction is the angle between the gun and sight (or antenna tracking axis), measured at the target.

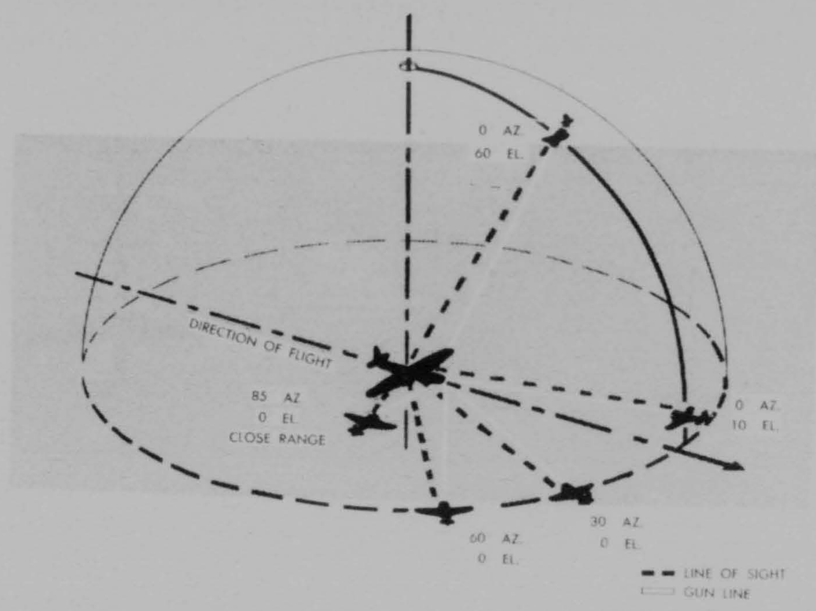

Figure 2—104. Parallax Corrections of Different Angles of Attack.

when the gun and sight are located at different positions on the airplane (Figure 2-104). This figure illustrates the desirability of making the parallax correction, as otherwise the guns would point parallel to the line of sight and would miss the target by the distance between the gun and the sight location. There is zero parallax correction when the gun and the sight are located at the same point. Parallax correction varies for different target positions or range (Figure 2-104). It is zero for straight forward or straight aft positions.

Affecting Factors

The factors affecting parallax correction are elevation and azimuth gun positions, range, and parallax base length (Figure 2-105).

The parallax correction increases from zero degrees to ± 90 degrees elevation and is great at ± 90 degrees.

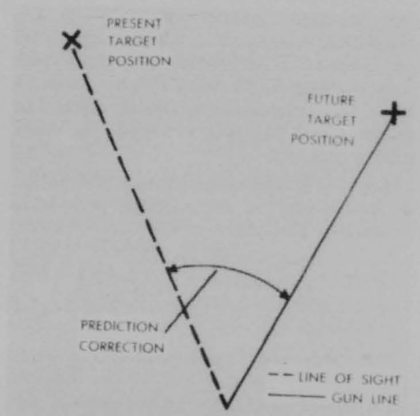

Figure 2—105. Effect of Prediction Correction on Gun Position.

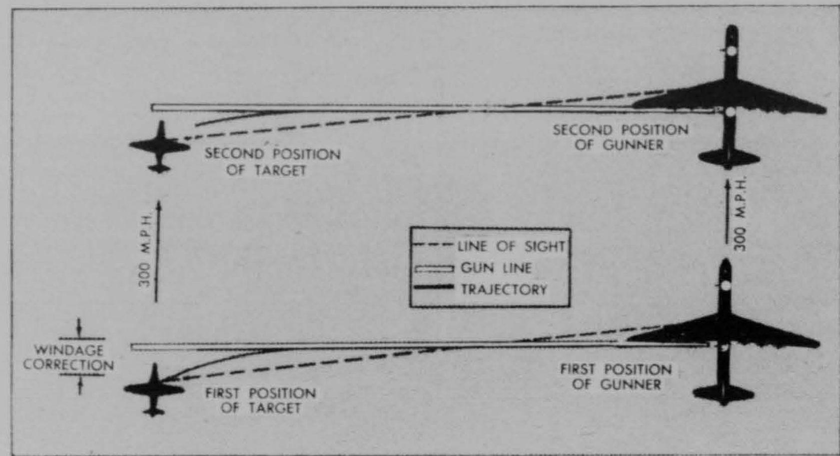

Figure 2–106. No Prediction Correction Required.

The parallax correction increases from zero degrees to 90 or 270 degrees and is greatest at 90 degrees and 270 degrees. The correction again decreases as the gun position moves from 90 or 270 degrees toward zero or 180 degrees azimuth. The parallax correction for a given azimuth position is changed by a change in the gun elevation position.

The parallax correction increases as the range becomes shorter and decreases for longer ranges. When firing at a target 1500 yards distant or farther, the gun line is practically parallel to the line of sight. At short range, the parallax correction increases. The greatest correction is at the minimum range of 250 yards.

Inputs Required. In order to calculate the parallax correction, the computer must have the following information:

Elevation gun position.
Azimuth gun position.
Range or distance of target from gun.
Parallax-base length.

Prediction (Lead) Correction. Prediction correction is an angular correction. It is the angle at the sight between the present and future position of the target (Figure 2-105). This correction is necessary to compensate for the movement of the target while the projectile is traveling from the gun to the target. It is the same correction that a hunter makes when he shoots ahead of a flying bird.

Affecting Factors. Since prediction correction is the angle through which the sight moves in following the target during the time of flight of the projectile (seconds), it is affected by target speed, gun position, windage, and range. To determine the prediction correction it is necessary to predict the future position of the target which is the location of the target at the time the projectile will reach it. The prediction of the future position assumes the path of the target to be essentially a straight line, while the time taken by the projectile to travel to a point on that path is determined from known characteristics of the ammunition. The proper gun orientation is obtained when the target and the projectile reach the same point (future position) at the same time. When the target is traveling in the same direction and at the same speed as the gunner's airplane (Figure 2-106) there is no change in the angle of sight and hence no prediction correction is necessary. Only the ballistic and parallax corrections are required. However, when the target is traveling in the opposite direction (Figure 2-107) there is a very rapid change in the sight angle, requiring a corresponding lead correction angle, or

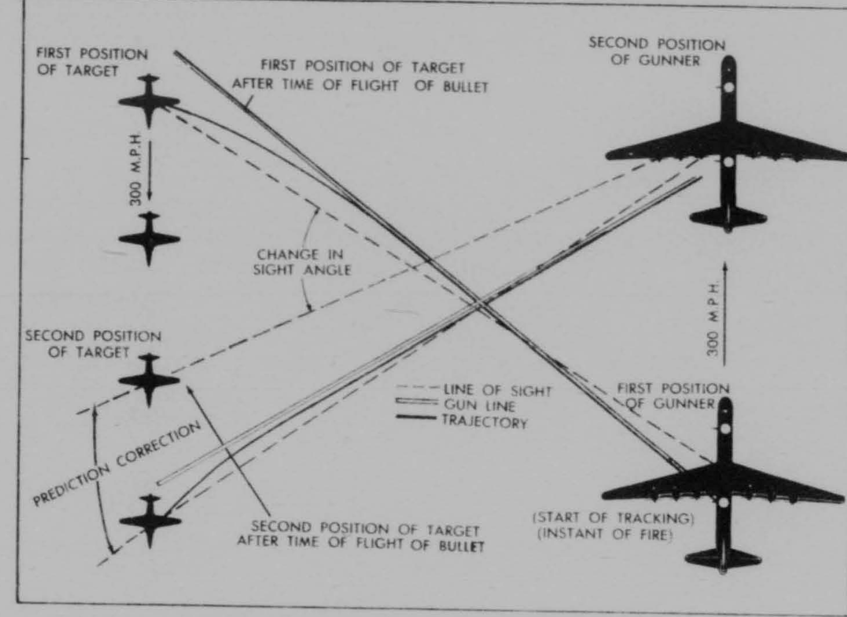

Figure 2–107. Prediction Correction.

"lead prediction." With the proper prediction correction, both the projectile and the target travel to the meeting point during the time of flight of the projectile.

Inputs Required. In order to calculate the prediction correction, the computer must obtain the following information:

Movement of the sight after the trigger is pressed; which requires an indication of the initial sight position, and a measure of its movement away from that position.

A time interval during which the change in sight angle is to be measured. This is a function of time-of-flight and attack factors, which are determined by: characteristics of the ammunition used; range of the target; air density (a function of altitude and temperature); ballistics, as it affects time-of-flight of the projectile; and gun azimuth position.

Totalizing Corrections. All ballistic, parallax, and prediction corrections are added together and appear as a single total correction.

Figure 2-115. Present Target Position.

A deflection of the projectile is caused by gravity (Figure 2-108). The vertical ballistic correction (Figure 2-109) is necessary to correct for this deflection.

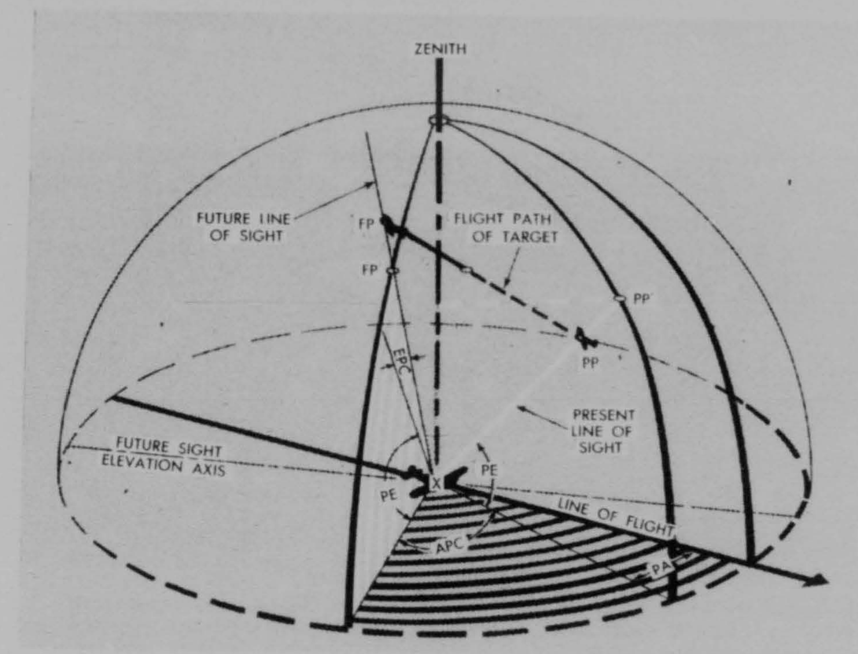
A deflection is caused by windage (Figure 2-114). To offset this it is necessary to introduce a lateral ballistic correction (Figure 2-111).

Parallax correction is also required (Figure 2-112). This is added to the ballistic correction to give the lateral ballistic and parallax correction (Figure 2-113).

The total lateral correction is the sum of the ballistic and parallax corrections and the prediction correction (Figure 2-114).

Corrections During a Burst of Fire. Ballistic and parallax corrections are continuously computed and continuously entered into the remote-control system, while the computer is in operation. However, to prevent setting up large false lead corrections, lead (prediction correction) is computed only when the trigger is pressed (because this is the period when the gunner is likely to be "on target," and tracking smoothly).

Geometry of Lead Computation. When the trigger is pressed to begin a burst of fire, the gun position is corrected only for ballistics and parallax. For the projectiles to hit the target, the prediction correction (lead) must also be computed and added to the other corrections. The prediction correction is computed from the change in target position during a given time interval (which is a function of the time of flight) immediately after the trigger is pressed. The following explanation of lead computation concerns this period from the instant the trigger is pressed until the first correctly aimed projectile is fired.



EPC ELEVATION PREDICTION CORRECTION
APC AZIMUTH PREDICTION CORRECTION

▭ ELEVATION
▬ AZIMUTH

Figure 2-116. Future Target Position.

The position of the target at the instant the trigger is pressed is called the "present" position of the target, and the position of the target when the first correctly aimed projectile is fired is called the "future" position of the target. Accordingly, the lines from the sight to the target at these two positions are called the "present" line of sight and the "future" line of sight. The angle between the present and future lines of sight is called the "total prediction correction," or "lead angle."

The gunner's airplane is shown at the center of a sphere (Figure 2-115), with the line of flight indicated by the arrow. The present position of the target is indicated by the airplane marked PP. Its advanced, or future, position along its flight path is marked FP (Figure 2-116). The radius XPP of this sphere is such that a plane perpendicular to the present line of sight XPP and containing the future target position FP is just tangent to the sphere at point PP (Figures 2-117 and 2-118).

To calculate the correct lead angle, the path of the target relative to the gun must be known during the time of flight of the projectile. Since the path of the target during a given time interval is a straight line, the position of the target can be completely determined by three polar space coordinates, each as a function of time. Since both the gun turrets and sights are mounted to move vertically in elevation and horizontally in azimuth, all corrections must be made in these two directions.

Figure 2—117. Projection of Target Path on Tangent Plane.

The line of flight of the gunner's airplane is considered as zero degrees azimuth and zero degrees elevation, and all target positions are measured from that reference point. The present target position is measured, from zero degrees elevation and zero degrees azimuth, by the number of degrees the sight must be rotated in azimuth, or raised in elevation, to line up with the target.

Two vertical planes through the zenith may be drawn (Figure 2-115), one passing through the line of flight and the other through the present target position. The angle between these two planes is the azimuth position of the target and is denoted by the letters, PA.

The sight elevation axis is perpendicular to the vertical plane through the present target position and the angle of present elevation of the sight about this axis is denoted by the letters PE (Figure 2-115). The elevation angle PE, which brings the sight into alignment with the target, is the elevation sight position. If the guns were fired directly at the present target position (even if the trajectory of the projectiles were a straight line), the projectiles would miss the target since the target would be traveling towards its advanced position FP while the projectiles were traveling from the guns to the present position of the target PP. This makes it necessary to point the guns ahead of the target so that the projectile and target both reach the point FP at the same time. In addition to this, it is necessary to make all ballistic, parallax, and range corrections.

The future position of the target (Figure 2-116) is at an azimuth position PA plus APC and an elevation position PE plus EPC. APC is the change in azimuth position and EPC is the change in elevation position of the sight,

changes necessary to align the sight with the future target position; they are the angles through which the sight mut be moved, in azimuth and in elevation, from the present target position to the future target position.

The movement of the sight necessary to follow the projection of the target path PP-FP (Figure 2-117) on the tangent plane is resolved into vertical and lateral components PP′-V and PP-L. These are measured as vertical prediction correction angle VPD and lateral prediction correction angle LPD. The angles lie in the vertical and lateral planes through the present target position.

It is emphasized that the vertical and lateral deflection angles VPD and LPD are not the same as the change in target azimuth and elevation correction angles APC and EPC (Figure 2-118).

Range is computed continuously, but no prediction corrections are made for any change in range between the present and future target position.

All ballistic and parallax computations by the computer are calculated separately as vertical and lateral deflections from the actual gun position and the future target position.

THIS PAGE IS DECLASSIFIED IAW EO 13526

These vertical and lateral deflections are measured in two planes, a vertical plane through the gun line, and a lateral plane which contains the gun line and which is perpendicular to the vertical plane through the gun line.

From the preceding discussion is seen that all ballistic and parallax corections are calculated as vertical and lateral deflections from the actual gun position to the future target position, while lead prediction is calculated as vertical and lateral deflections from the present line of sight to the future target position. The only possible correcting movements of the gun, however, are in elevation and azimuth. This necessitates conversion between these two sets of vertical and lateral deflection angles and the actual correction angles; this, is the function of the axis converter and the total-correction unit.

The free-gyro computer computes prediction from the fact the target will move through very nearly the same angle in any two consecutive equal intervals of time. This angle is determined during one such interval. In this system, the guns fire during the first interval, the projectiles raking across the target's path, as the theoretical solution is reached and held during a recomputing cycle.

Source of Compuier Inputs. All inputs to the computer are supplied from the following sources:

The altitude-and-airspeed handset supplies a signal proportional to the windage effect on the projectile.

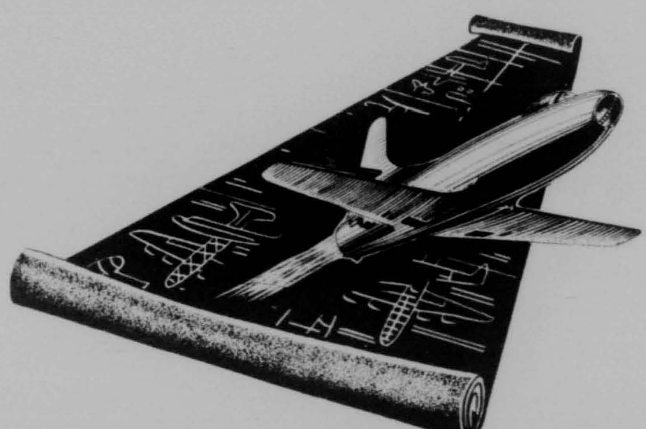
The Selsyn control circuit to the computer supplies sight-elevation, sight-azimuth, gun-elevation, and gun-azimuth position indications.

The radar set supplies range information for the tail system, only.

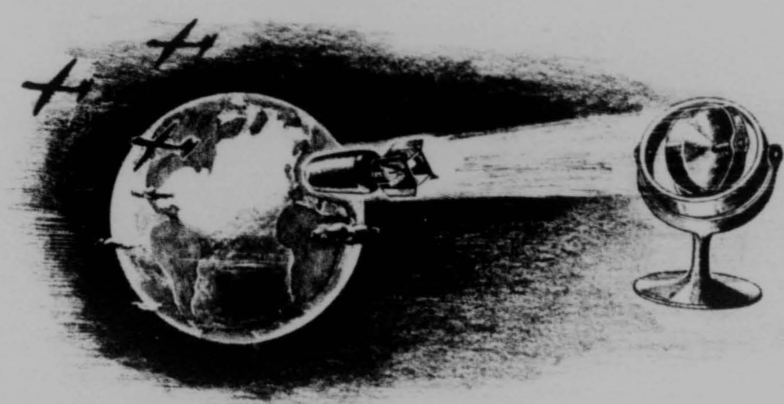
The retiflector sight on the sighting station supplies range information for all turrets other than the tail turret.

A gyroscope, which is mounted on the antenna assembly (radar) or the sighting station, supplies lead information. The gyroscope measures the angular movement of the tracking axis in the vertical and lateral planes during a time-of-flight interval.

The computer itself calculates the gravity correction. This is added to the ballistic and parallax corrections and to the lead prediction, to give the total-correction output which is required by the gun turret in order that its projectiles hit the target.



CHAPTER 3—GYRO PRINCIPLES, THEORY OF BOMBING



SECTION I—GYRO PRINCIPLE—PHENOMENA OF THE GYROSCOPE

1. GENERAL

The word gyroscope is of French origin. One of the first authorities on the subject of gyroscopic phenomena was Leon Foucault, a French scientist, who in 1852 succeeded in producing a gyroscope with which he was able to study the earth's rotation. There is nothing mysterious about the gyroscope, more commonly called "gyro". All of the practical applications of the gyro are based upon two fundamental characteristics, namely "gyroscopic inertia" and "precession". A gyroscope is simply an accurately-balanced, spinning flywheel. The flywheel spins about its central axis, which passes through its center of gravity, and it is so mounted that it is free to turn or tilt in any direction about this center of gravity and will maintain its spin axis in the same direction unless some outside force is applied to it (see Figure 3-1).

2. CHARACTERISTICS OF THE GYROSCOPE

Rigidity

One of the gyroscope's two special characteristics is gyroscopic inertia or rigidity. Gyroscopic inertia, or rigidity in space as it is sometimes known, is the tendency of any rotating body to preserve its plane of rotation. For example, a hoop when set in motion will keep on rolling approximately in a straight line if undisturbed, instead of tipping over as it would if not revolving. This characteristic is the result of the action of forces affecting the state of rest and motion of a gyroscope in the manner expressed by Newton's first law of motion. This law states that a body continues in its state of rest or of uniform motion in a straight line, unless it is compelled by forces to change that state. This

THIS PAGE IS DECLASSIFIED IAW EO 13526

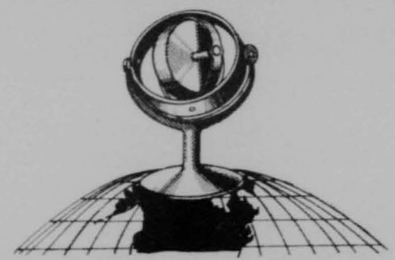


Figure 3—1. Gyroscope.

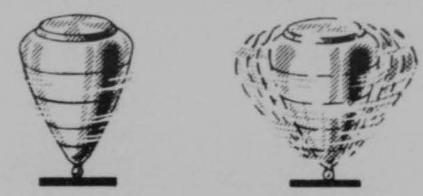

Figure 3—2. Characteristics of a Gyroscope.

law, as applied to a rotating wheel, may be expressed by stating that a rotating wheel tends to maintain its plane of rotation in space and the direction of its axis in space. Three factors determine a gyroscope's strength or amount of rigidity: the weight of its wheel or rotor, the distribution of its weight, and the speed at which the rotor spins. Thus rigidity may be increased by adding to the weight of the rotor; a gyro with a heavy rotor will have more rigidity than one with a light rotor if their speed is exactly the same. Increased rigidity may be obtained if the weight of the gyro is distributed to the outer rim of the wheel or rotor, as far from the spin axis as possible, yet without actually increasing the weight of the rotor. Rigidity is also increased if the speed of the rotor is increased. A slowly spinning rotor gives the gyro little or no rigidity. An example is a boy's top which wobbles and then falls over on its side when its speed of rotation decreases (Figure 3-2).

Apparent Precession

Because rigidity makes the gyro's spin axis fixed in space, (the axis will point in a fixed direction) the earth, which is actually rotating, turns under the gyro, and the axis of the gyro appears to tilt. (See Figure 3-3.) A gyro whose axis is vertical at six o'clock in the morning appears to be horizontal at noon and upside down at six o'clock in the evening. This creates the illusion that the gyro has turned over, end for end, and a complete revolution will be made every twenty four hours. Actually, however, the gyro has maintained its position in space, and the earth has moved around it. This movement of the earth in relation to the gyro is called "apparent precession". The greatest amount of apparent precession is at the equator. There, in four minutes a gyro will apparently precess 17.45 mils. The amount of apparent precession decreases as the gyro is moved toward the north or south poles, where apparent precession is zero. It can be determined, in mils, the amount of apparent precession that takes place in four minutes in any latitude, by using this equation: 17.45 x cosine of the latitude. Apparent precession of a gyro makes it unfit for use as a reference over an extended period of time without some sort of compensating or correction mechanism. Over a relatively short period of time, however, a gyro may be used to establish a satisfactory reference, as in the various gyro-stabilized instruments used by the armed forces today. One should remember that in apparent precession, the earth moves in relation to the gyroscope. However, the gyroscope may be made to move in relation to the earth, and this is called "induced precession".

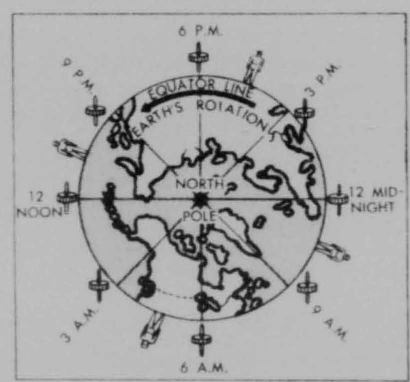

Figure 3—3. Apparent Precession.

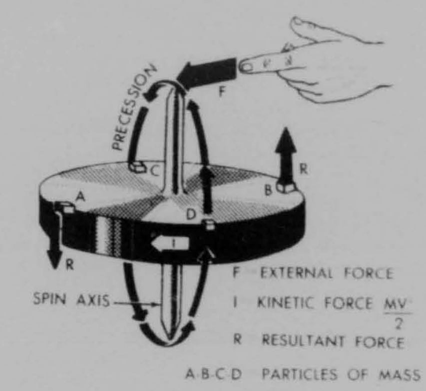

Figure 3—4. Gyroscopic Precession.

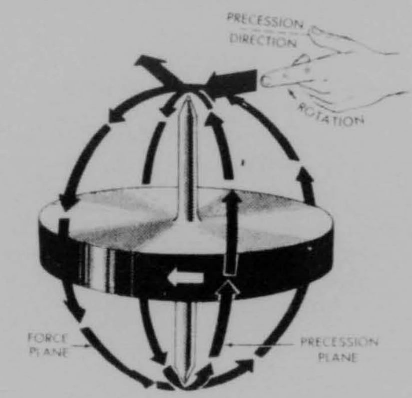

Figure 3—5. Hand Rule for Precession.

Induced Precession

The rigidity of a gyroscope resists any force applied which would tip its axis in any direction. When enough of a tipping force is applied to overcome this rigidity, the spin axis will tip, but not in the direction of the force, as would be expected. Instead the axis tips at right angles to the applied force and in the direction of the gyro's rotation. This peculiar action is called gyroscopic precession and is also exhibited by the rolling hoop. If we wish to change its direction of travel, we do not press against the rim at the front or back, but at the top, as though we intended to tip it over about an imaginary horizontal axis. The hoop resists this pressure and turns about a vertical axis which is at right angles to the axis about which the pressure was applied. Precession may be illustrated by applying a force or pressure to the gyro about the horizontal axis. It will be found that the applied pressure meets with resistance and that the gyro instead of turning about its horizontal axis, turns or precesses about its vertical axis. Similarly, if we apply a pressure about the vertical axis the gyro will precess about the horizontal axis. If there were a complete absence of inertia and friction about the precessional axis, the rate of precession would be such that the resistance of the gyro would be exactly equal to the applied pressure at any instant. No movement from this pressure could ensue until the gyro precessed so that its plane of rotating coincided with the plane of the plane of the applied pressure. Then the precession would cease and with it all resistance to the applied pressure. For explanatory purposes (see Figure 3-4), consider the effect of this external horizontal force, applied to the top of the gyro spindle, on selected particles of mass, A, B, C, and D, which at a given instant are in the position shown. The force applied at the top of the spindle, tending to tip the spindle about the force axis is equivalent to a downward force acting on particle A, and an upward force on particle B. No force, however, is exerted on particles C and D because they are in the force axis. However, these particles are spinning rapidly, and they are influenced by the forces of inertia which tend to make the particles move in a straight line I as shown at A and B. The resultant of the two forces I and F acting on particle A is represented by the arrow R, which can be seen to slant downward while the resultant of the forces at B slants upward. Therefore, as particle A revolves, it drops lower and lower until it reaches point C. At this point the applied force ceases to have a downward effect and begins to have an upward effect on particle A. Particle B reacts in the opposite way, with the result that the entire gyro tips at right angles to the applied force.

3. HAND RULE FOR PRECESSION

A good way to remember the direction in which a gyro will precess when an external force is applied is by hand rule shown in Figure 3-5. Using either hand, place the fingers in the direction of rotation and extend the index finger in the direction of the applied force. The thumb will then extend in the direction of precession. It is apparent from the preceding explanation of gyro precession, that if a force were applied to the gyro at the center of gravity it would not act to tip the gyro axis from its established position and therefore, no precession would take place. Thus a spinning gyroscope can be moved in any direction as easily as a gyro at rest, provided its spin axis remains parallel to its original position in space. The gyro, therefore, provides stability only against tipping its spin axis. It is also apparent that a spinning gyroscope can be used to provide stabilization only in planes containing its spin axis, and for complete stabilization in every plane, two gyroscopes, having their spin axis at right angles to each other, are required. This is why, as will be discussed later, both a horizontal gyro (in the stabilizer unit) and a vertical gyro (in the bombsight unit) are required to give complete stabilization to the optical system of the bombsight.

SECTION II—THEORY OF BOMBING

1. INTRODUCTION

It is impossible to outline briefly the improvements that have been made in bombsights and other bombing equipment in the past twenty-five years. To design an accurate bombsight required years of trials. Discouragements were many and progress slow. With the bombsight completed it took the best efforts of American industry to learn how to build these intricate devices to the close tolerances required, and in the large numbers called for by global war. Avoid the common impression that the bomb-sight is a superhuman, magic-brain device. True, it is an ingenious, precision mechanism, but it definitely is not a miracle machine which requires a miracle man to operate it; nor is it a device which relieves its user of all responsibility. What it does is to solve understandable problems in an understandable manner. Other equipment used includes the electronic copilot, which holds the airplane on its course; the computers, which save the time and trouble of making paper and pencil calculations; the intervalometer, which enables the bombardier to drop a train of accurately-spaced bombs, and oxygen equipment which makes possible ascents to altitudes higher than man ever went before. With the modern bombsight, that great group of men, the bombardiers, have proved beyond question the ability of the air force to pin-point ammunition dumps on tiny atolls in the Pacific, to destroy ships at sea, to blast bridges and communication lines far beyond artillery range, and to lay a ruinous pattern of fire and explosives on ANY of the enemy's industrial areas.

2. THEORY OF BOMBING

Before the invention of airplanes, the principal means of dropping explosives upon the enemy was the long-range cannon. An airplane, in effect, advances the range of a cannon. Bombing is really aerial artillery. To make a shell drop on a certain point, a cannon must hurl it up into the air, so that the path of the shell, or the trajectory, describes a wide arc in its flight through the air. The essential difference between firing a shell and dropping a bomb is that the airplane carries the bomb up into the air and releases it at the highest point of the trajectory. From that point on, the bomb follows the same downward path as the shell (see Figure 3-6). To make the bomb hit the target, the only thing that has to be done is to find the proper point in space from which to release it. Actually, the bombsight will find this point and release the bomb, provided that the proper data are put into it. A

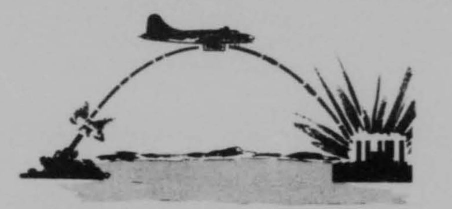

Figure 3—6. Aerial Artillery.

thorough study of bombing theory, however, will show what data must be set into the sight, how it is set in, and how the bombsight uses it to solve the bombing problem. The bombing problem has two parts; the course problem and the range problem. Course means that the bomb must travel in the right direction, that is, toward the target. Range means that it must be released the correct distance back from the target or over it. The course problem is fairly simple. A bomb always falls in the direction in which the airplane is headed at the moment of release. Therefore, the course problem is solved by putting the airplane on the correct heading. To understand the range problem, something must be known about falling bodies.

3. FORCES ACTING ON THE BOMB

General

The moment a bomb is released from an airplane, a number of forces begin acting upon it. These forces are: **gravity; airspeed; air resistance,** and **wind.** (See Figure 3-7). The result of these forces determines the path the bomb will follow and the point of impact.

Gravity pulls the bomb toward the earth at a continually increasing speed. It exerts the same force on all bodies, whatever their size, shape, or weight.

True Airspeed

At the same time that gravity is pulling the bomb downward, velocity is driving it forward. The airplane is traveling at a definite speed with respect to the air, and since the bomb is a part of the airplane up to the moment of release, it leaves the airplane with the same forward velocity. In bombing, this forward velocity of the airplane and the bomb relative to the air is called true airspeed (TAS). Gravity and true airspeed are acting on the bomb at the same time. During the time between release and impact the bomb follows a path between the direction of these two forces. This time is called actual time of fall (ATF).

Air Resistance

The third force affecting the bomb in its flight is one which acts against the first two. This force is air resistance. While true airspeed is driving the bomb forward, the air through which the bomb moves is resisting this motion. In other words, the air pushes back against the bomb, causing it to lag behind the airplane. The distance on the ground resulting from this resistance to the forward motion of the bomb is called horizontal lag. In the same way, air resistance acts against the force of gravity. This resistance tends to keep the bomb in flight longer. During the extra time required for the bomb to fall, the airplane continues to move forward. The distance on the ground over which the airplane travels during this extra time is called vertical lag.

4. BOMBING TERMINOLOGY

Trail

The sum of these two distances on the ground is called trail (T). This is a good name for it, since it is the distance the bomb has trailed behind the airplane that dropped it. Trail is the horizontal distance measured on the ground from the point of impact to a point directly beneath the airplane at the instant of impact. The amount of trail for various bombing altitudes, true airspeeds, and types of bomb has been determined by experience and is given in bombing tables. Trail is the result of several forces which are acting on the bomb. While true airspeed is driving the bomb forward, air resistance is tending to hold it back; while gravity is pulling it down, air resistance is tending to hold it up. If true airspeed increases, the resistance of the air increases; thus the horizontal lag is greater.

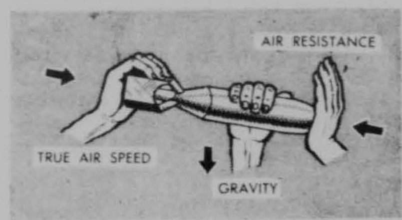

Figure 3–7. Forces Acting on Bomb.

Therefore, as true airspeed increases, trail increases. In the same way, if the downward velocity increases, the resistance of the air to that force increases and the vertical lag is greater. Since the downward velocity depends on the bombing altitude from which the bomb is dropped. As bombing altitude increases, trail increases. The amount of resistance which the air offers to the bomb depends on the size and shape of the bomb. Ordnance engineers classify bombs into different types according to the ballistic coefficient of the particular bomb, which means the relative amount of resistance the air offers to it. A bomb with a high ballistic coefficient falls faster and with less trail than a bomb with a low ballistic coefficient. Therefore, as ballistic coefficient increases, trail decreases.

Actual Time of Fall

The actual time of fall (ATF) of the bomb depends primarily on the exact height of the airplane above the target, or the vertical distance which the bomb must fall. It is also affected by true airspeed and bomb ballistics. The actual time of fall for each bombing altitude, true airspeed, and type of bomb has been determined by trial and error and is given in bombing tables. **ATF increases as bombing altitude increases; true airspeed increases; ballistic coefficient decreases.** Trail and actual time of fall are the two factors which must be set into the bombsight. The actual time of fall is set into the M-Series bombsight as a disk speed, but when some other sights are used, the actual time of fall is set in directly. Trail is set into the bombsight as a mil value. The tables give the correct actual time of fall or the correct disk speed for each bombing altitude, true airspeed, and type of bomb. Similarly, the tables give the correct trail for each bombing altitude, true airspeed, and type of bomb. Therefore, before the sight can do anything, the bombing altitude, true airspeed, and type of bomb must be accurate. When correct trail and actual time of fall have been obtained from the tables and have been set into the bombsight, it must be synchronized for course and range. If these few things are done correctly, the bombsight will automatically solve the bombing problem. It will find the correct point in space for the bomb release, and will release the bomb at that point. (See Figure 3-8.) Before considering wind, the fourth and final force on the bomb in its downward flight, fundamental bombing terms must be understood.

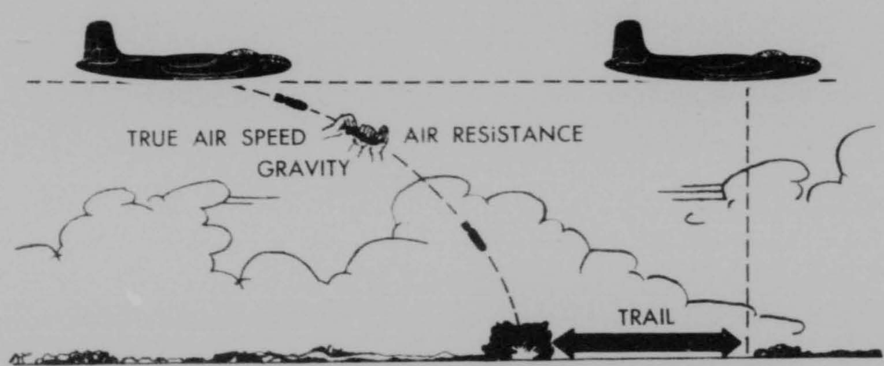

Figure 3–8. Bomb Release and Trail.

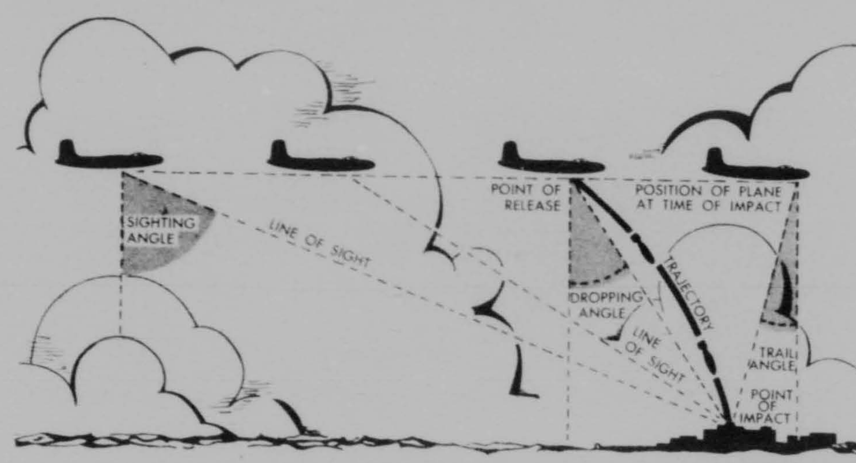

Figure 3–9. Factors in Bombing.

Whole Range and Groundspeed

Whole range (WR) is the horizontal distance traveled by the airplane from the moment the bomb is released until the bomb strikes the ground. To measure the distance covered by a moving object in a given time, the time is multiplied by the rate at which the object is moving. Whole range is measured on the ground. Therefore, the rate used is the rate at which the airplane is moving with respect to the ground. This rate is called groundspeed (GS), and in computing whole range, groundspeed must be in feet per second. The time used is the actual time of fall, and it is given in seconds. Therefore:

$$WR = GS \text{ (ft/sec) } X \text{ ATF}$$

A bomb is dropped from an airplane traveling at a groundspeed of 150 miles per hour. The bomb takes 20 seconds to reach the ground. In order to find the whole range, the groundspeed of 150 miles per hour must first be changed to feet per second. To do this, multiply 150 by:

$$\frac{5{,}280 \text{ (ft in a mile)}}{3{,}6000 \text{ (sec. in an hr.)}} \quad \frac{88}{60} \text{ or } \frac{22}{15}$$

The groundspeed in this problem is therefore 220 feet per second. Then $220 \times 20 = 4{,}400$ ft. whole range. In other words, the airplane flies 4,400 ft. while the bomb is falling.

Actual Range

Actual range (AR) is the horizontal distance that the bomb travels from the moment of release until the moment of impact. Since the bomb lags a certain distance behind the airplane (trail) actual range can be found by subtracting trail from whole range.

$$AR = WR - T$$

If the whole range is 4,400 ft. and from bombing tables, it is found that the trail is 270 ft. the actual range is 4,130 ft. While the airplane is traveling 4,400 ft. forward, the bomb travels only 4,130 ft. forward. See Figure 3-9.

Line of Sight

Whenever the target is looked at through the bombsight, vision follows a line, from bombsight to target, which is called the line of sight. As the airplane moves toward the target, the line of sight changes. When the proper course toward the target has been set up the actual range has yet to be found, that is, the correct distance back from the target that the bomb must be released in order to score a hit. If the proper data is set into the bombsight, it solves the problem automatic-

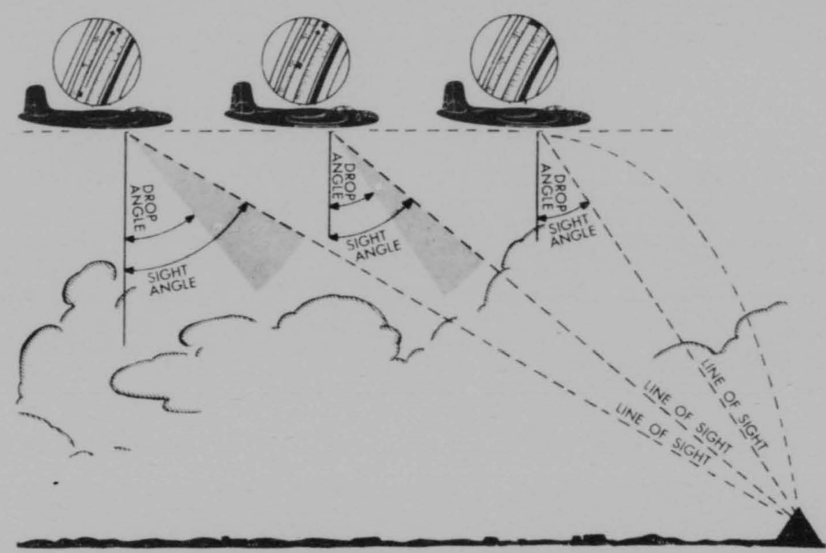

Figure 3–10. When Sighting ∠ Equals Drop ∠, Bomb is Released.

ally. It measures an angle which subtends actual range, thereby locating the proper point in space for the bomb's release.

Sighting Angle

To do this, the bombsight sets up a vertical line of reference between iself and the ground. The angle between this vertical reference and the line of sight at any instant is called the sighting angle. As the airplane approaches the target, the line of sight sweeps toward the vertical and the sighting angle grows smaller.

Dropping Angle

The particular sighting angle set up by the bombsight at the instant of release is called the dropping angle (Drop ∠). The dropping angle is the angle formed between the line of sight and the vertical reference at the instant the bomb drops from the airplane.

True Vertical and Bombsight Vertical

If the bombsight is operated correctly, it will establish as the vertical line of reference a line which is exactly perpendicular to the ground. If the bombsight is not operated correctly, the line of reference it sets up will not be true vertical. The sighting angle and the dropping angle are measured from the vertical reference set up by the bombsight, whether this is the true vertical or not. See Figure 3-10.

Range Angle

The range angle is the angle between the line of sight and the true vertical. At the instant of release, this angle differs from the dropping angle by the amount the vertical reference is out of the true vertical.

Actual Range Angle

The actual range angle (AR ∠) is the angle which subtends the actual range of the bomb. This means that the lines which form the angle strike off on the ground the actual range distance. If the bombsight sets up to a true vertical reference and the bombing problem has been properly solved, the dropping angle is the same as the actual range angle and also subtends the actual range of the bomb.

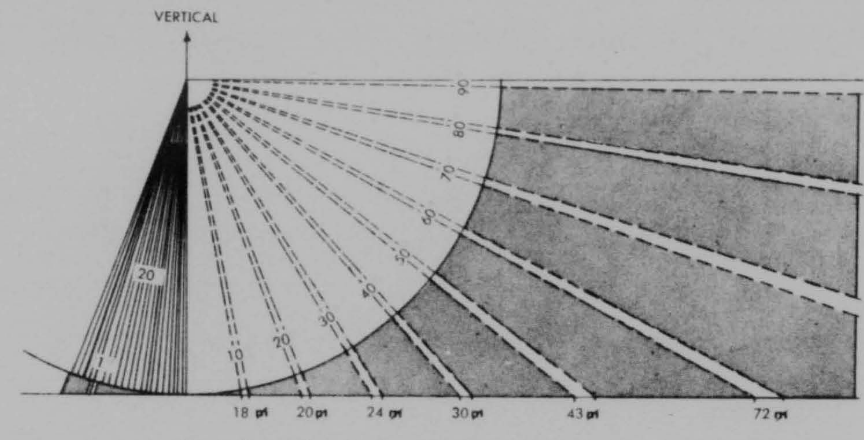

Figure 3–11. Dropping Angle Tangent.

Whole Range Angle

The whole range angle (WR ∠) is the angle which subtends whole range. It is measured from the true vertical at the instant of release.

Trail Angle

The angle which subtends trail is called the trailangle (T ∠). In bombing, trail is given and used in terms of mils.

Tangent Values of Angles

Angles can be measured by using what is called the tangent of the angle, and this is the method the bombsight uses. The tangent of an angle in a right triangle is the number resulting when the length of the side opposite the angle is divided by the length of the side adjacent to the angle.

$$\text{Tangent} = \frac{\text{opposite side}}{\text{adjacent side}}$$

Reading Angles From the Bombsight

The particular tangent which can be read from the bombsight is the tangent of the dropping angle (Tan Drop ∠). The side opposite the dropping angle is the actual range, and the side adjacent to the dropping angle is bombing altitude (BA). (Figure 3-11). Therefore:

$$\text{Tan Drop}\angle = \frac{AR}{BA}$$

In the same way:

$$\text{Tan T}\angle = \frac{\text{T (in ft.)}}{BA}$$

Since the trail angle is comparatively small, it is measured in mils rather than in degrees. A mil is an angle whose tangent is 0.001. An angle of 3 mils has a tangent of 0.003; an angle of 35 mils has a tangent of 0.035. One mil subtends a distance on the ground equal to 1/1,000 of the BA. At 1,000 ft. BA, 1 mil of trail subtends 1 ft. on the ground. At 8,000 ft., 50 mils of trail subtends 400 ft. Therefore:

$$(\text{Tan T}\angle) = \frac{\text{T (in mils)}}{1{,}000}$$

$$\text{T (in ft.)} = \frac{\text{T (in mils) BA}}{1{,}000}$$

THIS PAGE IS DECLASSIFIED IAW EO 13526

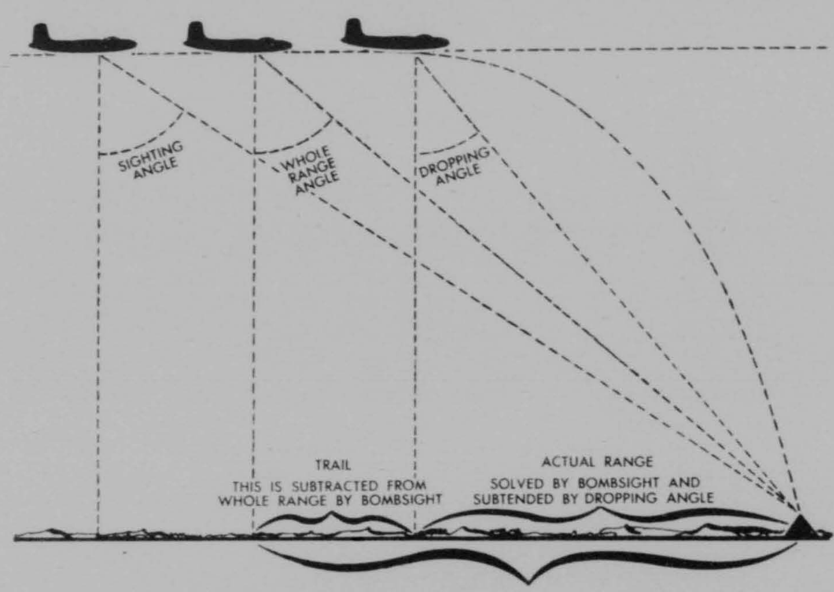

Figure 3—12. Whole Range Solved by Bombsight from GS x ATF.

Since whole range equals actual range plus trail, then:

$$\frac{WR}{BA} = \frac{AR}{BA} + \frac{T}{BA} \quad \text{Therefore:}$$

$$\frac{WR}{BA} = \text{Tan Drop} \angle + \text{Tan T} \angle = \text{Tan WR} \angle$$

When the whole range that the bombsight has measured is desired it must be computed from the tangent of the whole range angle which subtends it. The tangent of the whole range angle is found by adding the tangent of the trail angle to the tangent of the dropping angle. The tangent of the dropping angle can be read directly from the bombsight. The trail angle is read and can be converted to a tangent value by dividing by 1,000. The tangent of the whole range angle is equal to the whole range divided by the bombing altitude. Therefore:

$$NR = \text{Tan WR} \angle \times BA$$

5. SOLUTION OF THE RANGE PROBLEM

It is necessary to know the bombing altitude, true airspeed, and type of bomb to find from the bombing tables the trail and actual time of fall to set into the bombsight. By keeping the line of sight on the target, groundspeed is solved. This is called range synchronization. The actual time of fall set into the bombsight is automatically multiplied by the groundspeed obtained through synchronization to solve for whole range. During this operation the trail that was previously set into the sight is automatically subtracted from whole range, leaving the measurement of actual range. During this operation the bombsight sets up the dropping angle which subtends this actual range. When sighting angle reaches dropping angle, the bomb is released automatically. See Figure 3-12.

Headwinds and Tailwinds

In addition to gravity, forward velocity,

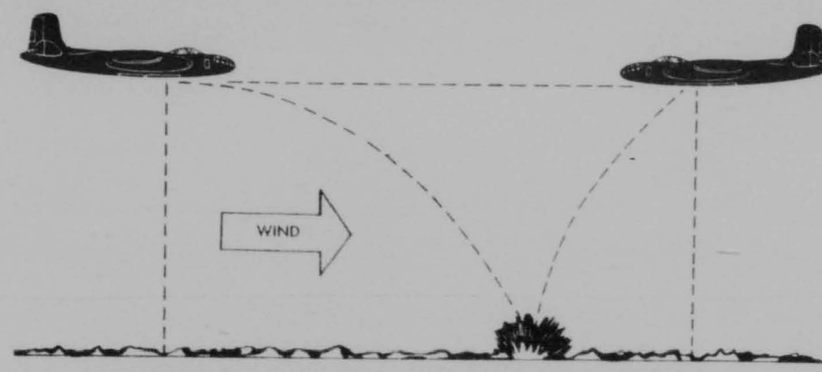

Figure 3—13. Solution of the Range Problem.

and air resistance, there is a fourth force acting on the bomb in its flight and affecting its trajectory. This is the speed of the wind. Consider first the simplest wind conditions; tailwinds and headwinds. The first thing to notice about a headwind or tailwind is that it does not affect the true airspeed of the airplane. Since trail depends only on true airspeed, bombing altitude, and type of bomb, neither a headwind nor a tailwind has any effect on the amount of trail. Groundspeed is the factor which is affected by a headwind or a tailwind. If an airplane is flying at a true airspeed of 150 miles per hour, with a tailwind which pushes the air forward at 10 miles per hour, then the airplane's speed over the ground is 160 miles per hour. Since whole range is found by multiplying groundspeed (in feet per second) by the actual time of fall, an increase in groundspeed causes an increase in whole range. Actual range is also increased, since actual range is found by subtracting trail from whole range. Therefore a tailwind causes an increase in whole range and a corresponding increase in actual range. See Figure 3-13. When actual range is increased, the bomb must be dropped at a greater distance from the target in order to hit it. This means that the dropping angle must be greater. When there is a tailwind the bombsight sets up a dropping angle with a larger tangent. When the airplane flies directly into a headwind, all these results are reversed. The groundspeed is less, and the actual range is smaller. The bombsight therefore sets up a smaller tangent of the dropping angle.

Crosswinds

When the wind comes from any direction except from dead ahead or directly behind the airplane, drift enters the bombing problem. Wind is the movement of the entire body of air surrounding the airplane. When the wind moves to the right, the airplane moves to the right. Similarly, if the body of air is moving to the left, the movement of the airplane is described as left drift. To make good a certain path over the ground (true course) when there is a crosswind, the pilot crabs the airplane into the wind. That is, he heads the airplane upwind sufficiently to compensate for the effect of drift. The angle formed between true heading and true course is called the drift angle. At the moment of release, true airspeed is driving both the airplane and the bomb in the direction of heading. Immediately on release, air resistance begins to reduce the forward velocity of the bomb. The engines, however, continue to drive the airplane forward at the same true airspeed as at bomb release. The speed of the wind causes both airplane and bomb to drift the same distance away from the true heading. Therefore, the bomb always

THIS PAGE IS DECLASSIFIED IAW EO 13526

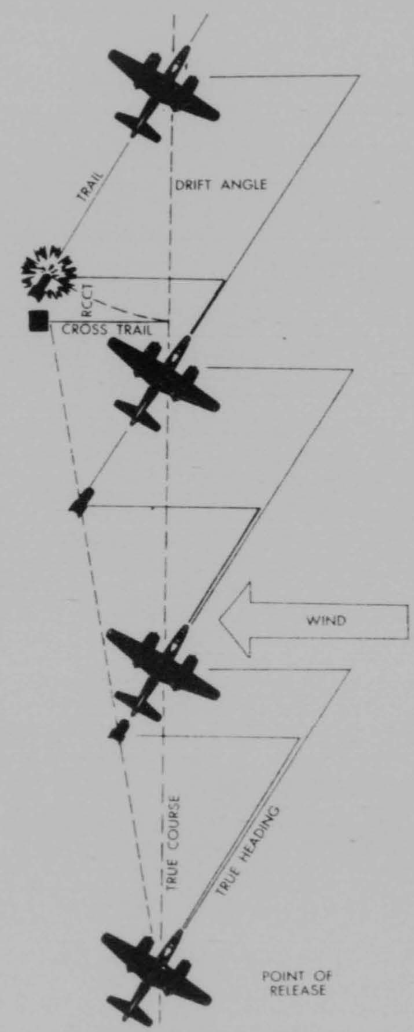

Figure 3—14. Influence of Crosswind on Bombing.

lags behind the airplane in the line of heading. The bomb will strike the ground behind the airplane, along the longitudinal axis of the airplane, and downward of true course. See Figure 3-14.

Crosstrail

If the airplane made good a true course which would pass directly over the target (a collision course), the bomb would strike the ground downwind of the target. The airplane must, therefore, make good a true course upwind of the target. The distance between the true course of the airplane and the collision course is called crosstrail (CT). Crosstrail is measured from the point of impact to the true course. The bombsight automatically measures crosstrail. Crosstrail depends on trail and drift. To make its computation, the bombsight uses what is called the sine of the drift angle. The sine of an angle in a right triangle is the sine of the drift angle. The sine of an angle in a right triangle is the number resulting when the opposite side is divided by the hypotenuse. The side opposite the drift angle is the crosstrail; the hypotenuse is the trail. Hence the sine of the drift angle is the crosstrail divided by trail. Therefore:

$$CT = T \times \text{Sin Drift}$$

The bombsight can compute crosstrail because trail has been set into it. Automatically the drift angle has been set up when the course is set. Naturally, if there is no drift there will be no crosstrail. In the same way if trail is not set in, the bombsight cannot compute crosstrail. Therefore trail MUST be set; if not the bomb will fall not only short but also downwind of the target.

RCCT

One final fact about the effect of crosswind on the bombing problem must be noticed. In the crosstrail drawing, Figure 3-14, the point of impact of the bomb is shown a small distance over the target. Although the distance is exaggerated in the drawing, nevertheless this error is always present in all computations performed by modern bombsights whenever a crosswind is present. The error is called range component of crosstrail (RCCT). It results from the fact that the bombsight measures trail along the course of the airplane,

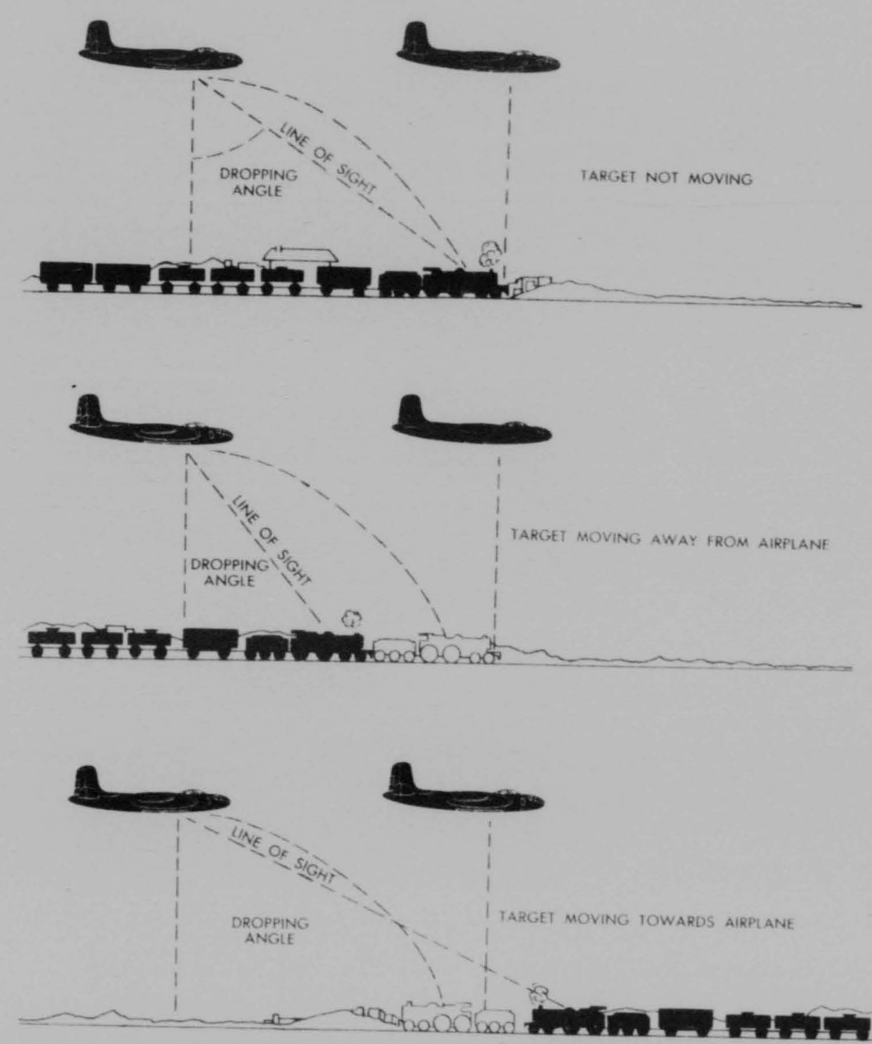

Figure 3—15. Bombing Stationary and Moving Targets.

whereas when there is a crosswind, trail actually occurs along the line of heading. When there is no crosswind, heading and course coincide; there is no crosstrail and no RCCT. But when wind and crosstrail exist, the bombsight still measures trail along the course. If the distance is measured from a point on the ground directly beneath the airplane at the moment of impact back along the course to a point opposite the target, the result is the trail as solved for by the bombsight. But if this same distance is measured back along the heading of the airplane, this trail distance does not reach the target. Instead, it reaches a point on the collision course ahead of the target. The distance from the target to this point of impact ahead of the target is the range error "over", known as RCCT. The equation for computing RCCT is:

$$RCCT = T\ (1 - \text{Cos Drift } \angle)$$

The RCCT depends on trail and the amount of drift. In low and medium-altitude bombing, trail and drift are usually small enough that the "over" caused by RCCT is negligible. RCCT produces significant errors when a high-speed bomber, flying at a high altitude, encounters a large drift. A moving target is often the object of attack. If the attack is made on a target which is moving in a straight line at a constant speed, no new element is introduced into the bombing problem. A target moving away from the airplane in the same line as the airplane's course presents the same problem as a stationary target when a headwind is blowing. Similarly, a target moving toward the airplane along the course is like a stationary target when a tailwind is blowing. Also a target moving in a straight line across the course presents the same problem as a stationary target with a crosswind blowing from the direction opposite to that in which the target moves.

A bombsight develops whole range, actual range, and dropping angle by analyzing the speed of closure between itself and the target, that is, the speed at which the distance between them is closed. When the target is stationary, the speed of closure is the same as the groundspeed of the airplane. When the target is moving, the speed of closure is the groundspeed of the airplane plus or minus the groundspeed of the target. When an airplane traveling at groundspeed of 150 miles per hour is overtaking a train retreating at 50 miles per hour, the airplane is actually closing with the train at a speed of 100 miles per hour. The bombsight solves for this speed of closure in setting up the dropping angle. When the train approaches the airplane, the speed of closure is 200 miles per hour and consequently the dropping angle is larger. See Figure 3-15. If the train moves in a straight line across the track of the airplane, the bombsight handles the situation just as if the target movement were drift caused by a crosswind. In fact, in setting up the course there is no difference between a left drift and an actual target motion to the right. In either case, the airplane must be crabbed to the right and a course set up to right of target. If the target is moving diagonally across the course and at the same time a crosswind is blowing, it would be very hard to determine the speed of closure mathematically. The bombsight automatically solves it and determines the correct course and dropping angle.

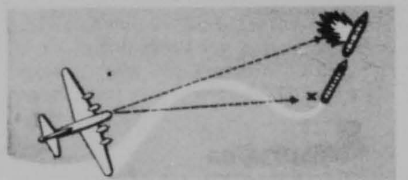

Figure 3–16. Bombing a Maneuvering Target.

However, there are two situations involving moving targets which the bombsight cannot handle adequately. First, if the target keeps changing its speed, the bombsight cannot synchronize for rate or determine the amount of crab required, and thus cannot set up the correct course of dropping angle. Second, if the target does not move in a straight line, the bombsight cannot set up either course or dropping angle accurately, since it has no means of predicting where the target will be at the time of impact. When trying to bomb a target which is maneuvering, the important element in solving the bombing problem is the experience of AF bombardiers. They have discovered that to hit a maneuvering target aim must be to the rear of the target movement and inside its turn. See Figure 3-16.

SECTION III—SYNCHRONOUS METHOD OF BOMBING

1. NORDEN BOMBSIGHT

The Norden or M-Series bombsight is a synchronizing, precision instrument. Synchronization means adjustment of flight path and travel of the optical system so that the bomb will be released at the proper point. The Norden sight is of American design and construction. There are several models in use, among them, the M-6, M-7, and M-9. The even-numbered models use 12 volts direct current; the odd-numbered models use 24 volts. The reasons for the voltage difference is that the newer bombers have 24-volt circuits. These four models are very much alike in principal and operation. The parts and steps to the Norden sight are inter-dependent. Each of them should be learned thoroughly. From study of the bombing problem, it is known what the bombsight must do. One must keep the bombing problem in mind by remembering that the sight solves the bombing problem only of the correct data is set in and the sight is properly operated and maintained. See Figure 3-17.

2. SIGHTHEAD

The bombsight has two main units, the sighthead and the stabilizer. The sighthead is attached to the stabilizer by a pivoting connection and two locking pins.

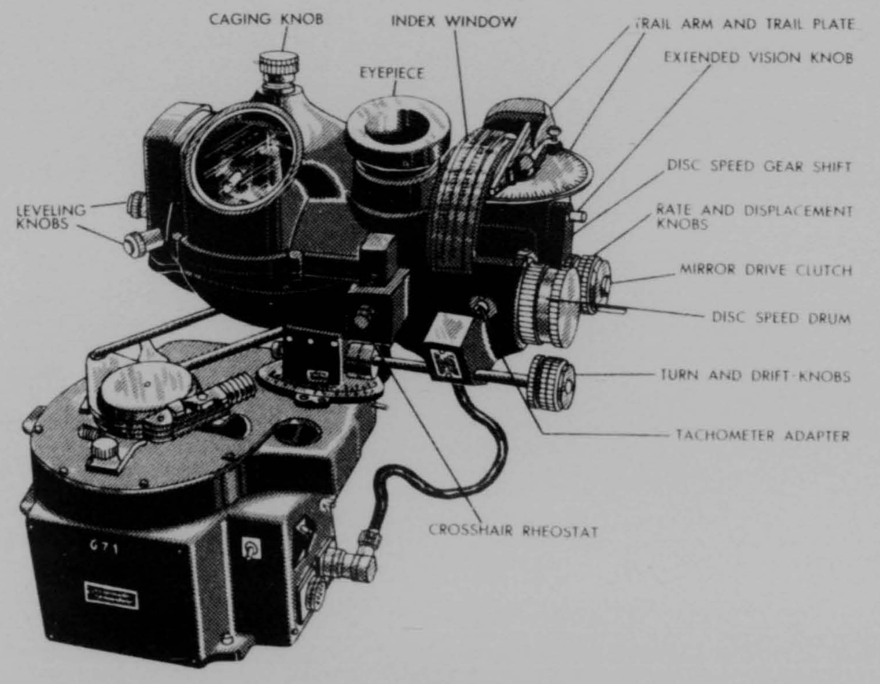

Figure 3–17. M-Series Bombsight.

Function

The sighthead's principal function, solving for range, is carried out by three main parts.

The rate end, which computes the exact release point for the bomb.

The optical system, through which the target is observed.

The vertical gyro, which stabilizes the optics so that roll and pitch of the airplane will not move the line of sight from target.

Solving the Range Problem

The rate end combines the values of ATF, groundspeed, and trail to compute the dropping angle. From the bombing tables are obtained the values of ATF and trail which are set into the sight. Then groundspeed remains the only unknown factor. The rate knob is used on the rate end to solve for it.

By turning on the rate motor switch, a motor is started which turns a disc in the rate end. The speed at which the disc turns represents ATF. The desired speed is set in by positioning the disc-speed drum. To find the correct disc-speed setting, the ATF is divided into the bombsight constant, 5,3000.

The disc drives a roller which can be moved from the center of the disc to its upper edge. When the roller is in the center of the rotating disc, it does not turn; when it is just off center, it turns very slowly. The farther the roller is moved from the center of the disc, the more rapidly the roller turns. The position of the roller on the disc is controlled with the rate knob and the trail arm.

Trail is set in by moving the trail arm to the desired position on the trail plate. This moves the roller out from the center of the disc a distance proportional to trail. Then looking through the optics, the rate knob is turned until the lateral cross-hair appears to stay on the target. By doing this, the roller has been moved an additional distance on the disc. This additional distance is proportional to actual range. The distance from the center of the disc of the roller is then proportional to whole range and the roller's speed of rotation is proportional to groundspeed.

At the same time that the rate knob positions the roller on the disk, it positions the dropping angle index on the tangent scale, thus setting up the correct dropping angle.

The roller drive is transmitted to a mirror which reflects the image of the target into the telescope. The mirror is hinged in such a manner that the roller drive changes the angle of reflection as the airplane approaches the target.

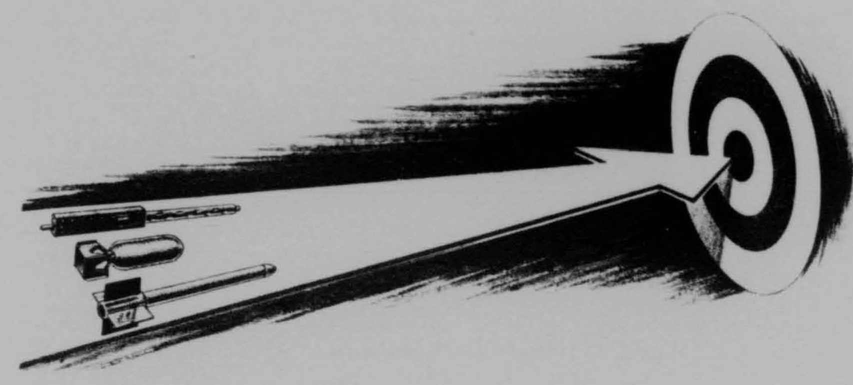
The sighting angle at any moment is shown by the sighting-angle index. The index can be seen on the degree scale in the index window.

When the sighting-angle index is exactly opposite the dropping-angle index, the sight automatically releases the bomb if the release lever is up. There are three types of release levers. One has to be held up manually. Another locks in the ON position when raised and has to be released after the bomb is released. The third, locks in the ON position and releases itself automatically after the bomb is released.

Before synchronizing, however, the line of sight must be made on the target. This is done manually. If at higher altitudes, the search knob is used which gives rapid displacement of the mirror for sighting angles from 70 degree to 0 degrees. When the target is picked up the mirror drive clutch is engaged to connect the drive of the roller to the mirror.

At lower altitudes, when more than 70 degrees forward vision is needed the extended vision knob is used which permits vision up to 90 degrees. When using the extended vision, the mirror drive clutch is not engaged until a sighting angle of 70 degrees is reached.

CHAPTER 4—SIGHT A-1B (GUN-BOMB ROCKET)



SECTION I—DESCRIPTION (GENERAL)

1. LIST OF COMPONENTS

The sight consists of the following units, (Figure 4-1), which are furnished by the manufacturer. Each sight is calibrated at the factory.

2. GENERAL DESCRIPTION

Purpose

The A-1B sight is an aircraft sight which automatically solves the fire control problems for gunfire from fixed guns, for bombing, and for rocketfire. The automatic feature enables the pilot to direct his full attention to the selected target. He must, however, fly the airplane so that a circular pattern of light, appearing on the windshield, is continuously superimposed on the target under attack. When this "tracking" action is performed correctly and smoothly, the airplane approaches a position from which its projectiles (shells, bombs, or rockets) will strike the target. In the case of gunfire or rocketfire, tracking should continue for four or five seconds, after which the pilot may close the firing switch. Bombs, however, may be released automatically by the sight when the airplane reaches the correct point on its approach.

Gunfire Function. The sight computes the required angle between the line of sight to the target and the boresight line of the fixed guns in the airplane. This prediction angle is generated as the resultant of two components. One, the elevation component, is the rotation of the airplane about the elevation axis of the sight. The elevation axis is perpendicular to the plane of symmetry of the airplane. The other, the deflection (or azimuth) component,

THIS PAGE IS DECLASSIFIED IAW EO 13526

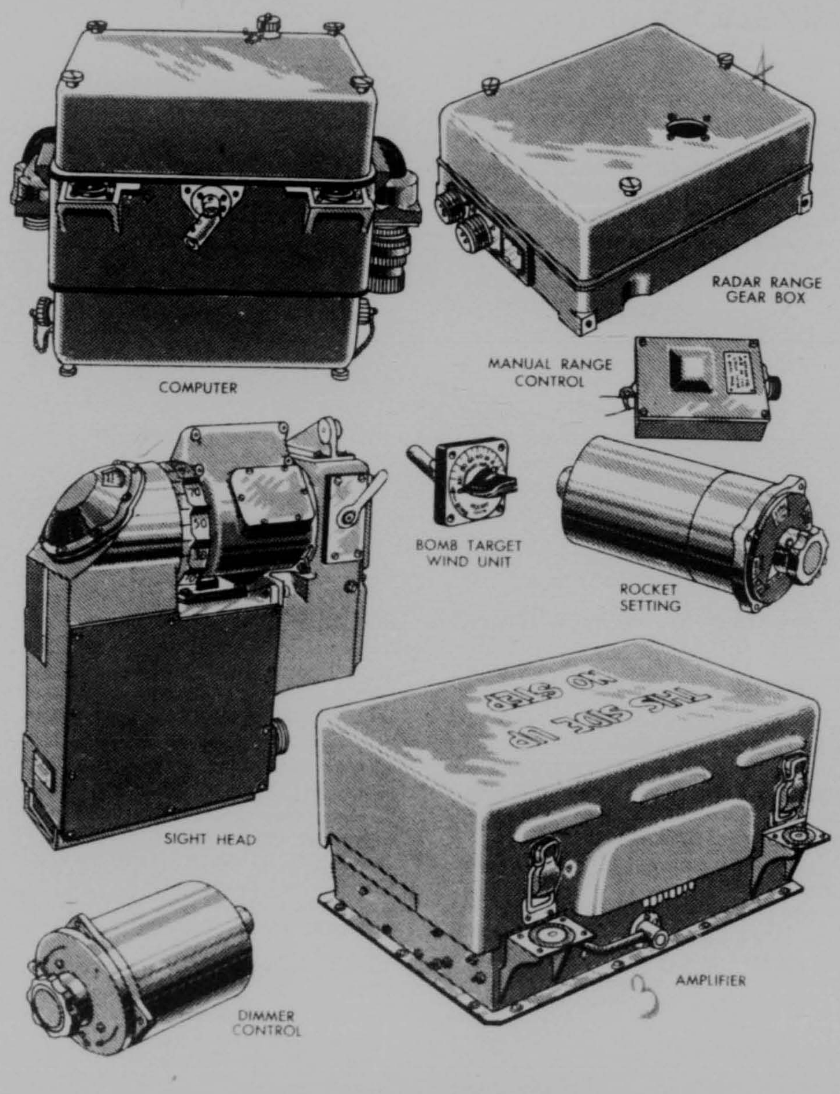


Figure 4–1. Type A-1B Sight (Gun-Bomb-Rocket) Components

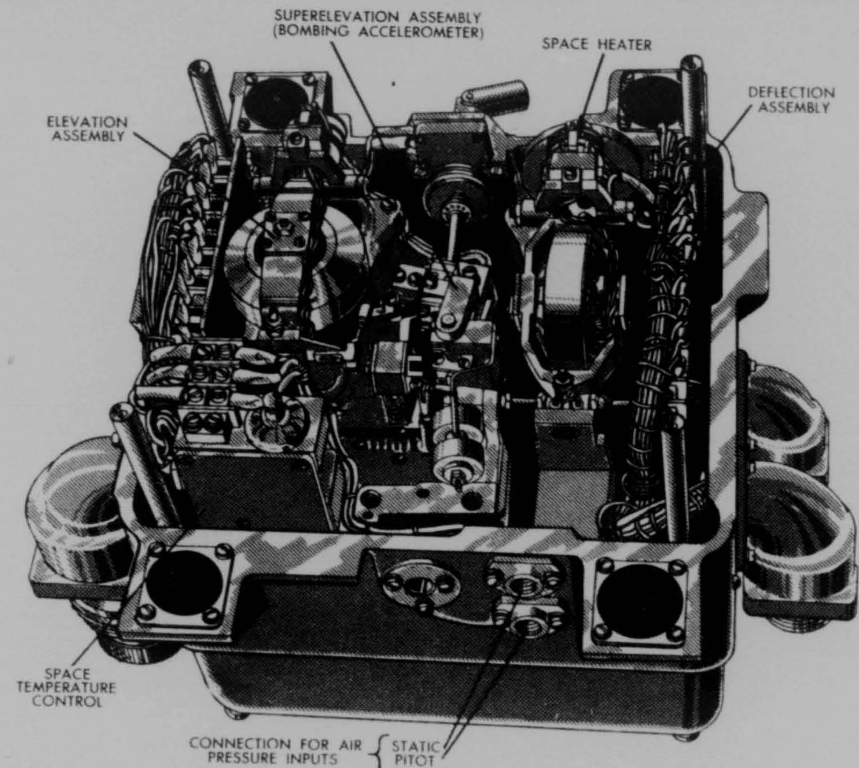

Figure 4–2. Computer, Top Cover Removed.

is the rotation of the airplane about the deflection axis of the sight. The deflection axis is in the plane of symmetry of the airplane perpendicular to the boresight line of the guns. It is necessary also for the sight to receive range data from an outside source, because the prediction angle increases with increased range. Under normal conditions, range is furnished by a radar set. If the radar set fails, the pilot may insert range into the sight manually.

Bombing Function. After the sight is set for this function, by adjusting the knob on the bomb-target wind unit, the sight operates automatically. The position of the reticle image requires the pilot to fly a downward path which becomes tangent to a bomb trajectory. The point of tangency is the bomb release point and is indicated to the pilot as a change in the pattern of the reticle image. Bombs are dropped automatically at this point, although the pilot may release them manually if desired. Less data is required for the bombing function than for gunfire. No range, altitude, or dive angle inputs are required.

Rocketfire Function. The sight furnishes automatic operation for rocketfire after adjustment of the knob on the rocket setting unit. This adjustment provides a constant reticle depression in elevation corresponding to the type of rocket to be used. Operation thereafter is similar to operation in the gunfire function.

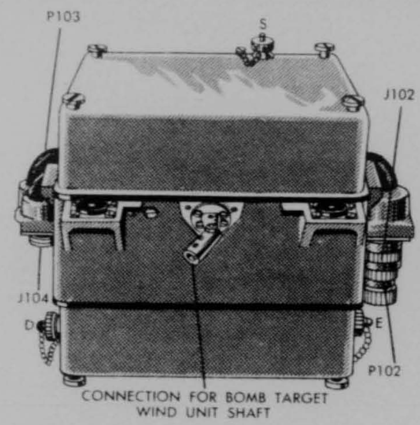

Figure 4–3. Computer, Rear.

Fixed Sight Function. The sight may be used as a fixed ring-sight by moving a lever on the sight head. When used in this manner no prediction angle is generated. The reticle image remains of constant size and at a fixed position on the windshield, not responding to airplane motion. As in other functions, however, the image is formed by a collimating lens (focused at infinity) and moderate motion of the pilot's head does not cause misalignment between reticle image and target.

General

The detailed description of the sight is closely allied to the discussion of operating principles given in section II. In the preparation of the remainder of this section, an endeavor has been made to avoid description that would require repetition with the presentation of operational information. Therefore, it is suggested that the reader might benefit by reference to corresponding subject matter in section II while reading the following paragraphs. The functional discussion in that section will supplement the physical description given here.

Components

The sight consists of the eight components listed in Figure 4-1. They are connected by flexible electrical cables, except for the computer and the bomb target wind unit, which are connected by a universal joint shaft. Consequently the location of the components, except for the two mentioned, need not be determined by the functional relationship between them. The sight head and computer, however, must be installed in proper relationship to the airplane. The sight head projects the reticle image on an optically flat section of the pilot's windshield. The computer contains the two gyros which provide the reference for calculation of the prediction angle.

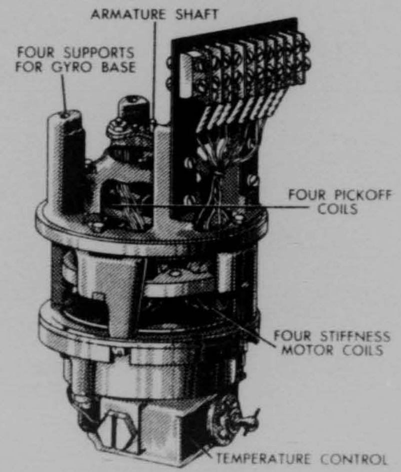

Figure 4–4. Elevation Assembly, Gyro Removed.

Computer. The computer (Figures 4-2 and 4-3) contains the principal mechanical components which compute the prediction angle for the three functions of the sight (gunfire, bombing, and rocketfire). The components are contained in a shock-mounted housing which is properly aligned with the airplane structure. The principal components are the elevation assembly (Figure 4-4), the deflection assembly and the superelevation assembly (also called the bombing accelerometer) (Figure 4-5). The deflection assembly and the elevation assembly each include a gyro (Figure 4-6) with its associated stiffness motor and pickoff coils and armatures. The gyro is connected to the stiffness motor and pickoff armature shaft by means of a ball arm. The stiffness motor controls gyro sensitivity, or the magnitude of gyro response to airplane motion. It is also used for electrical caging. The pickoff transforms the precession motion of the gyro into an electrical signal. The stiffness motor and pickoff are electrically separate, but their armatures are mounted on a common shaft. Each assembly also includes a temperature control unit (Figure 4-7). A temperature-sensitive bulb and heater coil maintain the fluid in the armature shaft damper at a constant temperature. The superelevation assembly is known as the "bombing accelerometer" because it is used only when the sight is in the bombing function. It consists principally of a weight, lever arm, and two pneumatic bellows. The computer housing also contains two heaters and a temperature control to govern its internal temperature.

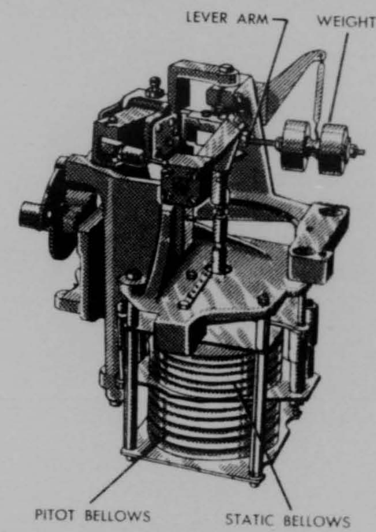

Figure 4–5. Superelevation Assembly (Bombing Accelerometer)

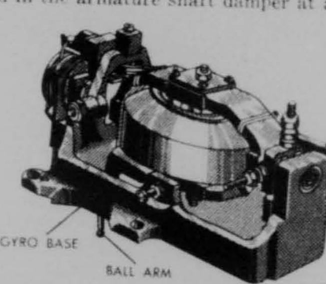

Figure 4–6. Elevation Gyro.

Connections to the computer are itemized in the following list. Not included in the list is the conventional shock mounting which secures the computer to the airplane. It is by means of this mounting that the airplane velocity and acceleration are transmitted to the two gyros and the bombing accelerometer, which use velocity and acceleration as data inputs.

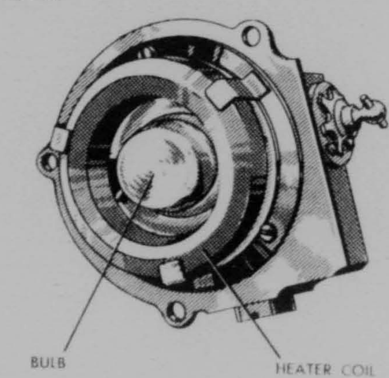

Figure 4–7. Temperature Control Unit.

Receptacle J102 (Figure 4-3), type AN-3102-28-16S, connects the computer with an electrical cable leading to the field test unit. This unit is not carried in the airplane and is used for test purposes only. It permits checking various signal voltages, gyro spin voltage, and temperature control heater voltage.

Receptacle P103 (Figure 4-3), type AN-3102-22-19P, connects the computer with an electrical cable leading to Jones socket S312 on the Amplifier. It carries excitation for the gyro pickoffs, stiffness motor current, gyro spin voltage, and supplies the temperature control units.

Receptacle J104 (Figure 4-3), type AN-3102-14S-5S, connects the computer with an

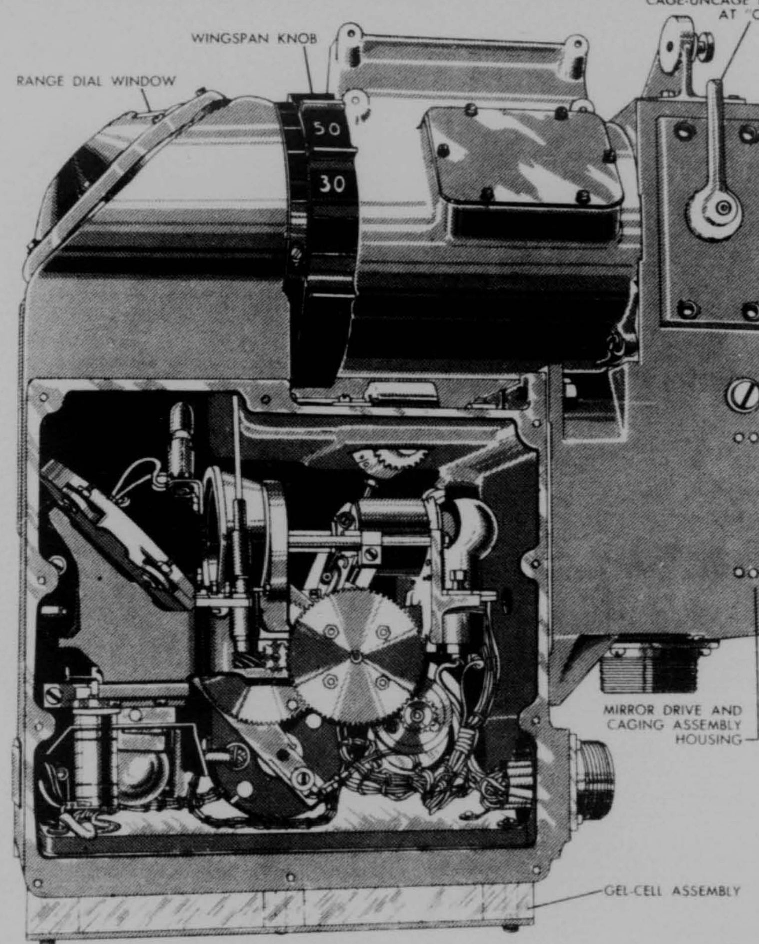

Figure 4—8. Sight Head, Rear Cover Removed.

electrical cable leading to Jones plug P306 on the amplifier. It carries the gyro pickoff signal voltages.

Connections (Figure 4-2) are provided for pneumatic tubes which supply static air pressure and pitot air pressure to the bombing accelerometer bellows.

A universal joint shaft connection (Figure 4-3) is provided for a shaft leading to the bomb-target wind unit. Rotation of the shaft, by the bomb-target wind knob, places the bombing accelerometer in the operating position (or swings it out of the operating position). At the same time, a switch is operated which controls three relays in the amplifier.

Sight Head. The sight head (Figures 4-8

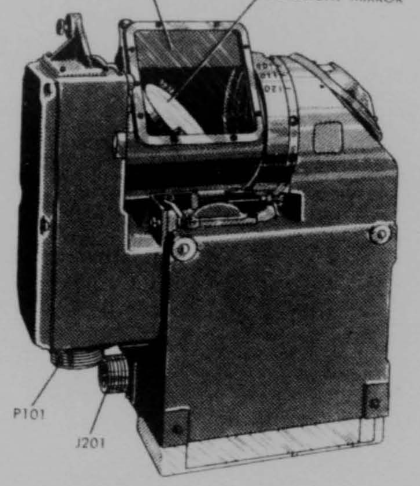

Figure 4—9. Sight Head, Front.

and 9) contains the optical system and associated electrical devices which position the reticle image. It is provided at the top with an inclined transparent window called the mirror shield. The light beam forming the reticle image is projected upward through the window to the airplane windshield. Therefore, the sight head is mounted with correct relation to the windshield. It is mounted also within the pilot's field of vision and within easy arm's reach, for it is provided with indicators and controls which must be adjusted prior to operation.

The principal components contained in the sight head are the elevation motor assembly, and the deflection motor and mirror assembly, which together comprise the essential units of the mirror drive and caging assembly. Also included in the sight head is the range-cone drive assembly. The elevation motor assembly (Figure 4-10) consists of a torque motor which is positioned mechanically by electrical signals, a pickoff which supplies a feedback signal, and a fluid damping unit. An armature shaft, common to motor and pickoff, terminates at one end in a lever, or ball arm. Motion of the ball arm positions the entire deflection motor and mirror drive assembly in elevation (Figure 4-11). This assembly consists of components which correspond to those of the elevation motor assembly, and the pivoted boresight mirror in addition. The ball arm on the armature of this assembly positions the mirror in deflection. Thus, the

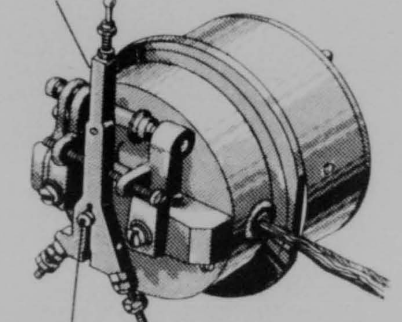

Figure 4—10. Elevation Motor Assembly.

THIS PAGE IS DECLASSIFIED IAW EO 13526

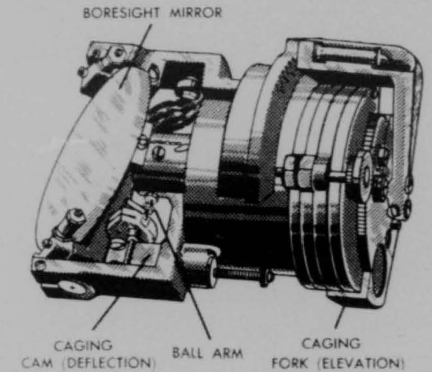

Figure 4—11. Deflection Motor.

mirror is positioned in elevation and deflection so that it reflects the reticle image upward to the windshield at the proper angle. This assembly also provides means for caging the mirror mechanically, or holding it stationary at the zero-prediction position. The range-cone drive assembly (Figure 4-12) consists of the light sources and components which provide the variable-size circle, the fixed-size circle, and the index dot for the reticle image. The variable-size circle is controlled in diameter by using a smaller or larger diameter of the cone to reflect a light beam from one light source. The fixed-size circle and index dot are formed by light from a second source as it passes through a fixed reticle. The two light beams are combined by a pellicle and other components of the optical system.

Connections to the sight head, and the indicators and controls provided, are described in the following list.

Wingspan knob (Figure 4-8). This large ring-shaped knob is mounted vertically with its indexed outer edge facing the pilot. It is used when the sight is operated with manual range instead of radar range. Then it must be set to the wingspan of the target, in feet.

"Cage-uncage" Lever (Figure 4-8). When this lever is at the "uncage" position the sight operates normally. When the lever is in the "cage" position the sight operates as a fixed-ring sight. The lever, in the "cage" position, actuates a fork and pin device which fixes the mirror in a zero-prediction position. The lever also actuates switches which remove operating power from the sight and provide a reticle circle image of fixed diameter.

Range Dial (Figure 4-8). This dial records the target range in hundreds of feet as determined by the ranging circuits, from either radar or manual range data.

Receptacle P101 (Figure 4-9), type AN-3102-PR-28-16P, connects the sight head with an electrical cable leading to Jones socket S318 on the Amplifier. It carries mirror pick-off excitation and signal voltages, torque motor current, and a 28-volt circuit controlled by the "cage-uncage" lever switch.

Receptacle J201 (Figure 4-9), type AN-3102-PR-22-14P, connects the sight head with an electrical cable leading to Jones socket S315 on the amplifier. It carries range data and energizing current for the bulbs which provide reticle image illuminations.

Amplifier

The amplifier (Figure 4-13) contains the electronic components of the sight, the air density unit (Figure 4-14) and six relays. It is shock-mounted, protected by an easily removable cover, and connected to other units by twelve electrical cables and the static pres-

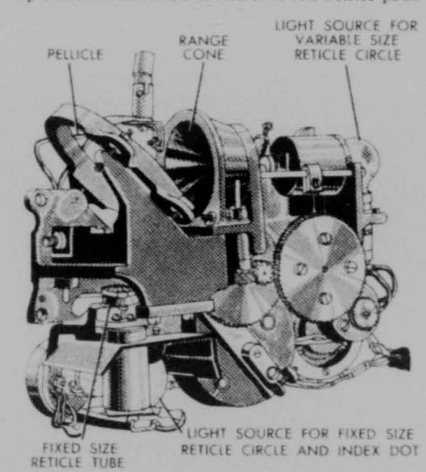

Figure 4—12. Range Cone Drive Assembly.

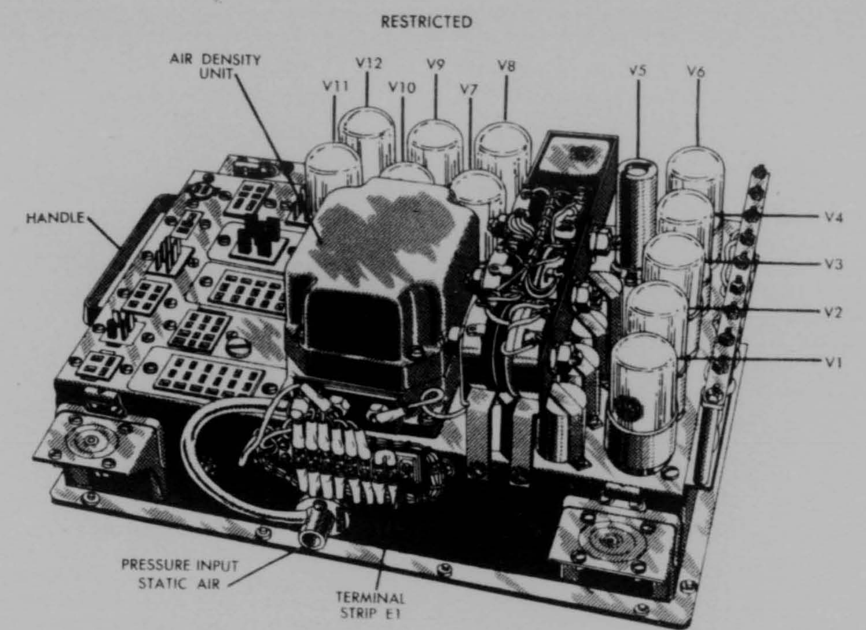

Figure 4—13. Amplifier.

sure tube. It is provided with a terminal strip, El, which is accessible after the cover is removed and which supplies convenient test points for the amplifier circuits. The amplifier may be divided functionally into four separate, but not independent, amplifier channels. These are the elevation channel (tubes V3 and V4), the deflection channel (tubes V1 and V2), the range channel (tubes V10, V11, and V12), and the sensitivity channel (tubes V5, V6, V7, V8, and V9). The three first named channels operate in the data circuits indicated by their names. The sensitivity channel supplies current to the stiffness motors in the computer. It thus limits the response of the gyros to airplane motion. The sensitivity channel operates from range data and air density data. Range data is supplied from radar or manual inputs. Air density data is supplied by the air density unit, which consists of a low-torque potentiometer with its arm linked and geared to an aneroid bellows, all mounted in a housing. The interior of the housing is maintained at static pressure and the bellows expands as altitude is increased.

The six relays are used to switch the sight from one function to another (gunfire, bombing or rocketfire), to energize the bomb release circuit in the airplane, and to cage the gyros electrically. The relays are operated automatically by the sight circuits, or by manually controlled switches located within reach of the pilot. The relays are described in the following list.

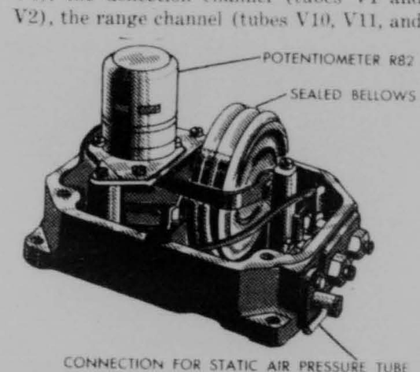

Figure 4—14. Density Unit Assembly.

Gun-bomb relay K2 is a double-armature relay but only one armature is used. It is energized when the bomb-target wind pointer is turned from "rocket-gun" to "bomb". When the relay is energized, the mirror in the sight head is positioned to give the fixed depression of the reticle necessary for bombing.

Gun-bomb relay K3 is identical with K2, but uses both armatures. It is energized in the same manner as relay K2. When energized, the sensitivity amplifier is disconnected and the elevation stiffness motor is pulled toward the lower elevation stop.

Gun-bomb relay K4 is identical with K2, but uses both armatures. It is energized in the same manner as K2. When it is energized, the output data of the elevation amplifier is used to operate the differential relay K1 instead of the mirror torque motors.

Differential relay K1 is a single armature relay with two energizing coils. It is energized by the output of the elevation amplifier (after relay K4 has been energized). When the current in one coil is the same as the current in the other coil, the relay is not energized. When the current is not the same in both coils, the relay becomes energized and, in turn, energizes relay K5.

Circle-bulb auto release relay K5 is identical with relay K2 but uses both armatures. It is energized by differential relay K1. When energized, it extinguishes the reticle image circle (but not the dot), and also completes a 28-volt circuit to the bomb-selector switch in the airplane. If the switch is at "auto" the bombs are then released.

Caging relay K6 is identical with relay K2 but uses both armatures. It is energized by the caging switch (airplane equipment) in the left grip of the airplane control stick. When energized, the gyros are caged electrically.

Connections to the amplifier are described in the following list. All electrical connections are made through Jones plugs or sockets mounted on top of the amplifier chassis (Figure 4-15). The connecting cables lead out and downward through the opening between the handle and the chassis. Some connections to the amplifier serve merely as convenient junctions for circuits between other units. For example, the circuit between the dimmer control and the reticle index dot-bulb in the sight head is completed through P304 and S315 in the amplifier.

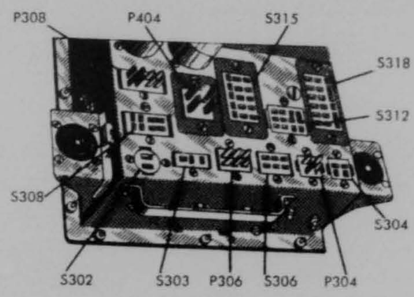

Figure 4—15. Amplifier Receptacles.

Socket S312 and plug P306 connect to cables leading to the computer, as previously described. Socket S315 and socket S318 connect to cables leading to the sight head, as previously described. Socket S315, in addition, provides an outlet for the 300 v fed to the manual range control.

Socket S302 connects with a cable leading to the electrical caging switch (airplane equipment) on the left grip of the control stick. The switch is used to cage the gyros electrically.

Socket S303 connects to a cable leading to the dynamotor, which is airplane equipment and located in the airplane power supply. The socket brings ±300 VC and ±28.5v DC into the amplifier.

Socket S304 connects to a cable leading to the phase adapter and three-phase transformer (115v to 29v), which are airplane equipment and located in the airplane power supply. The socket brings three-phase, 29-volt power to the amplifier.

Plug P304 connects to a cable leading to the dimmer control, which contains rheostats to adjust the intensity of reticle illumination.

Socket S306 connects to a cable leading to the bomb-selector switch and bomb-release relay (airplane equipment). The switch and relay are used when releasing bombs.

Plug P308 connects to a cable leading to the radar range unit. This connection brings both radar and manual range data to the amplifier.

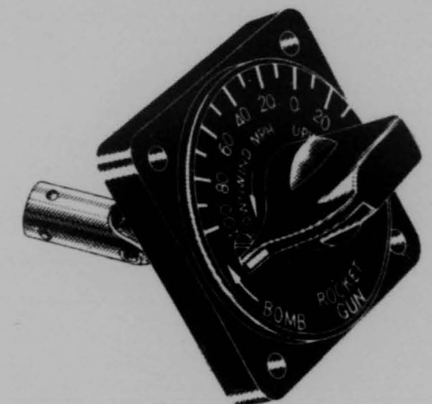

Figure 4—16. Bomb Target Wind Unit.

Socket S308 connects to a cable leading to the rocket-setting unit.

Plug P404 connects to a cable leading to the sight master switch and associated circuit breakers (airplane equipment).

Bomb Target Wind Unit

The bomb-target wind unit (Figure 4-16) consists of a rotatable pointer and fixed dial. It is mounted within reach of the pilot. The pointer is mounted on the outer end of a short shaft which projects inward through the dial and terminates in a universal joint. When the unit is installed, the universal joint is connected to a shaft leading to the computer. Rotation of the shaft places the superelevation assembly (bombing accelerometer) in operating position when the pointer is set at the "bomb" sector of the dial. In addition, a switch (S102) is closed which energizes gun-bomb relays K2, K3, and K4 in the amplifier. When the pointer is set at the "rocket-gun" position the bombing accelerometer is removed from operation and switch S102 is opened.

Radar-range Gear Box

The radar-range gear box (Figure 4-17) contains the components which receive the radar or manual range data from the radar

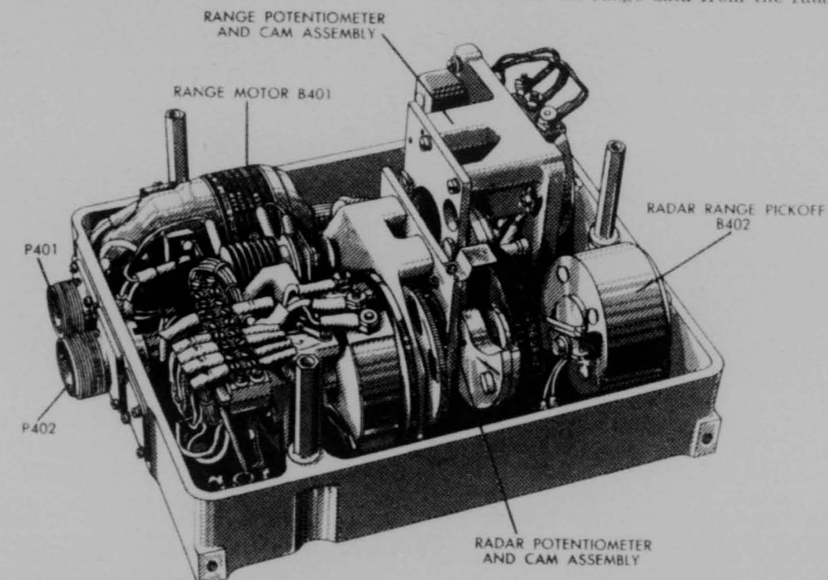

Figure 4—17. Radar-range Gear Box.

THIS PAGE IS DECLASSIFIED IAW EO 13526

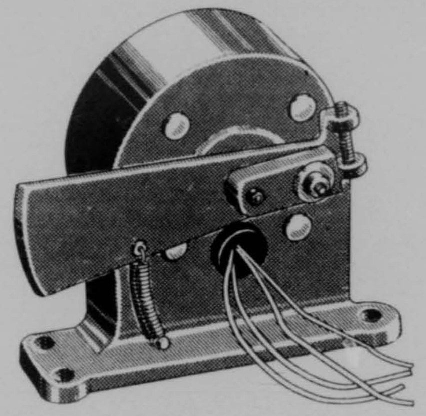

Figure 4—18. Radar-range Pickoff Assembly.

junction box J-271 APG-5C (airplane equipment) and which forward range data to other units of the sight. The principal components of the radar-range Gear box are the radar-range pickoff assembly, the range potentiometer and cam assembly, and the range motor. The radar-range pickoff assembly (Figure 4-18) is a signal source having a sector gear fixed to the armature shaft. The pickoff sector gear it driven by the range motor, through a gear train, pair of cams; and slip clutch on the radar potentiometer and cam assembly. The AC electrical data output of the pickoff is used to govern the size of the reticle image circle. The range potentiometer and cam assembly (Figure 4-19) consists of a potentiometer having its arm fixed to one of a pair of cams. The other cam is mounted on, and driven by, the same shaft that drives the pickoff sector gear. The DC electrical data output of the range potentiometer is used to control the sensitivity current in the gyro torque motors. The radar potentiometer and cam assembly (Figure 4-20) consists of a potentiometer having its arm driven by the range motor, through a gear and slip clutch. Also included are a range dial, and the pair of cams which drive the two assemblies previously mentioned. The DC electrical data output of the radar potentiometer is fed to the radar junction box J-271 APG-5C (airplane equipment). The range motor is a DC unit which is driven by electrical data from the radar junction box. The data rotates the motor to a position which is representative of target range. The motor is provided with limit switches and a rectifier network which prevent overtravel.

The radar-range gear box is provided with the indicator and connections described in the following list.

The range dial is visible through a window and is graduated in hundreds of feet from 600 feet to 6000 feet (Figure 4-17). The dial records target range.

Receptacle J401 (Figure 4-17), type AN-3102-16S-1P, connects with a cable leading to P308 on the amplifier. This connection carries the AC data output of the radar range pickoff and the DC data output of the range potentiometer.

Receptacle P401 (Figure 4-17), type AN-3102-18-1P, connects with a cable leading to the radar junction box (airplane equipment). It carries the output data of the radar potentiometer and brings to the unit the signals used to drive the range motor.

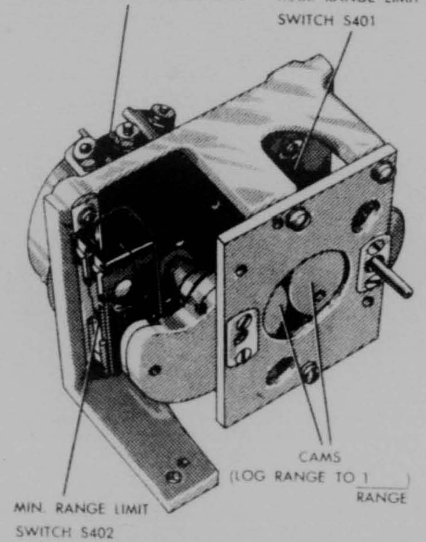

Figure 4—19. Range Potentiometer and Cam Assembly.

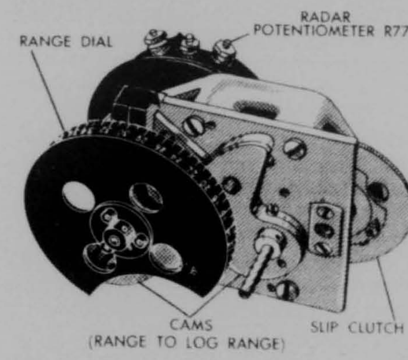

Figure 4—20. Radar Potentiometer and Cam Assembly.

Manual Range Control

The manual range control (Figure 4-21) contains the components which enable the pilot to insert range data into the sight manually. This is necessary when the associated radar set is not functioning. The control contains two switches and a potentiometer. These units govern components in the radar junction box (airplane equipment). The DC output data of the potentiometer, after the unit is set by the pilot, represents target range. The data is forwarded by the radar junction box to the radar range unit of the sight. In this unit the data performs the same functions as radar range data.

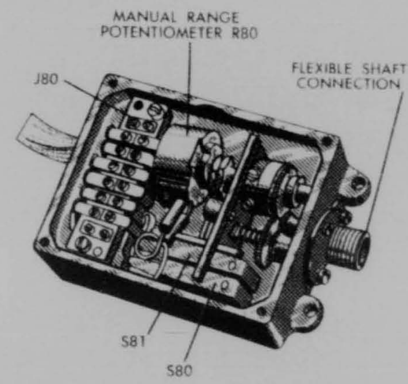

Figure 4—21. Manual Range Control.

The connections to the manual range control are described in the following list.

A flexible shaft is mechanically connected (Figure 4-21) to the potentiometer and switches, and leads to the airplane engine throttle control. This location is chosen for convenience of operation. The pilot, by rotating the throttle end of the flexible shaft, inserts range data into the sight.

The control is provided with an internal terminal strip (J80), (Figure 4-21), instead of an external receptacle. Connections to the terminal strip are led out through a hole in the housing, where they divide. Two leads, carrying the 300-volt supply for the potentiometer, are taken to S315 on the amplifier. The remaining leads, including one which carries the potentiometer pickoff voltage, are taken to the radar junction box (airplane equipment).

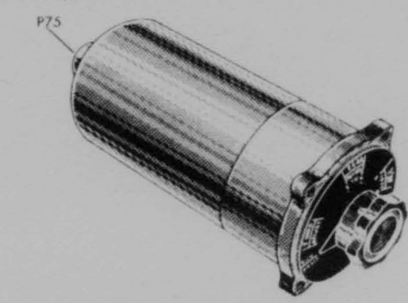

Figure 4—22. Rocket Setting Unit.

Rocket Setting

The rocket setting unit (Figure 4-22) contains the components used to adjust the sight for use in the rocket-fire function. It is mounted in the airplane within reach of the pilot. The principal components contained in the unit are a Selsyn-type signal source, a wafer switch, and three identical potentiometers. The signal source provides the signal which depresses the reticle image according to the type of rocket being used. The potentiometers provide a fixed sensitivity current for the gyro torque motors. The switch connects the signal source and potentiometers in the sight circuits or removes them from the circuits. The indica-

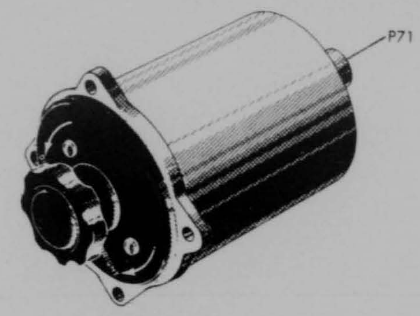

Figure 4—23. Dimmer Control.

tor and connection to the rocket-setting unit are described in the following list.

The rocket-setting pointer may be set at four positions. The "gun-bomb" position removes the rocket-setting unit from operation. The remaining three are used for rocketfire and connect the signal source and potentiometers in the sight circuits. The pointer shaft is connected directly to the wafer-switch arm and is connected by a gear and cam mechanism to the signal source. Each position of the pointer, except the "gun-bomb" position, provides a different reticle depression. Also, each of the three positions provides the fixed sensitivity current necessary for rocketfire.

Receptacle P75 (Figure 4-22), type AN-3102-18-8P, connects to a cable leading to S308 on the amplifier. It carries the output data of the signal source and the potentiometers.

Dimmer Control

The dimmer control, (Figure 4-23) contains the two rheostats which control the illumination intensity of the reticle image. One rheostat controls the variable-size reticle circle. The other controls the fixed-size reticle circle and the index dot for both reticle circles. Both rheostats are adjusted at the same time by the "dim-bright" knob. The dimmer control is provided with receptacle P71, type AN-3102-14S-2P, which connects with a cable leading to P304 in the amplifier.

3. INSTALLATION

General

The location of each of the eight components of the sight is determined by the function of the component, by the type of airplane in which the installation is being made, and by the length of the connecting cables. Four components (sight head, computer, amplifier and radar range) must all bear the same serial number, or an indication that all are part of the same sight. In addition, the sight head and computer must be installed in proper relationship to the airplane. Dimensions of each component are provided on the outline drawings in this section. As stated in this section no connecting cables, except the cable internally attached to the manual range control, are provided by the sight manufacturer.

When handling the computer it should be kept approximately upright. Do not allow it to remain tilted at more than 45 degrees for more than one minute at a time. Otherwise the damping fluid will tend to leak from the elevation and deflection assemblies.

The computer must be installed so that, when the airplane is in level flight, it will be correctly aligned.

The sight head must be located with the indicated points accessible for adjustment and so that two cables may be attached. It must be placed so that the wingspan knob and "cage-uncage" lever may be operated conveniently during flight. It must be located so that the plane of the four mounting pads is parallel to the windshield.

SECTION II—OPERATION

1. PRINCIPLES OF OPERATION

The motion of the airplane in which the sight is installed furnishes the principal data necessary for computation of the prediction angle. The data are derived from the precession of two gyros, one providing elevation (up-down) prediction and one providing deflection (left-right) prediction. The channel followed by elevation data from the gyro to the final purpose of positioning the reticle image on the pilot's windshield is similar to the deflection-data channel. For this reason, only the elevation channel will be discussed and the deflection channel differences pointed out in relation to it. Furthermore, it should be noted that the simplified schematics accompanying the text are not complete, and include only those components necessary for an understanding of the circuit. In addition to the data provided by the gyros, other input data are necessary for computation of the prediction angle. The additional inputs are range (from the radar range unit or the manual range control), air density, and indicated air speed.

2. THE FIRE CONTROL PROBLEM

The sight, which is the art of directing missiles so that hits are scored on selected targets. This problem is similar for bullets or shells, for bombs, and for rockets. The similarity depends upon the fact that each of these mis-

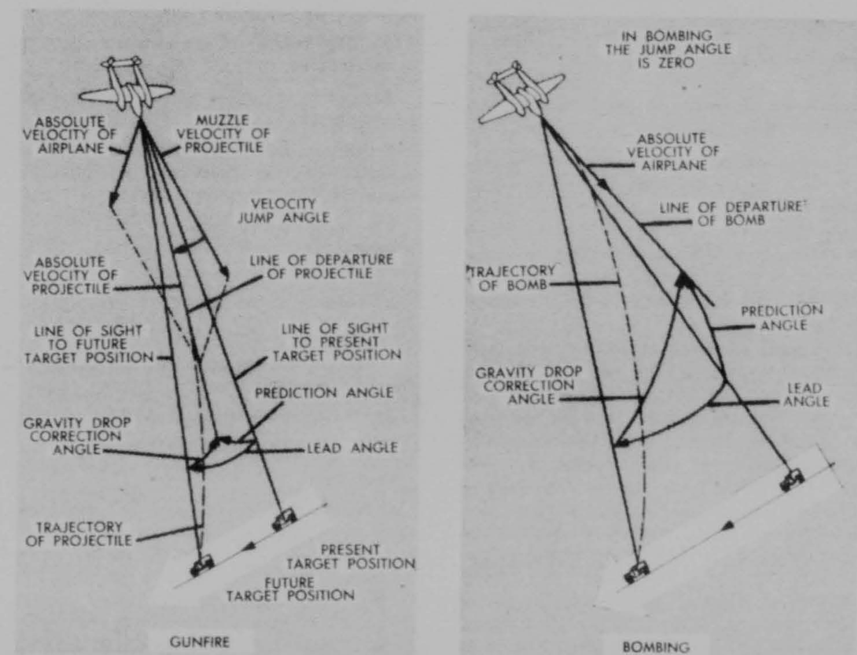

Figure 4—24. Gunfire and Bombing Against a Moving Ground Target.

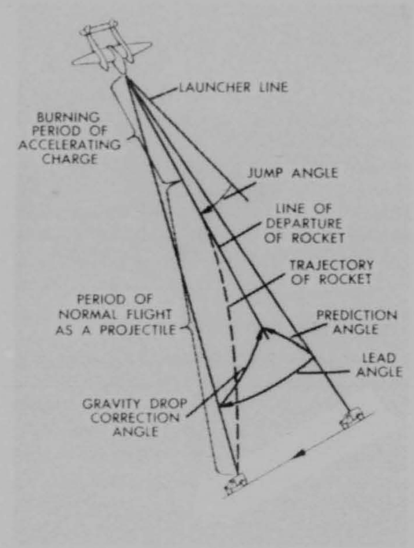

Figure 4–25. Rocketfire Against a Moving Ground Target.

siles ends its flight after a period of free motion under the laws of inertia and forces generated by motion through the air. A complete study of the aiming of projectiles is beyond the scope of this manual. A brief discussion is included, however, in order to aid an understanding of the operating principles on which the sight is based.

In order to score hits upon a moving target from a gun which is also moving, the gun must be aimed so that the proper angle, called the prediction angle, exists between the present line-of-sight to the target and the initial absolute velocity of the projectile. This velocity, for gunfire, is the resultant of airplane velocity and projectile muzzle velocity. For rocketfire, it is the resultant of airplane velocity and the launching velocity of the rocket. For bombing, the velocities of the airplane and bomb at time of release are the same. These relationships are indicated in Figures 4-24 and 4-25. This angular difference between airplane velocity and muzzle velocity (or launching velocity) is called the "jump".

The prediction angle is made up of the curvature correction angle and the lead angle (Figure 4-24). The curvature correction applied by the sight consists principally of the correction necessary for gravity drop. The lead angle is the angle between the line of sight to present target position and the line of sight to future target position. It is determined by range, projectile velocity, and the angular velocity of the line of sight as this line follows, or "tracks," the target.

3. GUNFIRE

The sight uses the following inputs for the control of gunfire:

Range (radar or manual).

Angular velocity of the airplane about the elevation axis (Figure 4-26).

Angular velocity of the airplane about the deflection axis (Figure 4-26).

Angular velocity of the airplane about the controlled line, or "roll" (Figure 4-26).

Atmospheric pressure (supplied by the density unit).

Resultant linear acceleration, including gravity, along the deflection axis (supplied by the gravity-drop accelerometer).

The sight uses the data inputs listed in the previous paragraph in order to make the following corrections, for gunfire:

a) Velocity of the target.

b) Velocity of the attacking airplane.

c) Rotation of the attacking airplane about the controlled line ("roll").

d) Gravity drop of the projectile.

e) Air density.

f) Range.

Corrections "a," "b," and "c" are based upon angular velocity data picked up by the gyroscopic elements from the motion of the airplane in which the sight is mounted. Correction "d" is based upon the linear acceleration of the airplane as picked up by the gravity drop accelerometer in combination with the dynamic behavior of the prediction mechanism itself. Correction "e" is based upon static

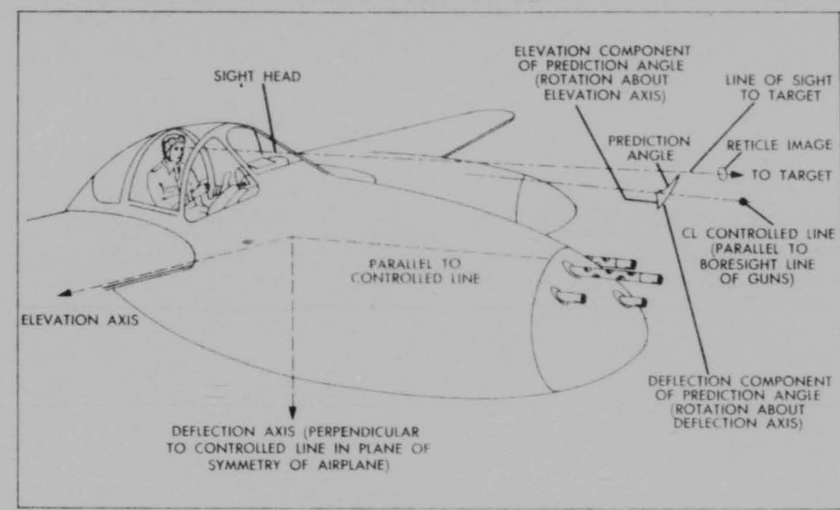

Figure 4–26. The Reference Axes of the Sight.

air pressure picked up by an aneroid bellows in the air density unit (not to be confused with the bellows in the bombing accelerometer). The calibration is based on the assumption that the actual pressure variation with altitude follows the standard pressure. Correction "f" is based upon range information, under the assumption that the airplane carrying the sight follows a proper pursuit curve against a target flying a straight line during an attack.

4. BOMBING

For bombing, the sight uses the following data inputs.

Angular velocity of the airplane about the elevation axis (Figure 4-26).

Angular velocity of the airplane about the deflection axis (Figure 4-26).

Linear acceleration along the deflection axis (supplied by the bombing accelerometer).

Component of gravitational acceleration along the deflection axis (supplied by the bombing accelerometer).

Indicated air speed (supplied by the bellows in the bombing accelerometer).

The sight uses the data inputs listed in the previous paragraph in order to make the following corrections, for bombing:

a) Gravity drop.

b) Target velocity.

c) Wind.

d) Air speed of bombing airplane.

e) Dive angle of bombing airplane.

f) Range.

g) Trail.

Trail, which may be defined briefly as the horizontal distance by which the bomb lags behind the airplane, is corrected, for an average bomb, by the calibration of the sight. Trail is caused by air resistance, or wind. The wind correction is complete only if the proper setting for the relative velocity of the wind with respect to the target is made on the bomb-target wind unit.

5. ROCKETFIRE

From the standpoint of fire control, rockets carried by aircraft and fired from "zero-length" launching rails are similar both to bombs and to projectiles fired from guns. They are similar to bombs in that they commence

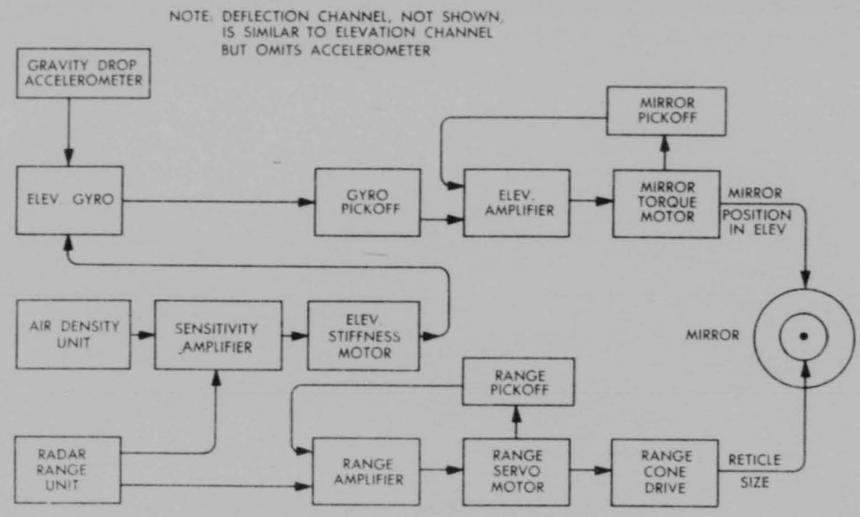

Figure 4–27. Gunfire, Simplified Block Diagram.

their independent flight with the same velocity as the airplane from which they are launched. After the rocket leaves the launching rails, a period of acceleration commences, which continues until the propelling charge has burned. During this period, the rocket may be considered as a projectile fired from an "equivalent gun" carried by the airplane. This imaginary weapon would have a long, curved barrel, shaped so as to give the projectile an absolute velocity identical in magnitude and direction with the actual velocity of the rocket at the end of the burning period. Following the burning period, the rocket behaves like a projectile fired from a stationary gun, with a muzzle velocity equal to the resultant of the airplane and propellant-produced velocities.

The sight uses the following data inputs for rocketfire:

Angular velocity of the airplane about the elevation axis (Figure 4-26).

Angular velocity of the airplane about the deflection axis (Figure 4-26).

Angular velocity of the airplane about the controlled line (Figure 4-26).

Linear acceleration along the deflection axis (supplied by the gravity drop accelerometer).

The sight uses the inputs listed in the previous paragraph in order to make the following corrections, for rocketfire:

a) Gravity drop.
b) Target velocity.
c) Wind velocity.
d) Air speed of the attacking airplane.
e) Range.
f) Dive angle of the attacking airplane.

6. ELEVATION PREDICTION

The elevation prediction system computes the elevation component of the prediction angle. This is the angle existing between the line of the gun barrel and the line of sight to the target when the gun is aimed so that a projectile will strike the target. The elevation prediction system receives its principal data input from the elevation gyro. Supplementary data inputs are range, atmospheric pressure, and linear acceleration (including gravity) along the deflection axis. The output of the system is represented by the elevation position of the mirror which reflects the reticle image to the pilot's windshield.

The block diagram of Figure 4-27 shows the flow of data through the sight when it is used for gunfire. Three data inputs are used, omitting the gravity drop accelerometer which is necessary in the elevation system only. The precession of the gyro provides mechanical motion which is a measure of the airplane's rate of rotation about the elevation axis. As shown in the diagram, the degree of precession is subject to an input that has its sources in the air density unit and the radar range unit. This input is discussed in the description of the sensitivity amplifier channel. Gyro precession is converted to an electrical signal by the gyro pickoff and sent through the amplifier and torque motor, which include a follow-up circuit. The torque motor positions the mirror by a mechanical linkage, and the position of the mirror is a measure of the prediction angle. The reticle image reflected by the mirror to the windshield furnishes the prediction angle to the pilot. The reticle image circle is controlled in size by the radar range unit, but if the radar range channel fails, the pilot must control the circle size manually. This is an emergency function and not included in the block diagram.

7. ELEVATION GYRO AND GRAVITY DROP ACCELEROMETER

The elevation gyro is a single-degree of freedom gyroscopic element, or "rate gyro". It differs from a free gyro in that the rotor has complete freedom of motion about one axis only. The gyro is mounted with its spin axis vertical, and the velocity of the airplane about the airplane's elevation axis causes the gyro to precess proportionately. This precession is the data output of the gyro. Precession is controlled by the elastic restraint of the stiffness motors, which are described as a portion of the sensitivity channel. Maximum precession is limited by mechanical stops.

The elevation gyro exhibits the usual gyroscopic properties of rigidity and precession. Rigidity resists any change in the gyro's plane of rotation. Precession results when the gyro's plane of rotation is forcibly changed. If this plane is changed by a torque applied about

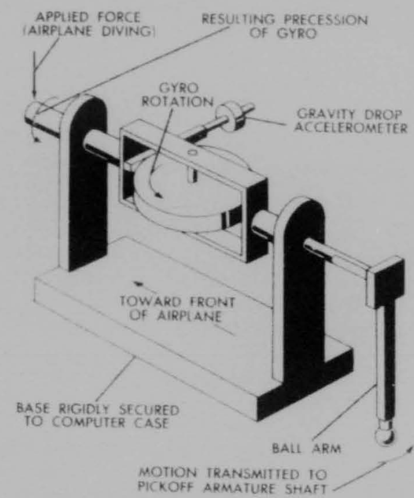

Figure 4–28. Elevation Gyro and Gravity Drop Accelerometer, Simplified Schematic.

either of the two nonspin axis of a gyroscope, the spin axis will rotate (precess) in a direction which tends to make its vector coincide with the applied torque vector. Precession resulting from diving motion of the airplane is illustrated in Figure 4-28. This figure also illustrates the method by which the precession movement is transmitted to the gyro pickoff.

The gravity drop accelerometer (Figure 4-28) inserts into the elevation system an angular correction for gravity drop of the projectile. This angle is one of the effects that must be taken into account by all fire control equipment. In aerial gunnery, the angle is so small that it differs a negligible amount from its own sine. It is maximum when the guns are aimed in the horizontal plane and is zero when the guns are pointing straight up (or down). The weight of the accelerometer tends to cause gyro precession in a direction which will depress the reticle image (elevate the guns).

8. ELEVATION GYRO PICKOFF

The elevation gyro pickoff converts into an electrical signal the precession of the gyro, in

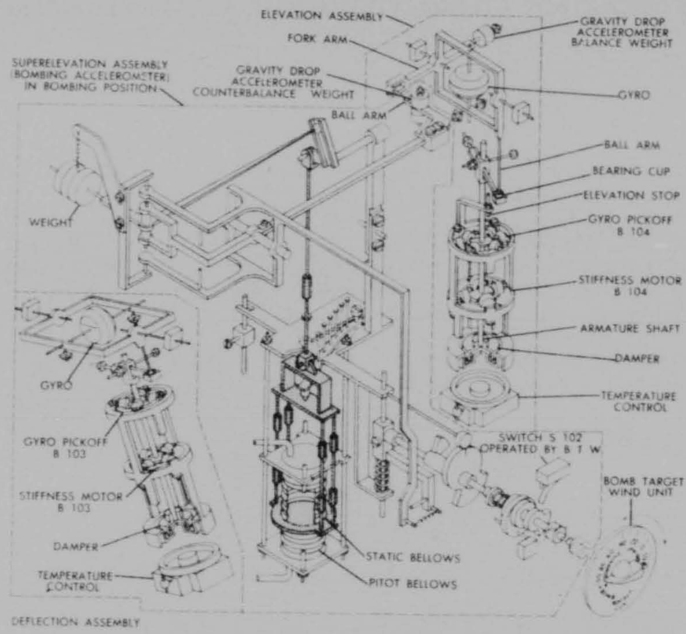

Figure 4–29. Mechanical Schematic, Computer

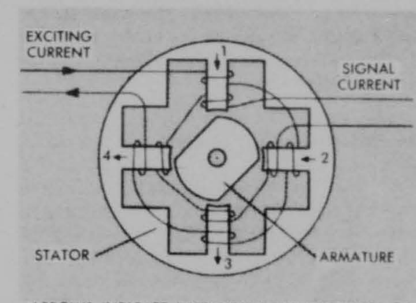
both magnitude and direction. When the gyro precesses it moves the ball arm (Figure 4-28). The ball on the lower end of the arm engages a bearing cup which serves as a socket for the ball. The cup is fixed to the armature shaft which carries the pickoff armature and the stiffness motor armature. The relationship between cup and shaft is that of a crank to a crankshaft. Unlike the usual crankshaft, however, the rotation of the armature shaft is limited by mechanical stops. Movement of the shaft turns the armature. Neither of the armatures are connected to any electrical source and each, with its stator winding, is a separate electrical component. The shaft, both armatures, and both sets of coils are contained in one unit called the elevation stiffness motor assembly and designated electrically as B103 (Figure 4-29).

The gyro pickoff coils are wound on a laminated stator having four coils spaced 90 mechanical degrees apart. Each coil has electrically isolated windings. The windings are connected in two series groups, each group composed of corresponding coil windings. The operation of the pickoff depends in part upon the direction in which the coils are wound. This direction is shown in Figure 4-30, as is the instantaneous direction of the exciting current flowing through them. The right-hand rule gives the direction of magnetic flux in each pole, which is indicated by the heavy arrows. The amount of the flux depends upon the position of the armature. When the armature is in the position shown, all air gaps are equal and the flux is the same in all poles. When the armature is rotated through a small angle clockwise, the overlap at poles 2 and 4 is greater than at poles 1 and 3, and the flux is correspondingly greater. This flux variation, over the range of motion allowed by mechanical stops, is a linear function of the armature angle from the equal flux position.

The signal current windings are cut by the flux which results from the exciting current and current is induced in them by trans-



ARROWS INDICATE INSTANTANEOUS DIRECTION OF MAGNETIC FLUX IN POLES, CAUSED BY 400-CYCLE EXCITING CURRENT

Figure 4—30. Pickoff, Simplified Schematic.

former action. Figure 4-30 shows that the signal winding direction at pole 1 is opposite to the direction at pole 2. Therefore, since the flux in both poles is in the same direction (from stator toward armature), the resulting voltage in these windings will be opposite in sign. When the armature is in the position shown, the voltage in signal windings at pole 1 and 2 will cancel each other. The same reasoning applies to the windings at poles 3 and 4. Thus the signal windings produce no output. However, when the armature is rotated through a small angle clockwise, the flux in poles 2 and 4 increases and the flux in poles 1 and 3 decreases. The flux in pole 1 aids the flux in pole 3, and the flux in pole 2 aids the flux in pole 4 because, between the two members of each pair, there is a reversal of both flux direction and signal winding direction. Thus the signal output is the amount by which the voltage across the windings at poles 2 and 4 is greater than the voltage at poles 1 and 3. The magnitude of the voltage is a linear function of the angular displacement of the armature. When the armature is rotated in the opposite direction (counter-clockwise), the voltage across poles 1 and 3 will be greater than the voltage across poles 2 and 4. Also, the 1-3 voltage is opposite in sign to the pole 2-4 voltage. Therefore, the output voltage will be opposite in sign to the output voltage for clockwise rotation of the armature. The opposite sign, for an instantaneous value, means that the phase has reversed.

The previous paragraphs have demon-

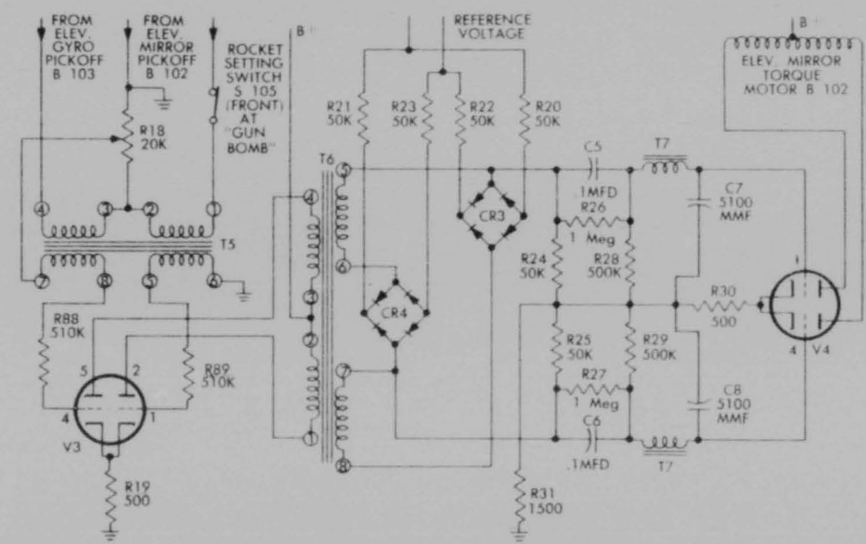


Figure 4—31. Elevation Amplifier, Simplified Schematic.

THIS PAGE IS DECLASSIFIED IAW EO 13526

strated that, for every angular position of the armature, the pickoff produces a signal voltage of corresponding magnitude. Further, the phase of the voltage depends upon the direction of rotation of the armature from the "no-signal" position. The output of the elevation gyro pickoff is applied to the elevation amplifier channel. In addition to the signal, the amplifier receives a feedback signal representing the elevation position of the mirror. This signal is developed in the elevation mirror pickoff B102, which is electrically identical with the gyro pickoff.

9. ELEVATION AMPLIFIER

The elevation amplifier (Figure 4-31) consists of tubes V3 and V4, together with associated components, and is located in the amplifier unit. Its purpose is to create a signal which drives the elevation-mirror torque motor B102 into correspondence with the elevation gyro pickoff on the armature shaft of B103. The armature of the elevation torque motor is connected mechanically with the mirror. When the gyro pickoff and mirror torque motor are in electrical alignment, the mirror is in the position directed by the gyro.

It should be observed that when the torque motor and mirror are not in alignment, the error must be identified to the amplifier in direction as well as amount. The direction of the error is indicated by the phase of the error signal, for the pickoff is phase sensitive and is excited by the same source as a reference transformer in the amplifier. The following discussion, for simplicity, assumes an error of one direction only, but is equally applicable to an opposite error. The combined signal input to the elevation channel is developed in the center-tapped primary of transformer T5 (Figure 4-31). Winding 3-4 receives signals from elevation gyro pickoff B103 which represent the position of the gyro. Winding 1-2 receives signals from elevation mirror pickoff B102 which represent the position of the mirror. (Note that mirror pickoff B102 is electrically separate from mirror torque motor B102). The algebraic sum of these two voltages is the elevation-channel input. The amplitude of the input measures the magnitude of the difference in position between the elevation gyro and the mirror. The phase of the input, with reference to the exciting voltage of the pickoffs, indicates the direction of the position difference.

A portion of the input voltage, taken from the center tap of the primary winding, is applied in series with secondary winding 7-8. This circuit applies a compensating voltage to grid 4 of V3. The voltage may be changed by means of potentiometer R18, permitting adjustment for any difference in sensitivity between the gyro pickoff and the mirror pickoff.

The elevation channel input voltage induces corresponding voltages in both secondaries of T5. Assuming that, at the instant under discussion, these AC voltages are positive at terminals 5 and 7: These voltages are applied to both grids of amplifier V3 through the grid current limiting resistors R88 and R89. This tube normally is conducting. The grid signals cause the voltage at plate 5 to rise and the voltage at plate 2 to fall. The change in plate current is coupled through transformer T6. The secondary voltages at T6 would be positive at terminals 5 and 7 for the original condition assumed.

The output of the transformer T6 secondary windings is applied to the selenium rectifier networks CR3 and CR4. These networks rectify the AC output of transformer T6, permitting current to flow through the circuit of only one winding at a time. Winding 7-8 of transformer T6 forms a series circuit with rectifier network CR3 and load resistors R24 and R25. Winding 5-6 is in series with CR5 and the same load resistors. The conducting condition of the networks, however, is not determined by the comparatively low signal voltage from transformer T6 but instead is determined by the 100-volt reference voltage from transformer T4 (not shown in Figure 4-31). The transformer is protected by resistors R20, R21, R22, and R23 in the event that the rectifier networks become shorted. The reference voltage is in phase with the excitation voltage supplied to both the gyro pickoff B103 and the mirror pickoff B102. Connection between reference transformer T4 and the rectifier networks CR3 and CR4 are such that each network conducts on alternate half-cycles of the reference voltage. For example, during

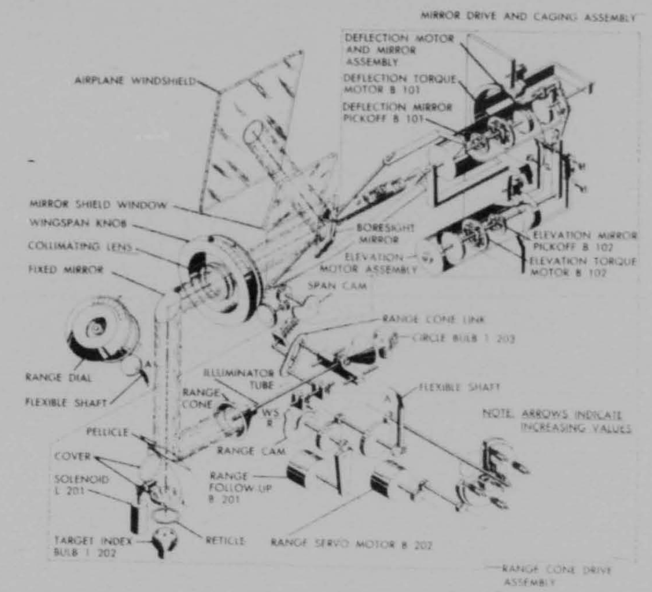

Figure 4—32. Mechanical Schematic, Sight Head

the half-cycle when the network terminals at R22 and R23 are positive (at this instant terminal 5 on Ty is also positive), CR3 is cut off and CR4 is conducting. For this condition of the rectifiers, winding 7-8 on T6 is open-circuited by network CR3. Current flows from winding 5-6 through load resistors R24 and R25 through one leg of CR4 to R21 and the winding of the reference transformer, returning through R23 and another leg of CR4 to winding 5-6. In the conventional sense, the flow is from top to bottom through the load resistors because terminal 5 on T6 was found to be positive.

During the half-cycle of reference voltage when the network terminals at R22 and R23 are both negative, CR3 conducts and CR4 is cut off. Winding 5-6 is open-circuited while winding 7-8 conducts. Also, because the pickoff exciting voltages and the reference voltage are in phase, terminals 6 and 8 on T6 become positive (instead of 5 and 7). Current flows through CR3 and again from top to bottom through R24 and R25. In this manner the AC output of V3 is converted to a DC signal.

The DC voltage, at the upper end of resistor R24 charges capacitor C5. The other side of this capacitor is grounded through R28 and R31. This RC circuit may be looked upon as a differentiating circuit which "peaks" the voltage signal. Thus, variations in the level of the DC will be effective immediately when applied to the torque motor which moves the mirror. After "peaking", the voltage signal is applied to inductor T7 and capacitor C7. These components reject any remaining 400-cycle fluctuations. Then the signal is fed to grid 1 of V4, which serves as a power amplifier. Grid 4 of V4 receives signals in a similar manner. They are developed at the opposite end of the two load resistors, however, and are always opposite in instantaneous polarity to the grid 1 signals.

The plate supply of the tube is applied through the center tap of the elevation torque motor B102 stator winding. The tube normally is conducting, so that the same amount of plate current flows in each half of the tube and also in each half of the torque motor winding. Any signal voltage on the grids of the tube disturbs the equality of the current flow in the halves of the motor windings and causes the motor to rotate. The direction of rotation depends upon the relative polarity of the grid signals, which in turn depends upon the direction of misalignment between the gyro pickoff and the mirror pickoff. The motor continues to rotate until the misalignment is cancelled and the mirror is in the position directed by the gyro.

An error of one direction (between gyro pickoff and mirror pickoff) was discussed in the preceding paragraphs. This error made terminals 5 and 7 on input transformer T5 positive at the instant when the reference voltage causes the rectifier networks to be positive at their junction with R22 and R23. Now assume that the error between gyro pickoff and mirror pickoff is in the opposite direction. Then the phase of the error voltage, with respect to the reference voltage, will change by 180 degrees, in other words, terminals 6 and 8 on T5 will be positive when the networks are positive at R22 and R23. Then current flows from winding 5-6 through one leg of CR4, R21, the winding of the reference transformer, R23, another leg of CR4, and upward through the load resistors R25 and R24. On the next half-cycle of both reference voltage and error voltage, current flows from winding 7-8 on T6 and again upward through R25 and R24. Thus an error of opposite direction produces a reversal of current through the load resistors. The reversed current, applied to output tube V4, in turn causes the torque motor to rotate in the opposite direction.

10. ELEVATION TORQUE MOTOR

The elevation torque motor armature (Figure 4-32) is mounted on the same shaft as the armature of the elevation pickoff. The shaft is connected mechanically to the mirror. Although the motor and pickoff are both part of the same unit mechanically, and are designated by the same electrical symbol B102, there is no direct electrical connection between them. The pickoff, as previously described, furnishes a signal to the amplifier representing mirror position. The torque motor drives the armature shaft, and thus the mirror, in a direction and to a position that will cancel the pickoff signal.

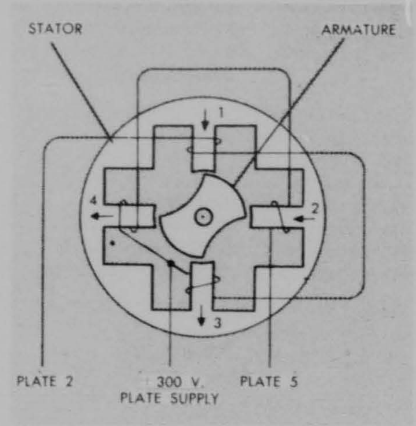

Figure 4—33. Torque Motor, Simplified Schematic.

The torque motor is somewhat similar to the pickoff, as may be seen by comparing Figures 4-30 and 4-33. The four poles of the torque motor, however, have identical single windings. These windings receive the output signal from the plates of tube V4 in the elevation amplifier channel (Figure 4-31). The conventional current in a vacuum tube is always the same, from plate supply through plate load to plate, and thence to cathode. This current in tube V4 is steady and is the same for each plate when no elevation signal exists. The current will create magnetic flux in the poles of the torque motor. The direction of the flux is shown by the heavy arrows in Figure 4-32. The flux in pole 1 has the same magnitude as the flux in pole 3, regardless of armature position, because the air gaps at these poles are always equal. For the same reason, the flux in pole 2 is of the same magnitude as the flux at pole 4. However, when an elevation signal does exist, the plate current in one half of tube V4 is not the same as the plate current in the other half. Then current around poles 1 and 3 is not the same as the current around poles 2 and 4. This difference creates the

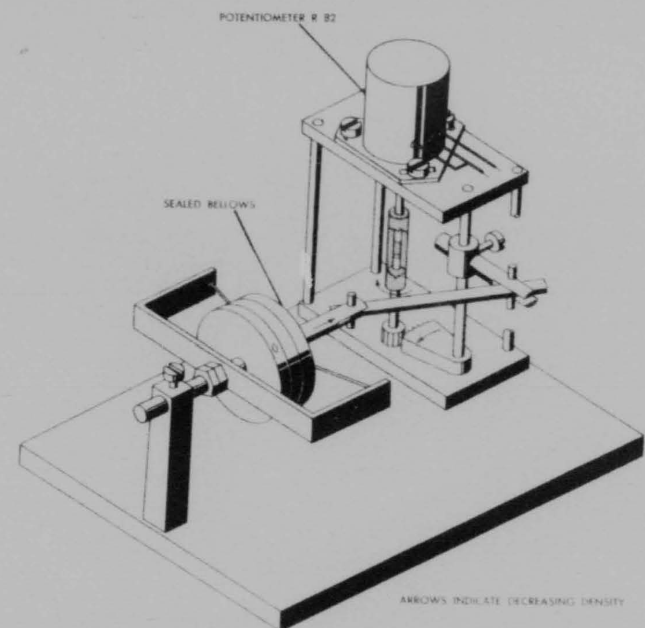

Figure 4—34. Mechanical Schematic, Density Unit.

torque which rotates the torque motor armature. When the torque motor armature rotates, the elevation mirror pickoff armature is rotated also because it is on the same shaft. The rotation is in the direction to drive the pickoff into electrical agreement with the gyro pickoff. When this agreement occurs, the input to the elevation amplifier channel becomes zero and the torque motor ceases to rotate. The mirror is then in the correct position for reflection of the reticle image at the correct elevation prediction angle.

11. AIR DENSITY UNIT

The mirror position in elevation, although determined principally by airplane motion as interpreted by the elevation gyro, is also subject to two additional sources of data (Figure 4-27). The air density unit is one of these. The unit receives barometric pressure and uses this information to partially control the DC input to the sensitivity amplifier.

Barometric pressure, at the plane's altitude, is used as a measure of air density. The aneroid bellows in the unit expands with decreased pressure. This motion, through a linkage and sector gear, rotates the arm of potentiometer R82 (Figure 4-34). This potentiometer is connected in the input circuit of the sensitivity amplifier as shown in Figure 4-35.

12. RADAR RANGE GEAR BOX

The remaining data input controlling the mirror position in elevation is derived from target range. This information is received by the radar-range gear box, from the APG-5 radar set, through the radar junction box. The radar-range gear box contains a motor which is driven by the target range data. The motor is connected to the rotor of a pickoff and also to the arm of the range potentiometer (Figure 4-36). The pickoff furnishes an AC signal to

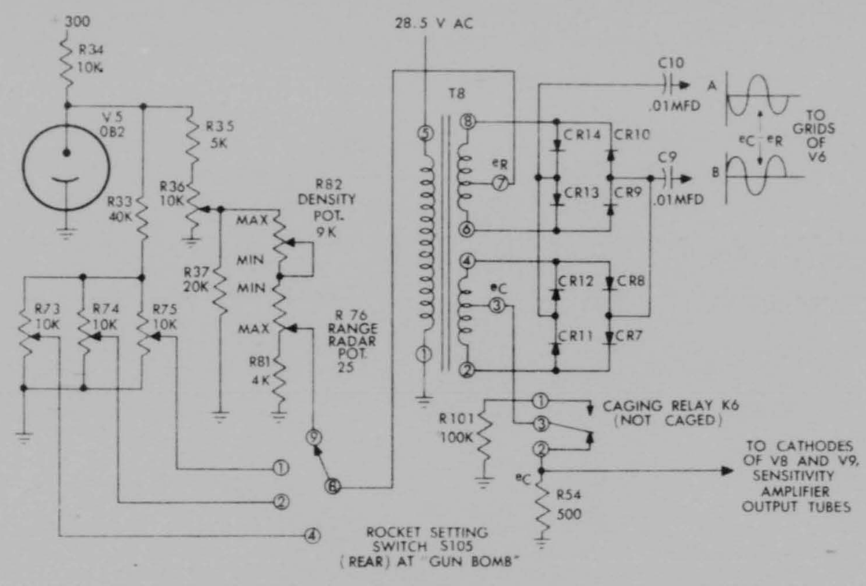

Figure 4—35. Sensitivity Amplifier Input Circuit, Simplified Schematic.

the range servo motor, in the sight head, which controls the size of the reticle image circle. This signal does not affect mirror position. The range potentiometer, however, furnishes a DC signal which is used as an input to the sensitivity amplifier. It is designated as R76 and is connected in the amplifier input circuit as shown in Figure 4-35. Range data is necessary in order to compute the prediction angle correctly. This necessity is evident when it is considered that a distant target flying at high speed will cause the same tracking rate as a nearby target flying at a correspondingly low speed. The required prediction angle for the distant target will be greater than the prediction angle for the target at the lesser range.

13. SENSITIVITY AMPLIFIER

The sensitivity amplifier consists of tubes V5, V6, V7, V8, and V9, together with associated components, and is located in the amplifier unit. Its purpose is to impose an elastic restraint upon the precession of the elevation and deflection gyros. The restraint is applied to the pickoff armature shaft of each gyro, through the stiffness motors, as an electrical torque. The magnitude of the torque is determined by the range of the target and by air density (Figure 4-27). The torque is used also to cage the gyros electrically. For this purpose sensitivity signals are applied to the stiffness motors at maximum value, because data signals are cut off.

When the sensitivity amplifier is functioning normally, the air density and radar range data are combined and applied to it as a DC signal. Tube V5, a voltage regulator, maintains a constant 105 volts between the upper end of R35 and ground (Figure 4-35). The density potentiometer R82 and the radar range potentiometer R76 are series connected, and pick off a portion of this voltage drop. This DC voltage (e_R) is the sensitivity amplifier input. It is applied to terminal 7 of input transformer T8 through rocket setting switch S105. A feedback voltage (e_c), developed by the flow of current through cathode resistor R54, is

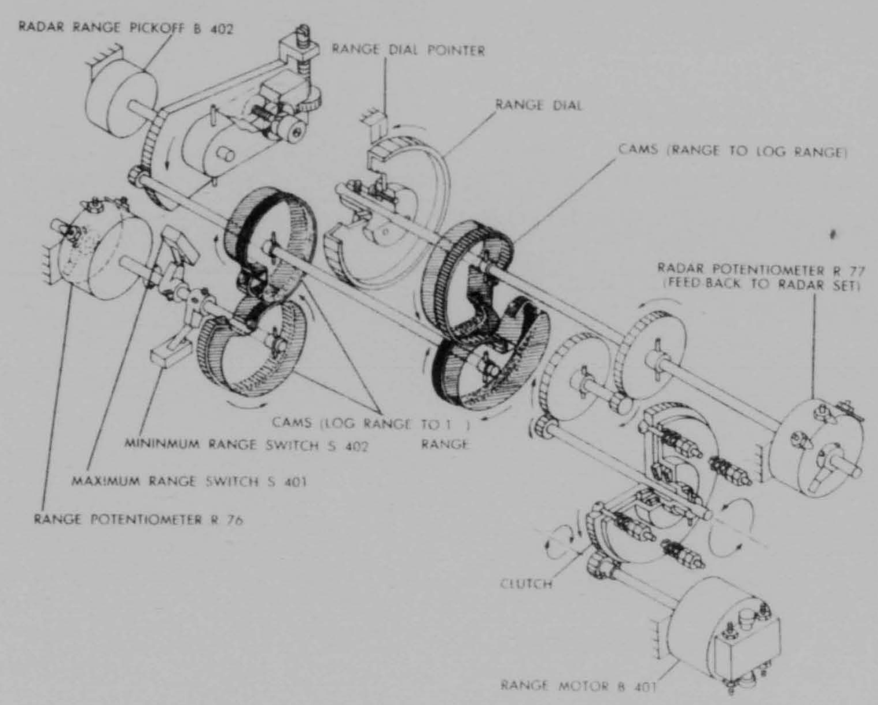

Figure 4—36. Mechanical Schematic, Radar Range Gear Box.

also applied to transformer T8, at terminal 3. The difference between these DC voltages ($e_R—e_c$) is alternately switched from lead A to lead B by the action of the AC reference voltage on the bridge-rectifier circuit. The voltage on leads A and B will then appear as shown in Figure 4-35. Capacitors C9 and C10 remove the DC level, resulting in AC signals being applied to the grids of V6. These signals will be 180 degrees different in phase, and their magnitude (which will be equal) will be determined by the difference ($e_R—e_c$).

The push-pull input to V6 is amplified by V6 and V7, with the primary of transformer T9 in the plate circuit of V7. The secondary of T9 is applied to a reference voltage-rectifier network similar to the equivalent network in the elevation amplifier. This network feeds a negative signal to the grids of output tubes V8 and V9 (Figure 4-37). The tubes receive their plate supply through one end of the series-connected stiffness motors V103 and B104. With no signal on the grids these tubes are conducting normally and current through the stiffness motors is maximum. This condition occurs when the DC sensitivity input is maximum (for minimum range). When the grids of V8 and V9 receive a negative signal the stiffness current decreases. This is the condition for increasing range.

When a heavy current is being drawn through V8 and V9 (minimum range) the voltage drop across R54 (e_c) will be high. At the same time, the range input voltage (e_R) will also be a maximum, and the net difference of the two will be fairly small. This will cause

THIS PAGE IS DECLASSIFIED IAW EO 13526

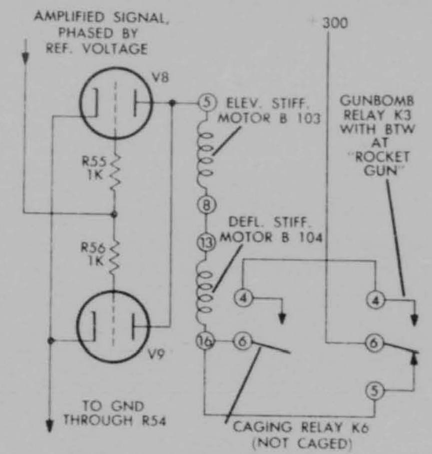

Figure 4—37. Sensitivity Amplifier Output Circuit, Simplified Schematic

a very low voltage signal ($e_R - e_C$) to be applied to the amplifier tubes (V6 and V7) and therefore there will be a small negative bias on the grids of V8 and V9, maintaining a heavy current flow. If the range voltage is decreased (increasing range) the difference ($e_R - e_C$) will increase, causing a larger negative signal to be put on the grids. This will cause the current flow to decrease appreciably reducing the torque of the stiffness motor B103. Multistage degenerative feedback is obtained in this amplifier channel by virtue of the fact that cathode resistor R54 is connected in series with the range potentiometer arm from which the input voltage e_R is obtained. The feedback factor is such that optimum linearity is obtained in the sensitivity channel.

14. ELEVATION STIFFNESS MOTOR

The elevation stiffness motor (Figure 4-29) is a part of the assembly which includes the elevation gyro pickoff. The deflection stiffness motor is correspondingly mounted. Both motors are similar electrically and this discussion of the elevation stiffness motor applies to the deflection stiffness motor as well. The armature of the motor is mounted on the same shaft as the armature of the gyro pickoff. When the gyro precesses, its precession is partially restrained by the torque caused by the current in the stiffness motor windings. This current is the sensitivity current. It affects the gyro directly, as indicated in the block diagram (Figure 4-26). If there is no sensitivity current, the stiffness motor has no effect on gyro precession. If the current is the greatest allowed by range and density data, gyro restraint is greatest. The stiffness motor is used also for electrical caging. For this purpose, range and density data are removed from the sensitivity channel input. The stiffness motor then receives a steady maximum current through its windings and holds the armature firmly in "neutral" position. This action cages the gyro.

A simplified schematic of a stiffness motor is given in (Figure 4-38). With the armature in the position shown, the air gap reluctances are the same at all poles. If the armature is turned slightly clockwise, the reluctance at poles 1 and 3 increases, while at poles 2 and 4 it decreases. Thus more flux will flow from the armature into poles 2 and 4 than from poles 1 and 3 into the armature. But the net inflow to the armature must be zero. Therefore some of

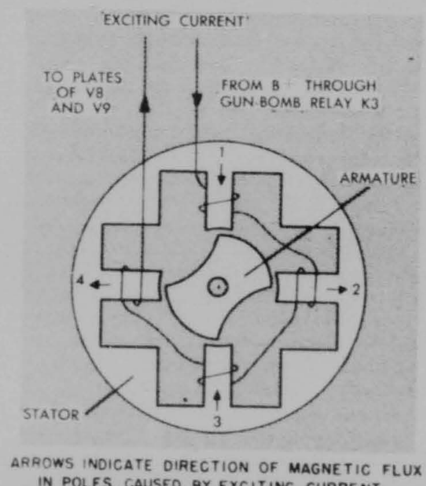

Figure 4—38. Stiffness Motor, Simplified Schematic.

the magneto-motive force at poles 2 and 4 is transferred to poles 1 and 3, and the flux density at 1 and 3 is increased. Thus, the counterclockwise torque of poles 1 and 3 exceeds the clockwise torque of poles 2 and 4, and creates the restoring effect of a spring. The effect is proportional to the square of the flux density and, therefore, of the current. The same effect is present for counterclockwise rotation, with torque at poles 2 and 4 predominating in this case. Over a useful range the torque is practically linear with angular displacement.

15. MIRROR DRIVE LINKAGE FOR ELEVATION

The elevation torque motor, as well as the elevation mirror pickoff, is housed in the elevation motor assembly (Figure 4-32). The armatures of both the torque motor and the pickoff are mounted on the same shaft. One end of the shaft extends from the elevation motor housing, and carries a ball arm on its outer end. The ball arm is mounted at right angles to the shaft. When the shaft is rotated by the torque motor, the ball on the end of the ball arm moves through a corresponding arc. Motion is limited by the elevation stop mounted on the end of the housing. The ball arm projects upward from the elevation motor housing and the ball engages a fork on the deflection motor and mirror assembly. The fork is attached rigidly to the rotating housing which supports the mirror. The mirror rotates in elevation when the fork is moved by the ball arm.

16. ELECTRICAL CAGING

The sight employs electrical caging to prevent precession of the gyros before the pilot begins to track a target. If this provision were not made, the maneuvering of the plane during the pilot's initial approach to a target would insert spurious rates into the sight. In order to cage the gyros electrically the pilot depresses the push button type of caging switch on the left grip of the plane's control wheel. This switch energizes caging relay K6. When the caging relay is energized, all data inputs are removed from the sensitivity amplifier. Relay contacts 2-3 open and 3-1 close (Figure 4-35). This action places a high value resistor in series with the range and density data inputs to the amplifier and effectively cuts them off. It also removes the voltage e_C, so that there is no difference signal ($e_R - e_C$) = 0, this results in cutting off the grid bias on V8 and V9, which therefore draw maximum current. Maximum current through the stiffness motor windings holds the stiffness motor armatures in a fixed position. As each armature shaft is mechanically connected to the gimbal of the corresponding gyro, movement of the gimbal is prevented. When the gyros are caged, the signals created by the gyro pickoffs hold the mirror in a fixed position.

The previous paragraph described the action of one of the two sets of contacts on caging relay K6. The other set does not affect the sight in the gunfire function. As shown in Figure 4-37, however, the plate supply to the sensitivity amplifier is cut off by gun-bomb relay K3 when this relay is in "bomb" position. Therefore, when the sight is in the bombing function, contacts 4-6 on caging relay K6 are used to close the circuit which has been opened by gun-bomb relay K3. Thus electrical caging is effective for both gunfire and bombing functions.

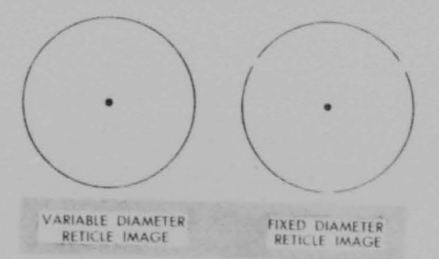

Figure 4—39. Reticle Image.

17. MECHANICAL CAGING

Mechanical caging is used when the sight is to function as a fixed sight. Under this condition a fixed reticle image (Figure 4-39) is projected on the pilot's windshield and no prediction angle is indicated. The sight may be caged mechanically by means of the "Cage-Uncage" lever located on the sight head. This

THIS PAGE IS DECLASSIFIED IAW EO 13526

lever, when in the "Cage" position, will engage a pin with a fork that is fixed to the elevation armature shaft, and hold the shaft steady. Deflection caging is applied at the same time in a similar manner.

In addition to this mechanical action, the lever also actuates the ganged switches S101 and S106. Switch S101 interrupts the plate supply for all the amplifier channels (elevation, deflection, sensitivity, and range). When the amplifiers are inoperative, no signals are fed to the torque motors, which are already held steady by mechanical means. Thus although the gyro pickoffs continue to create signals, these signals are ineffective. Switch S106, ganged with S101, extinguishes the circle reticle bulb when the switch is placed in the cage position. At the same time, S106 energizes solenoid L201. The solenoid lifts the disk-shaped cover which shields the target index bulb. This bulb is the light source for the dot at the center of the reticle image. The dot is formed by a small hole at the center of a reticle. The reticle is placed between the bulb and the solenoid-operated cover, which is opaque except for a hole at its center. The reticle, however, is provided with an annular ring opening which permits passage of a circle of light as well as the central dot. When the cover is removed, the circle of light and dot are both projected on to the pilot's windshield. The image is fixed in position because the mirror mechanism is caged. The circle is also fixed in size, and should not be confused with the circle formed by the range prediction system. The two circles never appear simultaneously.

18. DEFLECTION PREDICTION

Deflection prediction is computed in essentially the same manner as elevation prediction. The principal data inputs are derived from the deflection gyro. This is mounted with its spin axis in the horizontal plane, parallel with the elevation axis of the airplane (Figure 4-26). The gimbal is inclined with its forward end down. Therefore the deflection component of the controlled line angular velocity is slightly reduced and a small roll component is added. The reason for this arrangement is based upon the fact that an airplane rolls as it turns (or tracks in deflection). The roll component furnished by the tilt of the gimbal improves the performance of the sight when tracking a target that is below the attacking airplane. The deflection gyro is not provided with an input from the gravity drop accelerometer, but otherwise the deflection data channel from gyro to torque motor is similar to the elevation channel shown in Figure 4-27. The mirror drive linkage between torque motor and mirror is different because it is necessary to tilt the mirror in a different plane.

The deflection torque motor is mounted in the deflection motor and mirror assembly. The armature shaft of the torque motor extends through one end of the housing. It carries the mirror drive ball-arm mounted transversely on its outer end. The ball on the ball arm engages a fork plate mounted on an arm that is rigidly connected to the mirror. When the arm is rotated by the torque motor, the mirror tilts in deflection. It should be remembered that the housing containing the linkage just described also supports the mirror. The housing, mirror, and deflection mirror drive are all rotated by the elevation mirror linkage.

19. RANGE PREDICTION

The range-prediction system receives from an outside source the information which represents target range. Under normal operation, a range signal is furnished by Radar Set AN APG-5. The radar set is not a part of the sight. In the event of radar set failure, a range signal from the manual range control unit of the sight may be substituted for the radar signal. Either signal performs two functions after its reception by the radar-range gear box of the sight. The two uses of either range signal are, first, to control elevation and deflection prediction by means of the sensitivity amplifier, and, second, to drive the mechanism which determines the size of the reticle image circle on the pilot's windshield. The range signal aplied to the prediction channels will be described first.

20. RANGE SIGNAL (PREDICTION)

This is a DC signal which originates in the radar range potentiometer R76 (Figure 4-35).

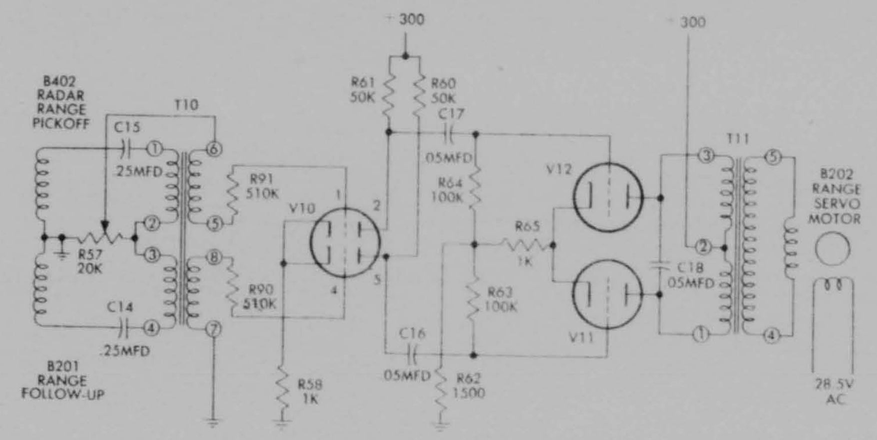

Figure 4-40. Range Amplifier, Simplified Schematic.

This potentiometer is located in the radar range gear box. It receives regulated DC from tube V5 in the sensitivity amplifier, and is grounded through R81 at its low end. The arm of the potentiometer is driven by the radar range motor B401. The motor, in turn, is driven by range signals (radar or manual) received from the radar junction box. The junction box is not part of the sight. The gear train connecting the drive motor B401 and the range potentiometer R76 includes a friction-disk, spring-loaded clutch, and two pairs of cams (Figure 4-37). The clutch protects the device in the event that the motor attempts to drive the potentiometer beyond its mechanical limits. The two pairs of cams convert the linear displacement of the motor rotor into non-linear displacement of the arm of R76. The motor displacement is proportional to target range. The potentiometer arm displacement is proportional to the reciprocal of range. This signal is combined with the air density signal and sent to the sensitivity amplifier. The output of the amplifier is used to modify elevation and deflection prediction as previously described.

21. RANGE SIGNAL (RETICLE SIZE)

This signal is an AC voltage which originates in the radar range pickoff B402. The pickoff rotor is driven by the same drive motor, and a portion of the same gear train, which drives the range potentiometer. The pickoff drive gearing omits one of the pairs of cams. The angular position of the rotor is proportional to the log of target range. The signal created in the pickoff as a result of the rotor position is applied to the range amplifier.

22. RANGE AMPLIFIER

The range amplifier (Figure 4-40) consists of tubes V10, V11, and V12, together with associated components. It is located in the amplifier unit. Its purpose is to create a signal which drives the range follow-up B201 in the sight head into correspondence with radar range pickoff B402 in the radar range gear box. After the follow-up has been driven to the correct position the output of the range amplifier becomes zero.

The signal supplied by the radar range pickoff is applied to primary winding 1-2 on input transformer T10 (Figure 4-39). The signal from range followup B201 is applied to primary winding 3-4 on the same transformer. Potentiometer R57 performs the same compensation function as the corresponding potentiometer in the elevation channel. The algebraic sum of the two signals is the input to

THIS PAGE IS DECLASSIFIED IAW EO 13526

the range channel. The amplitude of the resultant signal gauges the degree of misalignment between the pickoff and the follow-up. The phase of the signal is determined by the direction of the misalignment. Assume that at the instant under discussion this primary voltage induces secondary voltages that are positive at terminals 6 and 8. The voltage across winding 5-6 is impressed upon grid 1 of V10 through resistor R91, which limits excessive grid current when the grid is driven positive. The voltage across winding 7-8 is impressed upon grid 4 through R90. Tube V10 normally is conducting. For the signal polarity assumed, the voltage at plate 2 increases and the voltage at plate 5 decreases. These voltages are coupled to the grids of the power amplifiers V11 and V12.

The output tubes receive their plate supply through the center-tapped primary of output transformer T11. When the plate current of V12 increases and the plate current of V11 decreases, the change induces a voltage in the secondary of T11. The polarity of the secondary voltage, for the original condition assumed, would be positive at terminal 4. The secondary voltage is applied across one of the two stator windings of the range servo motor B202. The other winding of B202. The other winding of B202 is excited by 28-volt DC. The motor rotates when it receives a signal voltage from transformer T11. As the motor rotates, it also rotates the range follow-up B201, to which it is geared. Rotation continues until the follow-up is in electrical correspondence with pickoff B402. When this occurs, the signal input to the range amplifier is reduced to zero and the range motor B202 stops. The direction of motor rotation depends upon the phase relation between voltage in the winding excited by the amplifier and the voltage in the winding excited by 28-volt AC. The phase of the amplifier winding is determined by the phase of the input to the amplifier at transformer T10, as outlined in the preceding paragraphs.

23. RANGE CONE DRIVE

The range servo motor B202, and range follow-up B201 which is geared to B202, control the reticle size by means of the range cone drive (Figure 4-32). The gear train which connects B202 and B201 drives a cam. The associated cam follower translates a guide rod. The motion of the guide rod is transmitted by means of the range cone link to the illuminator tube. This tube is solid, made of quartz, and placed so that light from the circle bulb shines into one end. At the other end is an opaque cap and the side of the tube, except for a narrow band near the cap end, is coated with an opaque finish. The light shining through the tube emerges through the band, or ring.

The capped end of the tube projects into the vertex of the 90-degree range cone, the cone and tube axes being coincident. The inside surface of the cone reflects light which strikes it from the clear, ring-shaped area on the tube. The reflected light pattern is a circle, and is the source of the reticle image circle which appears on the pilot's windshield. The size of the circle increases as the illuminator tube moves deeper into the range cone, and decreases as the illuminator tube recedes. Thus the size of the reticle circle is controlled by the range data received from the Radar Set AN/APG-5.

24. MANUAL RANGING

In the event of radar set failure, the pilot may insert range data manually. Before this is done, however, he must position the span cam (Figure 4-32), which inserts target size data into the sight. The span cam is positioned by means of the wingspan knob at the left end of the sight head. This knob, by means of a gear-cam-link mechanism, translates the illuminator tube to a position determined by target size. After this adjustment has been made, further translation of the illuminator tube is accomplished by means of the manual range control unit.

The manual range control unit is connected by a flexible shaft to the handle of the pilot's throttle control. The pilot can rotate the shaft by rotating the throttle handle grip. Rotation of the shaft first operates two switches (S80 and S81) and then a potentiometer (R80), all located in the manual range control unit (Figure 4-41). The pilot rotates the handle grip so as to keep the target continuously and ac-

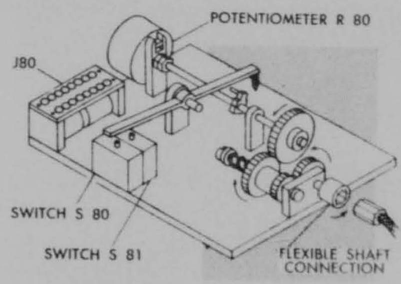

Figure 4—41. Mechanical Schematic, Manual Range Control.

curately framed by the reticle image circle. The switches set the radar junction box (not part of the sight) for manual range operation or for radar range operation. The potentiometer is furnished with dc from the sight. It picks off a voltage, as determined by its setting, which is sent to the radar junction box through S80. The junction box returns this signal to the radar-range gear box of the sight, where the signal operates motor B401. At this point the flow of range data becomes identical with the flow when radar range data is supplied.

25. OPTICAL SYSTEM

The optical system of the sight consists of the optical components which present the reticle image to the pilot. The components are closely related to the elevation, deflection and range prediction elements. As these portions of the optical system have been described previously, they will be discussed only briefly in the following paragraphs.

Two sources of light are used to produce the reticle image on the pilot's windshield. One, the reticle circle bulb, is the light source for the variable-diameter circle. The other, the target index bulb, is the source for the reticle index dot and also for the fixed-size circle. The fixed-size circle appears only when the sight is being used as a fixed sight. The reticle circle bulb (for the variable size circle) furnishes the light which shines through the illuminator tube. Emerging from the illuminator tube it is shaped into a circle (or annular ring) by the range cone and reflected to the pellicle. The pellicle is a flat, oval-shaped, transparent film. It is rigidly mounted so that the light from the range cone strikes it at 45 degrees. The light is reflected by it and does not pass through it appreciably. The pellicle reflects the light from the range cone upward to a mirror which is fixed in position. The mirror reflects the light, through a collimating lens, to the flat, oval-shaped mirror which is rotated in elevation and deflection. This is the boresight mirror, indicated in Figure 4-32. Its angular position determines the precise angle at which it reflects the beam of light forming the reticle circle. The light always is reflected upward to an optically flat area of the airplane's windshield. The angle at which the light meets the windshield causes the image to appear as a circle, not as an ellipse. The image also appears to the pilot to be at an infinite distance in front of him because the collimating lens projects the light which passes through it in parallel lines.

The second light source in the optical system, the target index bulb, is mounted directly below the pellicle at the lower end of a tube. The upper end of the tube, under normal conditions, is closed by a cover. The cover is pierced at its center by a small hole which permits a narrow shaft of light to project vertically upward to the pellicle. The light strikes the pellicle at an angle of 45 degrees and at the center of the light ring formed by the range cone. The light passes through the pellicle, and follows the same path as the light which forms the reticle circle. At the windshield, the light provides the dot at the center of the circle.

When the sight is used as a fixed sight, the cover carrying the index dot hole is swung upward. This action permits light from the target index bulb, which has passed through a reticle, to reach the pellicle. The reticle is an opaque disk pierced not only by a hole similar to the hole in the cover but also by three arcs which form an almost complete circle. Light from the target index bulb passes through the hole and circle in the reticle upward to the pellicle. At the time when the cover is swung upward from its normal position, the light reaching the pellicle from the range cone is extinguished automatically. The pellicle therefore receives light from the target index bulb only. This light, passing through the

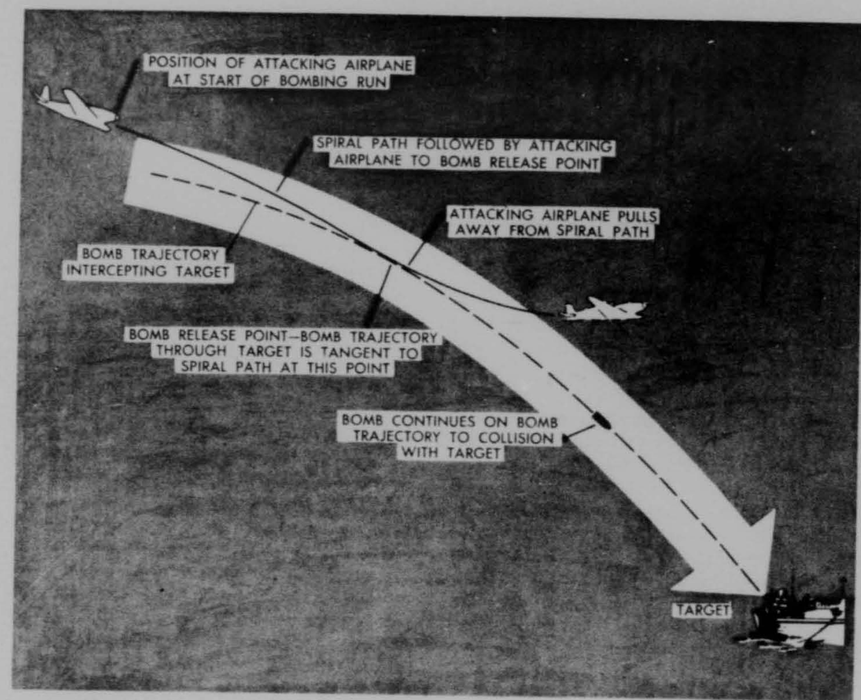

Figure 4–42. Spiral Path Bomb Trajectory.

pellicle, follows the path previously described. At the windshield the light forms an image consisting of a fixed-size circle with a dot at its center.

26. ELEVATION PREDICTION

General. When the sight is used for bombing, the pilot flies his airplane along a path which will keep the reticle image dot, or index, continuously aligned with the target. He keeps his wings horizontal so far as permitted by the necessity of making tracking corrections. The only requirement in choosing the position from which to start a bombing run is that the resulting course at some point will be tangent to a bomb trajectory intersecting the target. No range, altitude, or dive angle inputs are required, although range data is not cut off. When the proper release point is reached, the reticle circle image disappears (the circle bulb is extinguished). In normal operation, the bombs are dropped automatically, although manual control may be substituted.

During a bombing run, the reticle image dot is depressed below the controlled line (Figure 4-24) by a constant angle in elevation. In deflection, the sight mechanism continuously introduces a prediction angle to correct for the relative motion between the target and the attacking airplane. The relative motion is caused by components of the wind and target velocity across the line of sight. The depression of the reticle image dot forces the pilot to fly a spiral type of course toward the target in a vertical plane (Figure 4-42). In following the spiral path, the velocity vector of the airplane continuously changes direction. When the velocity vector becomes tangent to a bomb trajectory through the target, a definite relationship is reached between the angular velocity and the linear acceleration of the airplane. This relationship is detected by the superelevation assembly (bombing accelerometer) and the elevation gyro. Their data outputs combine to extinguish the reticle circle bulb and to actuate the bomb release relay. The effect of the airplane speed is introduced by an aneroid bellows in the superelevation assembly, which makes it possible for the sight to operate over the entire speed range of the airplane.

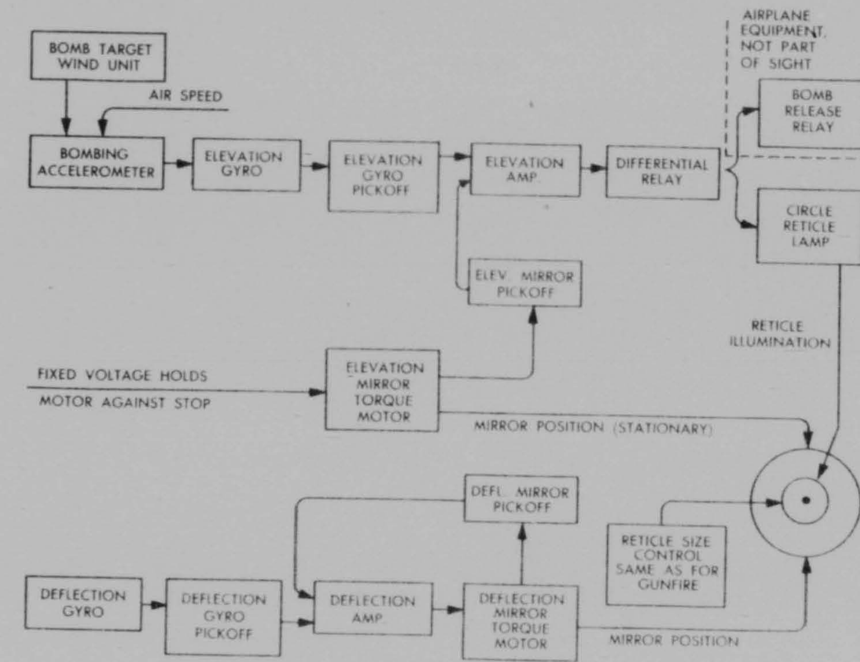

Figure 4–43. Bombing, Simplified Block Diagram.

The actual functioning of the sight when used for bombing (Figure 4-43) is similar in many respects to operation for gunfire (Figure 4-27.) Deflection and elevation prediction for bombing differs from prediction for gunfire in that the bombing function does not utilize any stiffness motor control (as is indicated in Figure 4-44). With this exception, however, the deflection channel operates in the same manner in each function. The principal difference beween the bombing and gunfire functions occurs in the elevation channel. During a bombing run the elevation amplifier does not control the position of the mirror, which is held stationary. The amplifier output is applied instead to a differential relay. This relay, when actuated, operates the bomb release relay in the airplane and also extinguishes the circle reticle bulb in the sight. The following paragraphs discuss the means used to accomplish these results.

27. BOMBING ACCELEROMETER (SUPERELEVATION ASSEMBLY)

The superelevation assembly is used only when the sight is in the bombing function. When the sight is to be used for this purpose

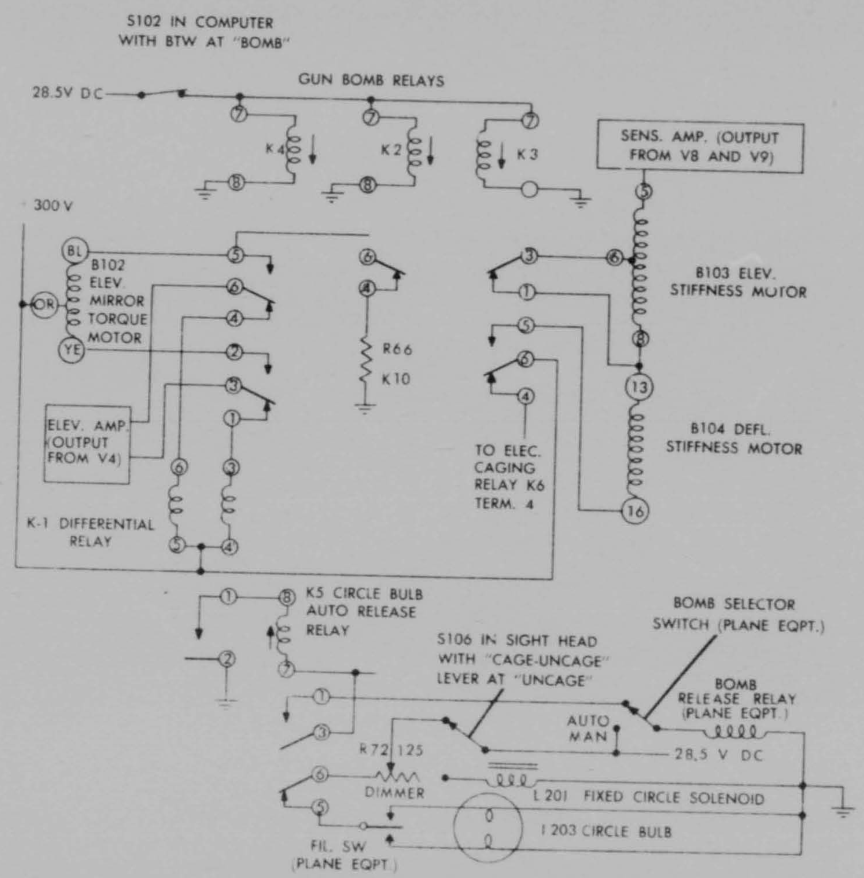

Figure 4-44. Gun-Bomb Relay Switching Circuits, Simplified Schematic.

the knob on the bomb target wind unit is turned to the "bomb" position and adjusted to the setting indicated by the pilot's estimate of wind at the target. The knob is connected by means of a universal joint shaft to a cam on the bombing accelerometer in the computer. Rotation of the cam engages a ball arm on the accelerometer with a fork arm on the gimbal of the elevation gyro. The effect of this connection is to apply a weight and lever arm to the gimbal. The cam also is used to adjust the effective length of the lever arm to correspond with the wind estimate. The weight and lever prevent precession of the gyro, holding the gimbal against a stop. The weight responds, by its tendency to move, to the acceleration and the diving angle of the airplane. Its tendency to move also is controlled by air speed by means of an aneroid bellows which is supplied with air pressure through pitot and static tubes. Furthermore, a counterweight on the bombing accelerometer lever arm cancels the effect of the gravity drop ac-

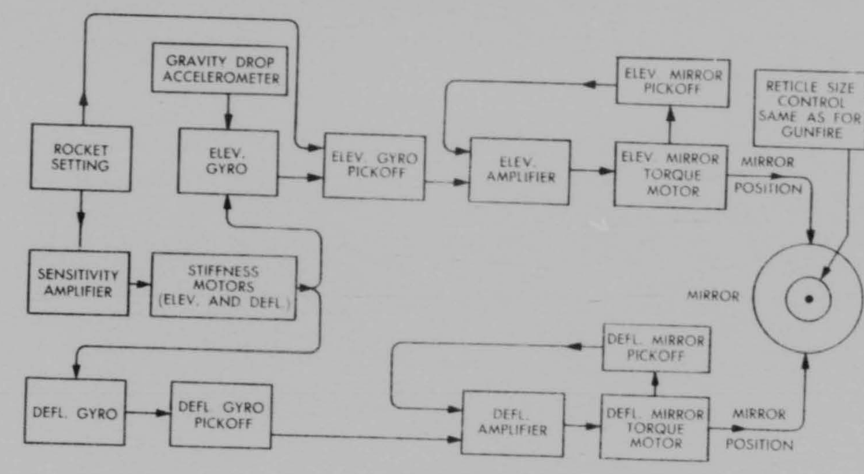

Figure 4-45. Rocketfire, Simplified Block Diagram.

celerometer. When the airplane reaches the point in its spiral approach when the precession tendency of the gyro overcomes the restraint of the accelerometer weight, the gyro gimbal moves.

28. ELEVATION GYRO PICKOFF

The gyro pickoff armature shaft is connected mechanically to the gyro gimbal, as stated in the discussion of the gunfire function. When the gyro gimbal is held against the stop, the signal output of the pickoff is constant. When the gyro gimbal starts to move, the pickoff signal changes from this constant value. The signal at all times is sent from the pickoff B103 to the elevation amplifier input transformer T5. Connections are the same as for the gunfire function and are shown in Figure 4-31.

29. ELEVATOR TORQUE MOTOR AND MIRROR PICKOFF

The elevation mirror torque motor, when the sight is in the bombing function, does not receive the same input that it receives during gunfire. The torque motor receives instead a DC voltage of constant value. This voltage holds the torque motor at a fixed position. The torque motor armature shaft holds the mirror steady at a position which depresses the reticle image by a fixed $9\frac{1}{2}$ degrees. As the position of the armature shaft is fixed, the mirror pickoff signal is also unchanging because the pickoff armature is mounted on the same shaft. This signal remains unchanged during the time that the sight is in the bombing function. The signal is not affected when the gyro starts to precess. Furthermore, this signal has the same magnitude as the signal output of the gyro pickoff when the gyro is held against its stop by the bombing accelerometer. The signal is sent from the elevation mirror pickoff B102 to the elevation amplifier input transformer T5. Connections are the same as during gunfire and are shown in Figure 4-31.

30. DIFFERENTIAL RELAY

The differential relay K1, when the sight is in the bombing function, is placed in the plate circuit of the elevation amplifier output tube V4. It replaces the elevation-mirror torque motor B-102, as indicated in Figure 4-44. When the inputs to the elevation amplifier are equal, that is, when the bombing accelerometer holds the gyro against the stop, the current in one coil of differential relay K1 is the same as the current in the other coil. Under

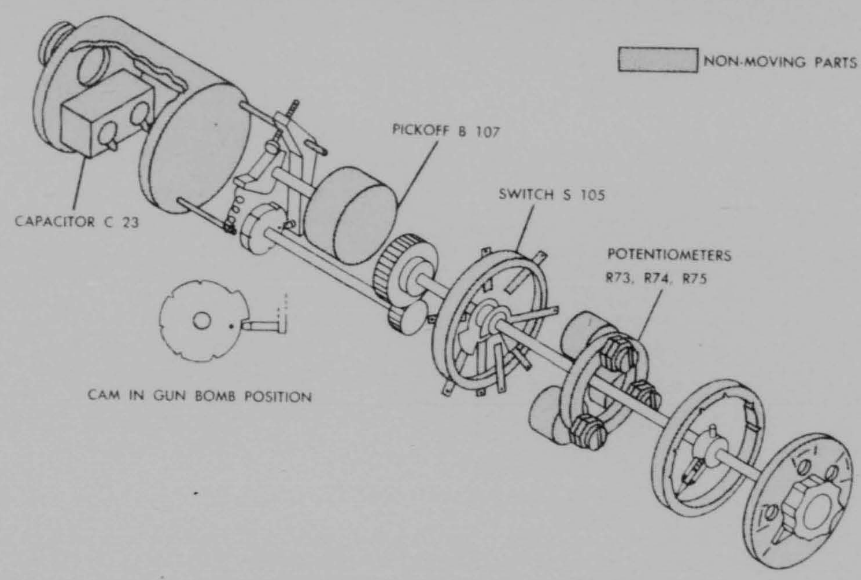

Figure 4-46. Mechanical Schematic, Rocket Setting Unit.

this condition the relay is not energized and contacts 1 and 2 are open. When the inputs to the elevation amplifier are unequal, that is, when the gyro starts to precess, more current flows through one relay coil than through the other. Contacts 1 and 2 then close; relay K5 becomes energized, closing contacts 1-3 and opening contacts 5-6 (Figure 4-44). Contacts 1 and 3 furnish 28 volts DC to the bomb-release relay, provided that the bomb-selector switch is at the "automatic" position. Contacts 5 and 6 break the circuit to the circle reticle bulb 1203, and the circle reticle image is extinguished.

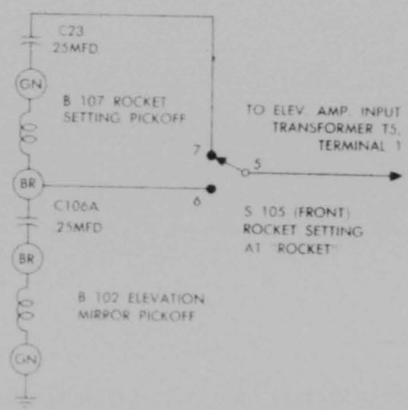

Figure 4-47. Elevation Amplifier Input Circuit for Rocketfire, Simplified Schematic.

31. ROCKETFIRE SOLUTION

The operation of the sight when used for rocketfire is similar in many respects to gunfire operation. The similarity may be noted in Figure 4-45. The size of the reticle circle is controlled in the same manner, by range data. Deflection prediction is accomplished as in gunfire. A fixed sensitivity control, however, is applied to the deflection stiffness motor and the elevation stiffness motor instead of the range and air density control used in the gunfire function. Elevation prediction differs in that a fixed depression of the reticle image in

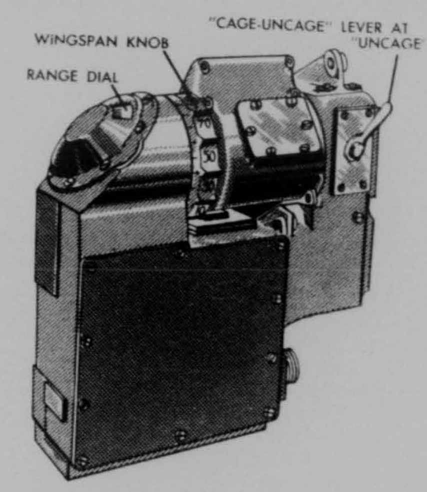

Figure 4-48. Sight Head.

elevation is applied as in the bombing function. Instead of a constant depression at all times, however, the depression is adjusted for the particular type of rocket to be used.

32. ROCKET SETTING UNIT

The rocket-setting unit includes the pickoff B107 (Figure 4-46). The rotor of B107 is turned by the rocket-setting knob, which also operates the wafer-type switch S105 within the unit. The rear contacts of the switch are connected in the sensitivity amplifier input circuit as shown in Figure 4-35. When the rocket setting knob is at "gun-bomb" the density potentiometer and the radar range potentiometer control the input to the sensitivity amplifier. When the knob is set at any of the three "rocket" positions these two potentiometers are removed from the circuit. In their place is substituted one of the three identical variable resistors R73, R74, or R75. These resistors provide that a constant voltage is fed to the sensitivity amplifier as the data input.

The front contacts of S105 are connected in the elevation amplifier input circuit as shown in Figure 4-47. When the rocket setting knob is turned from the "gun-bomb" position to any of the three "rocket" positions, contacts 5 and 7 on S105 close. This action places rocket setting pickoff B107 in the input circuit of the elevation amplifier. The pickoff is connected in series with elevation mirror pickoff B102. The rocket setting knob, in addition to operating S105, turns the rotor of rocket setting pickoff B107. This action causes the pickoff to generate a signal which depresses the reticle image in elevation. The rocket setting pickoff continues to supply this depression signal as long as contacts 5 and 7 on S105 remain closed. The magnitude of the depression is determined by the particular "rocket" position at which the rocket setting knob is placed.

33. OPERATING INSTRUCTIONS

Whenever the airplane power source is in operation, 115-volt, 400 cycle, single-phase current is supplied to the phase inverter, which is also airplane equipment and is not part of the sight. The phase inverter supplies 28.5-volt, 400 cycle, three phase current to the stators of the gyros in the sight. Thus the gyros are spinning whenever the airplane's power source is in operation. Furthermore, the airplane's power source supplies 28.5-volt DC to the heaters which control the temperature of the fluid in the dampers on the stiff-

Figure 4-49. Rocket Setting Pointer.

Figure 4—50. Bomb Target Wind Pointer.

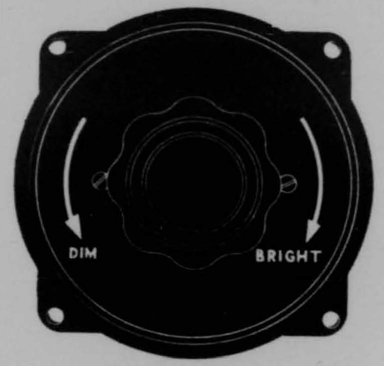

Figure 4—51. Dim-bright Knob.

ness motor armature shafts, and also to the space heaters in the computer. Therefore the following instructions assume that the gyros are spinning, that the dampers are at the correct temperature of approximately 160 degrees F (70 degrees C), and that the space heaters are maintaining the correct air temperature of approximately 135 degrees F (57 degrees C) in the computer, before the sight is started. If the heaters have not been energized, it will be necessary to operate the airplane's power source and energize the heaters for twenty minutes before starting the sight.

34. STARTING

To start the sight, the "sight master" switch (airplane equipment) is placed at "on" (provided that power already has been supplied as described in the previous paragraph). After a short wait (one minute) to permit the amplifier tubes to heat up, the sight is ready for operation.

A check should be made to see that the reticle image, a circle with a dot at its center, appears on the windshield (Figure 4-44). The reticle image is checked further by moving the "cage-uncage" lever from one position to the other (Figure 4-48). The dot should flicker as the lever is moved and the circle should change to three circular arcs.

35. GUNFIRE OPERATION WITH RADAR RANGE

The following controls must be in the positions indicated.

Rocket-setting pointer (Figure 4-49) at "gun-bomb."

Bomb-target wind pointer (Figure 4-50) at "rocket-gun."

Manual-range control on throttle in descent (at clockwise end of rotation).

"Cage-uncage" lever on sight head (Figure 4-48) at "uncage."

"Dim-bright" knob (Figure 4-51) at the position which gives satisfactory reticle illumination.

When searching for targets, the push-button type of caging switch is pressed on the left grip of the control stick. This action will stabilize the reticle image and prevent spurious prediction when tracking begins. "Tracking" may be defined as the act of minimizing the difference between the target position and the apparent position of the reticle image by controlling the attitude of the attacking airplane.

When a target is located and tracking is started, the push-button type of caging switch is released. The reticle image will swing from the target. The airplane should be flown so that the reticle image is continuously and

accurately centered on the target. The reticle circle will change in size as the range changes. The circle will become larger as the range decreases and smaller as the range increases. This action is controlled automatically by the radar set associated with the sight. After the target has been tracked smoothly, without slipping or skidding, for four or five seconds, fire the guns.

36. GUNFIRE OPERATION WITH MANUAL RANGE

The position of each control for this function is the same as the position for gunfire operation with radar range, with one addition and one exception. The additional control is in the wingspan knob (Figure 4-48). This knob is graduated with markings from 30 feet to 120 feet. It must be set to correspond with the wingspan of the target being attacked. The exception previously mentioned is the manual range control on the throttle. The setting of this control is described in the following paragraph.

Searching for a target is carried out in the same manner as for gunfire operation with radar range. Tracking, however, requires operation of the manual tracking control as the target is being tracked. This control governs the size of the reticle image circle. When the control is turned clockwise the diameter of the circle decreases. When the control is turned counterclockwise the diameter of the circle increases. The control should be turned so that the circle continuously and accurately "frames" or encloses, the target. As range decreases, the size of the circle must be increased. As range increases, the size of the circle must be decreased. When the attitude of the target foreshortens or obscures the wingspan dimension, the size of the circle must be determined by good judgment. After the target has been framed and tracked smoothly for four or five seconds, without slipping or skidding, fire the guns.

37. BOMBING OPERATION

A check should be made to see that the following controls are in the positions indicated.

Rocket-setting pointer (Figure 4-49) at "gun-bomb."

Bomb-target wind pointer (Figure 4-50) at "bomb" sector of the dial and at the figure corresponding to the estimated wind speed at the target.

"Cage-uncage" lever on sight head (Figure 4-48) at "uncage."

"Dim-bright" knob (Figure 4-51) at the position which gives satisfactory reticle illumination.

"Bomb-selector" switch (airplane equipment) at "auto" if it is intended to release the bombs automatically. It should be set at "manual" if it is intended to release the bombs by means of the "bomb-release" button (airplane equipment).

Searching for targets is carried out in the same manner as during gunfire operation with radar range. Tracking, or the bombing run, is not the same. The reticle image position is depressed at a fixed angle as a result of the adjustment made on the bomb-target wind unit. This depression makes it necessary to fly the airplane along a downward curve in a vertical plane, or bombing spiral, in order to keep the reticle image aligned on the target.

The bomb-release point is the point on the bombing spiral where the path of the airplane is tangent to a bomb trajectory. At this point the reticle image circle is extinguished automatically, and a red, flashing light is reflected on the windshield. If the "bomb-selector" switch was set at "auto," the bombs will be released automatically. If the "bomb-selector" switch was set at "manual," the "bomb release" button is pressed to release the bombs.

38. ROCKETFIRE OPERATION

A check is made to see that the following controls are in the positions indicated.

Rocket-setting pointer (Figure 4-49) at the "rocket" sector of the dial corresponding to the rocket being used. The pointer is set to "S" on the sector if a steep dive angle is to be used. The pointer is set to "N" if a normal dive angle is to be used.

Bomb-target wind pointer (Figure 4-50) at "rocket-gun."

Manual-range control on the throttle in descent (at clockwise end of rotation).

THIS PAGE IS DECLASSIFIED IAW EO 13526

"Cage-uncage" lever on sight head (Figure 4-48) at "uncage."

"Dim-bright" knob (Figure 4-51) at the position which gives satisfactory reticle illumination.

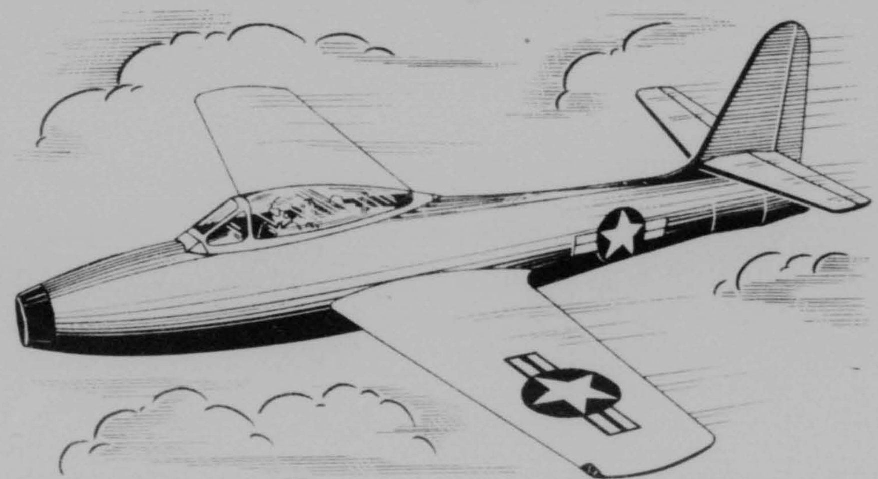
Searching for targets is accomplished in the same manner as for gunfire operation with radar range. Tracking targets is accomplished in the same manner as for gunfire operation with radar range or manual range, as the case may be.

39. FIXED SIGHT OPERATION

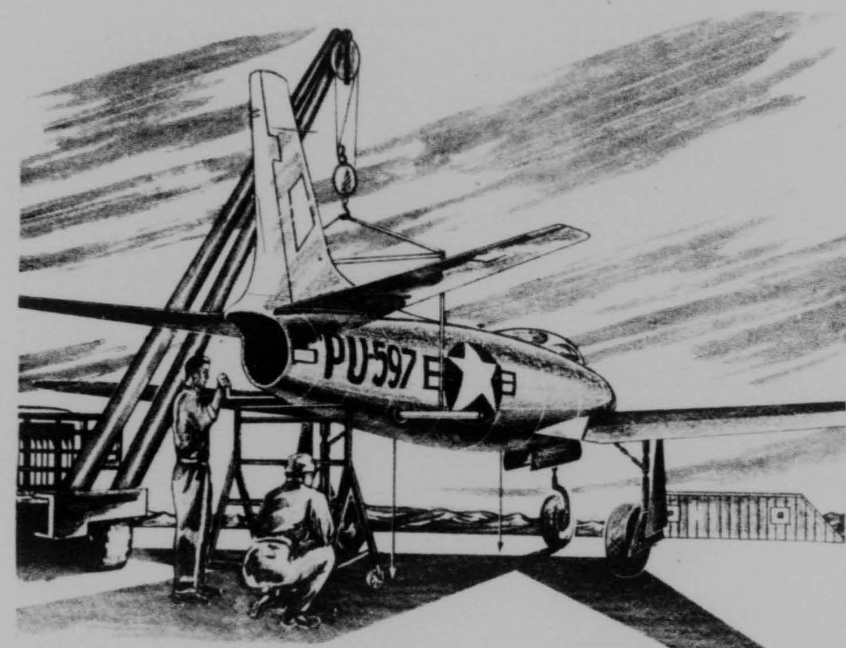
The sight may be used as a fixed "ring sight" if desired. It is superior to the usual ring sight because the reticle image appears to be at an infinite distance from the pilot. A two-inch sideways motion of the pilot's head, for example, will not cause misalignment of the reticle image and target. Instead, it will cause an apparent two-inch motion of the reticle image on the target, which is negligible. The sight may be used as a fixed sight after placing the "cage-uncage" lever on the sight head (Figure 4-48) at "cage." When the sight is used in this manner no prediction angle is generated and the diameter of the reticle circle remains constant.

40. STOPPING

To remove the sight from operation place the "sight master" switch (airplane equipment) at "off." Also place the "cage-uncage" lever on the sight head at "cage" (Figure 4-48). The gyros will continue to spin, the heaters for the dampers on the stiffness motor armature shafts will remain energized, and the computer space heaters will remain energized. These items continue to function as long as the airplane's power source supplies power.



CHAPTER 5—HARMONIZATION



1. GENERAL

Harmonization is the process of adjusting the gun sight, boresighting the guns and camera so that the sight line will be parallel to the flight line and so that the camera will record the action during the firing period. At different airspeeds, gross weights and altitudes variance exists between the fuselage reference line and the flight line. In the F-84, the airplane tends to fly nose up. At 20,000 ft. altitude with a gross weight of 12,000 lbs. the airplane will have a seven mil nose-up altitude when the airspeed is 549 miles per hours. The guns are adjusted so that their fire parallels the sight line at the desired range under these conditions. By leveling the airplane to the sight-adjustment mark which is seven inches above the gun-sight marks on the target, and then boresighting the guns, gun sight, and camera to their respective crosses, the desired 7 mil nose-up condition is obtained without changing the airplane's level position. If it is desired to boresight for a different airspeed, position of sight-adjustment mark is changed accordingly. The gunsighting chart, Figure 5-1 contains the data for various other conditions of speed.

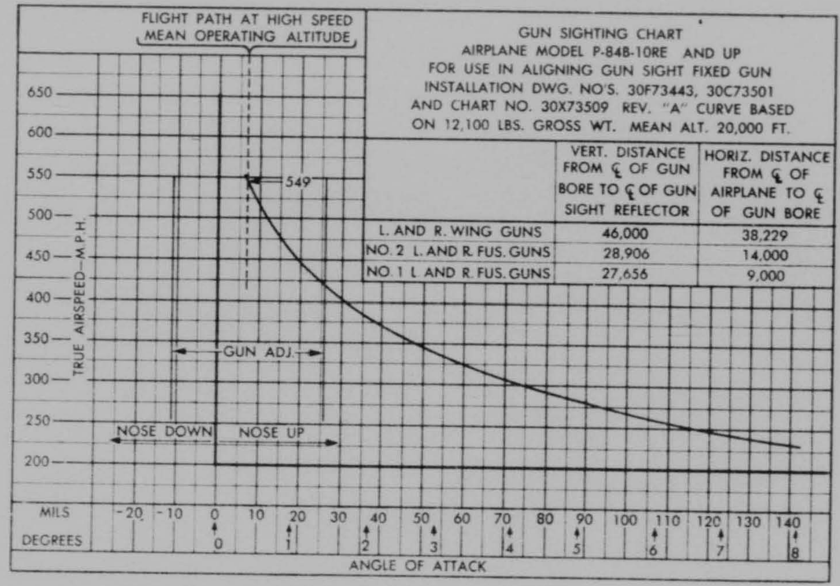


Figure 5—1. Gunsighting Chart.

2. TARGET PREPARATION

Manufacture a target in accordance with Figure 5-2. The target must be adjustable so that it can be raised or lowered or moved laterally.

Preparing the Airplane

A suitable location is selected that will provide at least 100 feet of level surface.

The airplane is jacked up. See Figure 5-3.

Note: Screw-type jacks will be used if available, as hydraulic jacks have a tendency to creep.

A spirit level is placed across the leveling lugs in the cockpit and the airplane is levelled laterally by adjusting one of the wing jacks. The longitudinal-level lugs are stowed on the left longeron in the gun deck. When in use they are bolted to the plate nuts in the top of the longeron. The transverse-level lugs are on the cockpit longerons. By placing spirit levels on the lugs the amount of jack adjustment necessary to level the airplane can be determined.

The gun deck cover is removed and the longitudinal leveling-lugs are installed on the top side of the longeron. The longitudinal level-lugs are stowed on the left longeron in the gun deck. When in use they are bolted to the plate nuts in the top of the longeron. The transverse-level lugs are on the cockpit longerons. By placing spirit levels on the lugs the amount of jack adjustment necessary to level the airplane can be determined. Normally, the lugs are stowed on the side of the longeron. A spirit level is placed on the lugs and the airplane is levelled longitudinally by adjusting the nose jacks.

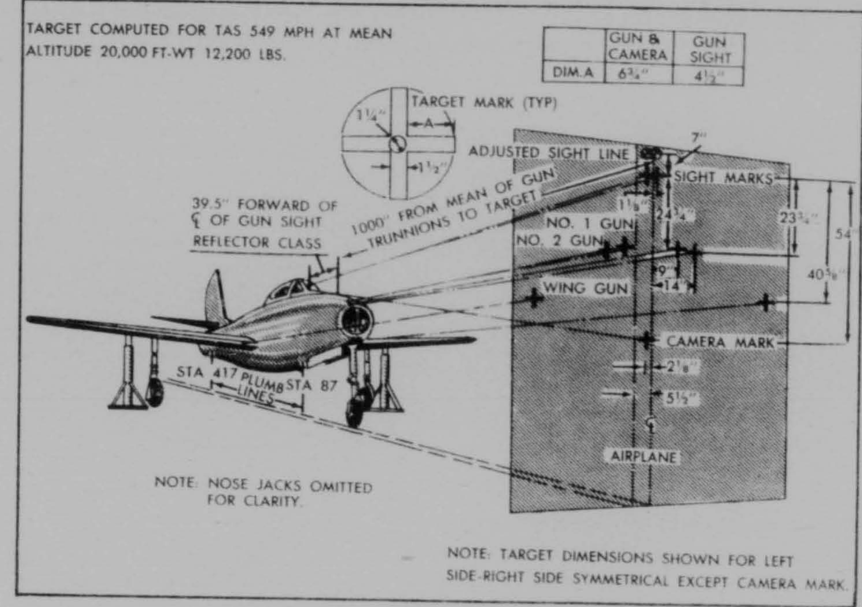

Figure 5—2. Boresighting Target.

Plumb bobs are suspended from the plate nuts on the lower right-hand side of the fuselage marked "Gun Sight Alignment." These plate nuts are five and one half inches from the vertical center line of the airplane, at stations 87 and 417.

The plumb bobs are adjusted so that they are approximately one inch from the ground.

Note: If the suspended plumb bobs sway too freely due to the wind, they should be immersed in receptacles containing oil to reduce sway.

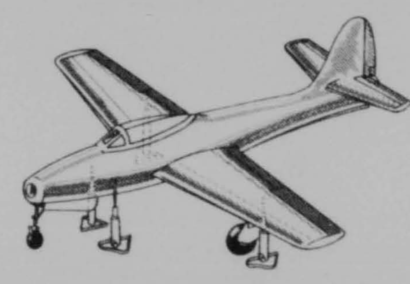

Figure 5—3. Normal Jacking Arrangement.

The target surface is placed at right angles to the longitudinal axis and in front of the airplane, at a distance of 1,000 inches, measured from the center line of the mean pivot point of the gun trunnions.

Note: The mean pivot point of the gun trunnions is 39.5 inches forward of the center of the gunsight reflector glass.

The target is levelled laterally and raised or lowered so that its mid-point approximates that of the airplane's nose.

From a position aft the airplane, one sights along the plumb lines. The eye is kept at a sufficient distance behind the aft bob line, so that both bobs are clearly visible, and the target is moved laterally to align the plumb lines with the vertical line on the target which is five and one half inches to the right of the target's vertical center line.

A sight-line level indicator is placed (Type A-2) on the gun sight glass reflector.

THIS PAGE IS DECLASSIFIED IAW EO 13526

Note: It is important that the windshield glass is clean.

The level is rotated by means of the knob of the frame until the hand level is approximately horizontal with the level bubble thereof on top.

By looking through the small hole in the eyepiece of the hand level, the knob is adjusted until the bubble, which is visible through the eyepiece, is centered on its reference mark.

Next, one sights through the indicator and the target is raised or lowered to align the sight adjustment mark on the target with the bubble reference mark in the level.

The level indicator is removed.

The target is now ready for boresighting and should be affixed in position.

3. SIGHT ADJUSTMENT (K-14B)

External power is connected to the airplane.

Armament selector switch is turned to "Sight and Camera." Gunsight selector control is turned to "Fixed and Gyro." Dimmer control is turned to "BR'T." If sight has adjustable reflector glass dial is turned to zero. Starting with airplane Serial No. 46-638 the gunsight controls have been changed by the addition of a relay and resistor to the selector dimmer, by the installation of a "Rocket Sight" switch on the throttle twist grip. These changes will permit the installation of a modified sighting head which will include an adjustable reflector glass. The reflector glass can be tilted by operating a calibrated knob on the side of the sight. By changing the angle of the reflector glass the sight line can be deflected for rocket firing. A chart installed in the nose-wheel well lists the various dial settings in degrees and the corresponding angular deflection of the sight line. When it is desired to use the gunsight as a rocket sight the pilot presses the switch on the throttle. This actuates a circuit through the relay and resistor which, in effect, cages the gunsight gyro.

Sight is allowed to warm up for ten minutes. Range control is set to 1,500 feet.

Gunsight position is adjusted so that gyro sight aligns with the right hand cross on the target. Elevation adjustments are made at the vertical screw in the sight mounting bracket. Locknut is tightened after completing elevation adjustment. Adjustment for azimuth is made by turning the two screws by which the mount is pivoted in its bracket. If additional azimuth adjustment is necessary the mounting bolt is loosened and the sight head rotated. The adjustment is accomplished by the differential-toothed adjusting ring. This ring, containing 109 fine teeth on one side and 36 coarse teeth on the other, is sandwiched between the fine-toothed ring attached to the base of the sighting head, and the coarse-toothed ring incorporated in the mounting bracket. This arrangement permits large and small adjustments to within plus, or minus one mil. A movement of the sighting head combined with the differential ring as a unit, of one large tooth, represents 10 degrees, while a movement of the sighting head alone, of one small tooth, represents 3.30 degrees. To make this latter adjustment the mounting bolt must be removed and the retaining ring loosened.

The silica gel cell is removed from the sight and by trial and error adjustment of the two screws projecting from the plate assembly near the gyro motor on the back of the sight, the center of the cross in the fixed sight is brought to align with the left hand cross on the target.

The sight is turned off and external power is disconnected from airplane.

4. SIGHT ADJUSTMENT (A-1B)

The two cover plates on the sight head that expose the sight boresight and adjustments are removed.

The electrical caging button (on the stadiometric control) is depressed and held in the depressed position.

Rocket Setting Unit is placed on Gun, and Bomb Target Wind Unit on Gun.

Sight master switch is turned On. The reticle image should appear on the sighting glass.

Uncage-Cage lever is placed at Uncage.

Elevation-adjustment lock-nut is loosened.

While observing the relation between the reticle-image dot and the reference point on the boresight target, the elevation adjustment nut is turned until the reticle image and reference point are aligned in elevation. The reticle image and reference point must be aligned when the wrench is not touching the adjusting nut or any of the moving mechanism.

The lock-nut is tightened carefully to avoid changing the position of the adjusting nut. The alignment is rechecked.

The deflection boresight adjustment screw is loosened.

While observing the relation between the reticle image and the reference point on the boresight target, the deflection adjusting cam is turned until the reticle dot is aligned with the reference point in deflection. The reticle image and reference point must appear to be aligned when the screwdriver is not touching the adjustment or any of the moving parts.

The locking screw is tightened carefully without changing the position of the adjusting cam. The alignment is rechecked.

Both elevation and deflection alignments are rechecked and if not correct, the above procedure is repeated.

Caging button is released. Cage-Uncage lever is placed at Cage, sight master switch is turned Off, and cover plates are replaced on sight head.

5. BORESIGHTING THE GUNS

Note: It will facilitate boresighting if the outboard nose guns are boresighted before the inboard nose guns are installed. The following procedure is applicable when boresighting any gun.

Gun deck and or wing gun-bay covers are removed.

Electrical plug is disconnected from gun solenoid.

The cover plate is lifted off the gun receiver.

The ammunition belt is disconnected from the gun receiver.

For the nose guns, the anti-siphoning pin is inserted to lock the ammunition belt.

Gun is charged to remove unfired round.

Muzzle or breech tool from J-1 or J-2 boresighting kit is inserted. The muzzle tool cannot be used for boresighting the fuselage guns due to the position of the guns in the blast tubes.

To insert breech tool, the gun cover is opened, the bolt moved back and locked. Care must be exercised when inserting the breech tool, as accidental release of the bolt will injure the armorer, and destroy the tool. If convenient, the backplate may be removed, the driving spring released and the bolt moved rearward. In the latter condition, there is no danger of the bolt being forced forward.

The gun is aligned to its respective cross on the target. All adjustments are made at the lockbolt assembly.

Elevation adjustments are made by means of the two vertical screws in the lockbolt. The lockwire is cut and the retainers are rotated out of the way. Both screws are turned simultaneously to raise or lower the gun.

Azimuth adjustments are made by adjusting the Allen head screws on each side of the cam locks. Each locknut is loosened with the special wrench (30X19711) and the screws are turned in or out to obtain the necessary alignment (See Figure 5-4).

After adjustment, the locknuts are tightened to hold the azimuth setting and the retainers are lockwired in their down position to lock the elevation adjusting screws.

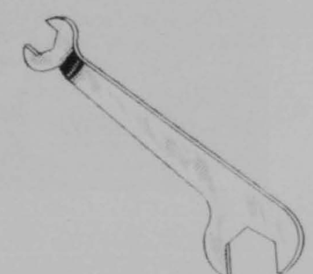

Figure 5–4. Wrench—.50 cal.

The boresighting tool is removed.

The backplate is replaced if it was removed.

The feed chute is connected.

The gun receiver cover is closed.

The plug is reconnected to the gun solenoid.

The longitudinal-leveling lugs are removed and stowed on the gun deck longeron (See Figure 5-5).

The access covers are replaced.

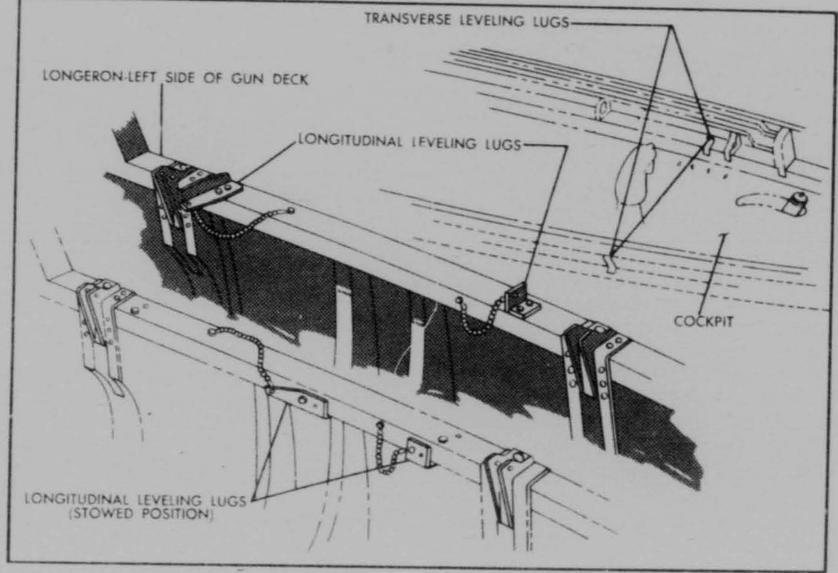

Figure 5—5. Longitudinal Leveling Lugs and Gun Deck Longeron.

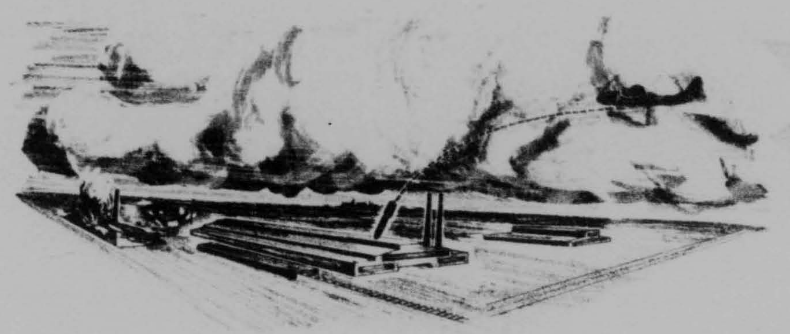
CHAPTER 6—RADAR BOMBING EQUIPMENT



SECTION I—INTRODUCTION TO RADAR

1. MEANING OF RADAR

Radar means "radio direction and ranging." The basic principles upon which its functioning depends are simple. Therefore, the seemingly-complicated series of electrical events encountered in radar can be resolved into a logical series of functions.

2. PRINCIPLE OF OPERATION

The principle upon which radar operates is simple. Briefly, it consists of creating and detecting a radio echo. Some of the sound waves sent out by a loud shout may strike against a wall or hillside and reflect back to the ears of a listener as an echo. In the same way, some of the pulses of high-frequency radio energy sent out by a radar transmitter from the antenna may strike objects in their path and reflect back to the antenna where a radar receiver detects them. This out-and-back cycle is repeated from 60 to 2,000 times per second, depending upon the design of the set. High-frequency radio energy travels in a straight line only and will not bend with the curvature of the earth. Thus, it is impossible for the wave to strike objects which are beyond the optical horizon. This is known as line-of-sight transmission. If the outgoing wave is sent into a clear sky, very little energy is reflected back to the receiver. The wave and the energy which it carries simply travel out into space and are lost for all practical purposes.

If, however, the wave strikes an object such as an airplane, a ship, a building, or a hill, some of the energy is sent back as a reflected wave. If the object is large and a good conductor of electricity, a strong echo is returned to the antenna. If the object is a poor conductor, or is small, the reflected energy is small and the echo is weak.

Radio Waves

Radio waves of extremely high frequencies travel in straight lines at a speed of 162,000 nautical miles per second as compared to 1,100 feet per second for sound waves. Accordingly, there will be an extremely short time interval between the sending of the pulse and the reception of its echo. It is possible, however, to measure the interval of elapsed time between the transmitted and received pulse with great accuracy—even to one ten-millionth of a second.

The directional antennas employed by radar equipment transmit and receive the energy in a more or less sharply defined beam. Therefore, when a signal is picked up, the antenna can be rotated until the received signal is maximum. The direction of the target is then determined by the position of the antenna.

The echoes received by the radar receiver appear as marks of light on a specially-constructed instrument called the "oscilloscope". This oscilloscope may be marked with a scale of miles, or degrees, or both. Hence, from the position of a signal echo on the oscilloscope, an observer can tell the range and direction of the corresponding target.

3. USES OF RADAR

Modern defense against aircraft attack requires that the presence of hostile planes be made known long before the planes can be seen or heard. This knowledge must be available irrespective of atmospheric conditions; fog, clouds, or smoke during the day or night must not interfere with the detection of hostile aircraft. Radar has provided a source for such information, and at the same time has opened new fields for greatly improving traffic control and safety for both airplanes and ships.

Long-range Reporting

This is done by fixed stations constantly searching a specific area to warn of enemy attack. Information from such stations is recorded continuously. The data are used to guide interceptor craft toward an enemy target.

Gun-laying or Fire Control

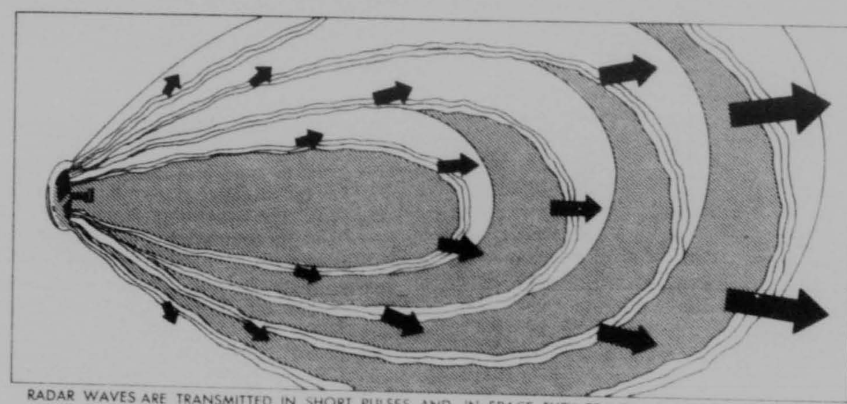
This is the short-range determination of range, azimuth, and elevation of the enemy target for the control of defense equipment, such as search-lights and anti-aircraft batteries. Such bearings must be made rapidly and accurately.

Air- or Ship-borne Use

Portable equipment is used in patrol craft to search for the presence of enemy craft, and in combat craft to locate the target, and for fire control. The equipment may be designed for the detection and location of cities, rivers, bridges, aircraft, surface vessels, or surfaced submarines. It may also be used as an aid to navigation by a ship or plane to determine its course or position in relation to ground targets or a home beacon station. Air-borne equipment is used in night fighter aircraft to locate and to destroy enemy aircraft. Air-borne radar equipment is used also to identify friendly ships to fighter command to distinguish them from the enemy.

4. HISTORICAL DEVELOPMENT

One of the first observations of "radio echoes" was made in the United States in 1922 by Dr. Albert H. Taylor of the Naval Research Laboratory. Dr. Taylor observed that a ship passing between a radio transmitter and receiver reflected some of the waves back toward the transmitter. Between 1922 and 1930 further tests proved the military value of this principle for the detection of surface vessels which were hidden by smoke, fog, or darkness. Further developments were conducted with carefully guarded secrecy. During this same period Dr. Breit and Dr. Tuve, of the Carnegie Institute, published reports on the reflection of pulse transmission from electrified layers in the upper atmosphere which forms the earth's ceiling. This led to the application of the principle to the detection of aircraft. Other countries carried on further experiments independently and with the utmost secrecy. By 1936, the United States Army was engaged in the development of a radar-warning system for coastal frontiers. Between 1936 and 1940 the pulse system of transmission was further developed. By the end of 1940 mass production of radar equipment was under way. By September 1940, the



RADAR WAVES ARE TRANSMITTED IN SHORT PULSES AND, IN SPACE, THEY TRAVEL TO INFINITY. A SYMBOLIC CROSS-SECTION OF THESE PULSES IS SHOWN ABOVE. THE ARROWS INDICATE THE DIRECTION THEY ARE TRAVELING AWAY FROM THE REFLECTOR.

Figure 6—1. Radar Pulses in Space.

British had developed radar to such a point that they were able to bring down great numbers of enemy planes with little loss to themselves. Beginning in 1941, British-American cooperation in the development of radar has given the United Nations the best radar equipment in the world. The Germans also made great strides in radar development. This was evidenced by the sinking of the British battle-cruiser Hood by the German battleship Bismarck, by means of radar finding, before the Hood could fire her second salvo.

5. BASIC RADAR

In the applications of radar, three elements are of primary interest, namely, the range, azimuth, and altitude of any given target. Therefore, equipment must be designed so that range, azimuth, altitude, or any combination of the three can be determined.

Range Measurement

The measurement of range will be considered first. Radio waves travel at a known velocity of approximately 162,000 nautical miles per second. For a radio wave to travel one nautical mile, therefore, would take 6.2 microseconds. (A microsecond is one-millionth of a second.) For a radio wave to travel one nautical mile to a target and return would require 12.4 microseconds. In radar the time required for a radio wave to travel one mile to a target and return is called a "range mile" in time. Now, if a device is incorporated in the equipment to measure the time required for a pulse to travel to a target, be reflected, and return, the range can be measured directly. In other words, instead of calibrating the range scale in time, it is calibrated with mile marks every 12.4 microseconds.

Transmitted Radio Energy

To determine azimuth and relative altitude, the radio energy must be transmitted in only one direction at any given instant. To do this, a highly-directional transmitting and receiving antenna is used. The directional antenna acts like a nozzle on a hose, so that the radio energy can be directed in any direction desired. Now, if two protractors are placed on the directional antenna, one on a horizontal plane and one on a vertical plane, the position in which the antenna rests at a given instant can be measured. This would indicate the azimuth and the elevation of the object reflecting the transmitted energy. The directional antenna allows the use of a low-power transmitter because all its energy can be concentrated on a small area.

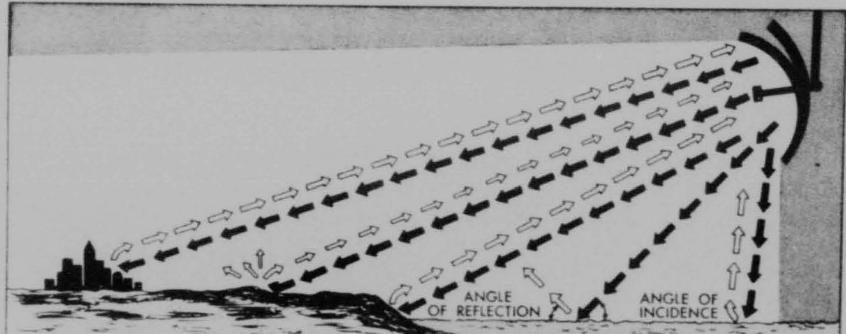
THIS PAGE IS DECLASSIFIED IAW EO 13526

6. PULSE TECHNIQUE

Most radar systems utilize the pulse technique of transmission of radio energy. By this method extremely short, powerful, pulses of radio energy are transmitted at regular intervals. The time duration of the pulse is one-half to two and one-half microseconds with a peak power of 50 to 150 kilowatts. The pulses are transmitted at frequencies ranging from 60 to 2,000 pulses per second. Pulsing provides an easy way to measure range since the transmitted pulses can be used as starting points for measuring range. Pulsing is necessary to measure range in order to distinguish which echo is being received. The idea is to send out a pulse of energy and start measuring time until a reflection or echo is received. The time which elapses between the transmitter pulse and the received echo will determine the range. Then another pulse will be sent out and the same procedure will be repeated. To search for targets over a wide range in azimuth, the directional antenna is rotated so that it can transmit radio energy in the direction desired. (Figure 6-2.)

Pulsing

Pulsing also has its limitations. To concentrate energy on a given area often enough, as the antenna rotates, to give a good, clear return from the target, the pulses must be transmitted at a high-repetition frequency. If the pulses are transmitted too often, however, the range of the equipment is limited by not allowing enough time for the long-range echoes to return before another pulse is transmitted. For instance, suppose pulses were transmitted at a rate of 1250 per second. This would allow only 800 microseconds between pulses, so only targets up to a range of $\frac{800}{12.4}$ or 64 miles approximately could be received. Thus, it can be seen that a compromise must be struck between range and pulse-repetition rate.



WHEN A RADAR PULSE STRIKES A SURFACE, THE ANGLE OF ITS REFLECTION IS EQUAL TO THE ANGLE OF INCIDENCE. AN ECHO IS REFLECTED BACK TO THE RECEIVER, THEREFORE, ONLY WHEN THE ANGLE OF INCIDENCE IS 90°. SINCE THE RADAR INDICATIONS OR SCOPE PICTURE DEPENDS UPON THE STRENGTH OF RECEIVED ECHOES, ONLY THOSE OBJECTS WHOSE SURFACES ARE 90° TO THE LINE OF TRAVEL OF OUTGOING PULSES WILL BE VISIBLE. SIZE AND CONCENTRATION OF SUCH SURFACES DETERMINE STRENGTH OF ECHOES AND, HENCE THE SIZE AND CLARITY OF OBJECTS ON THE SCOPE PICTURE. IN THE SCHEMATIC DRAWING ABOVE, SOLID ARROWS REPRESENT THE LINE OF TRAVEL OF THE OUTGOING PULSES AND SHADED ARROWS, REFLECTION OF PULSES BY VARIOUS TYPES OF OBJECTS.

Figure 6—2. Reflection of Radar Pulses.

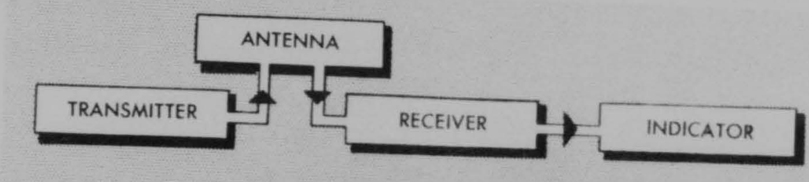


Figure 6—3. Block Diagram of a Simple Radar System.

7. THE PLAN POSITION INDICATOR (PPI)

A basic radar system consists of the following components: transmitter, receiver, antenna, and indicator. See Figure 6-3 and Figure 6-4.

Transmitter

The transmitter generates a high-power, ultra-high frequency pulse which is radiated by the antenna.

Receiver

Reflection or echoes are received by the same antenna and fed into the receiver. The receiver acts as an ordinary broadcast receiver in that it detects the return echoes and converts them into voltage pulses. Consequently, instead of feeding the received signals into a loudspeaker so they can be heard, the signals are fed into the indicator unit where they can be seen visually on a cathode-ray tube screen.

Antenna

A radar system can use a single antenna for both transmission and reception because transmission is necessary only during the short initial pulse. This is accomplished by using a switch in the antenna feed line, so that either the transmitter or the receiver is connected to the antenna at any given instant. The switch is referred to as the Transmit-Receive, or T-R box and is operated electronically.

Indicator

The indicator units are essentially a cathode-ray tube with its associated circuits. The cathode-ray tube is a special type of vacuum tube in which electrons emitted from a cathode are caused to move at a very high velocity, are formed into a narrow beam, and are then allowed to strike a chemically-prepared screen which fluoresces, or glows, at the point where the electron beam strikes. The importance of the cathode-ray tube is that it provides a visual means of examining the signal-return voltages which are reflected into the receiver unit. Because electrons are so very light in weight, the electron beam can be deflected very quickly. This property enables the cathode-ray tube to be used in measuring currents and voltages in terms of millionths of a second.

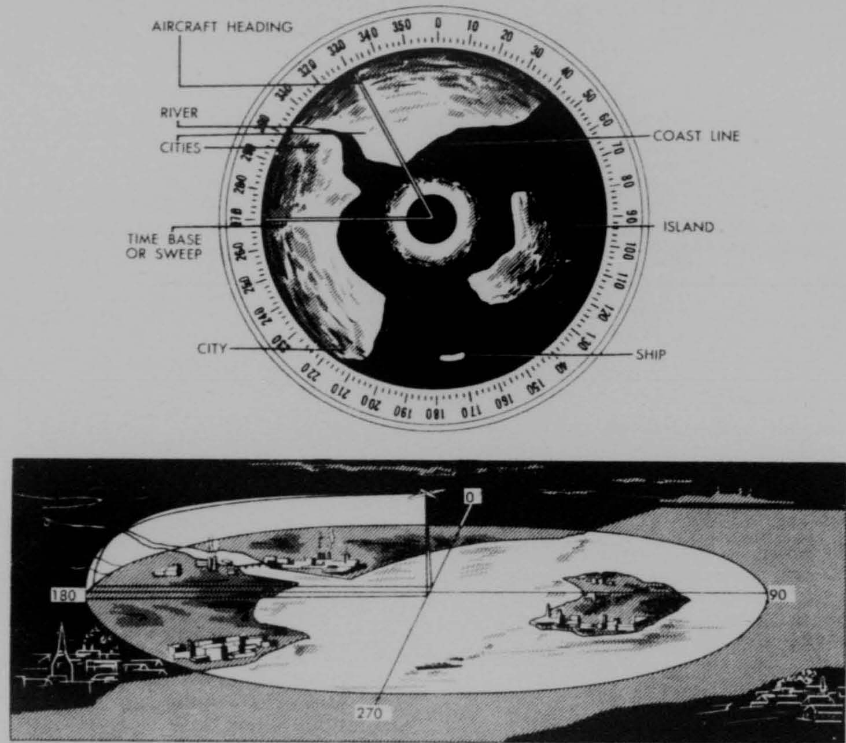
8. CATHODE-RAY TUBES

There are two general types of cathode-ray tubes: electrostatic and electromagnetic. These types refer to the method used to introduce the signal voltages into the tube and to focus the electron beam.

Electromagnetic and Electrostatic Tubes

In the airborne equipment, the magnetic deflection type of cathode-ray tube is used in preference to the electrostatic deflection type. The advantages of the electromagnetic tube are its greater structural simplicity, its greater ruggedness, and its shorter length for a given size screen.

The electromagnetic type of cathode-ray tube has come into recent use because of the greater definition possible with magnetic focusing. Also, electromagnetic deflection has a number of advantages over electrostatic deflection, particularly when a rotating radial sweep is required to give polar indications as in the case of Plan Position Indicator, or PPI, type of presentation.



IN THE PERSPECTIVE DRAWING ABOVE, THE RADAR BEAM IS SWEEPING THROUGH 360 IN AZIMUTH. THE SCOPE PICTURE OF THE AREA SCANNED IS PRESENTED AT THE TOP. NOTE THAT THE SWEEP ON THE SCOPE ALWAYS IS IN STEP WITH THE RADAR BEAM. HERE BOTH ARE AT 270.

Figure 6–4. The Radar Beam in Action.

Referring to Figure 6-5, electrons are emitted by the cathode. A control grid surrounds the cathode and acts as a valve to control the number of electrons passing toward the screen. The control grid thus controls the intensity of the beam. Incoming signals are converted into a series of voltage pulses fed to this grid. Each voltage pulse allows more electrons to flow which intensifies the electron beam during the time of the pulse and produces a bright spot on the cathode-ray tube screen. The negatively-charged electrons are attracted by the positively-charged first anode. Some of the electrons pass through a hole in the first anode toward the screen. The focus coil of an electromagnetic tube is wound on an iron core which may be moved along the neck of the tube to a limited extent to focus the beam. The magnetic field created by the focusing coil tends to form the electrons into a fine point as they strike the screen. The deflection coils also make use of the magnetic field to produce the sweep in the indicator. The deflection coils are so wound that a changing current through them causes a deflection of the electron beam from the center of the PPI screen to the outside rim. By rotating the deflection coils around the neck of the

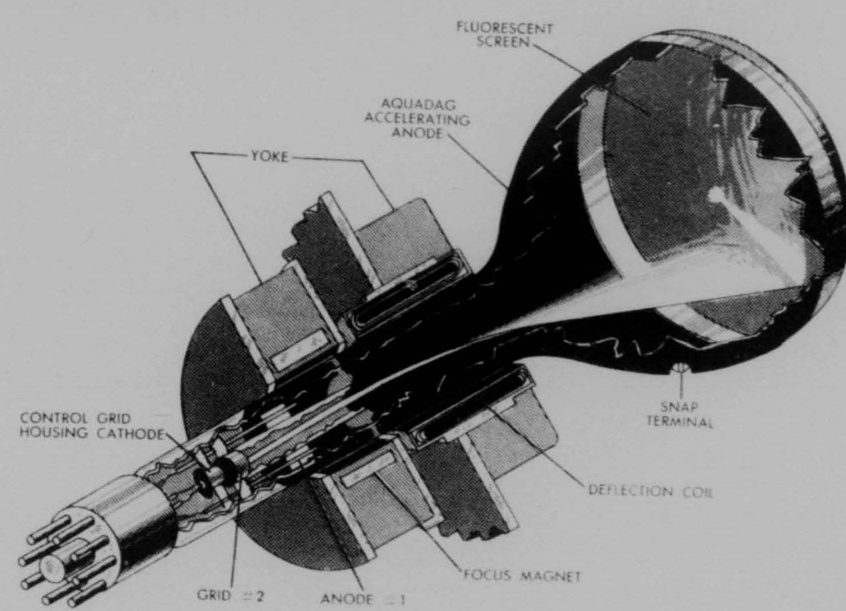


Figure 6–5. Electromagnetic Cathode-Ray Tube.

tube, we can thus create a radial sweep on the PPI screen. The second anode is called the "Aquadag accelerating anode" in this tube. The inside of the tube is covered with a compound of graphite known as "aquadag" and a high positive voltage is placed on it to accelerate the electrons toward the screen. The screen of the tube is coated with a chemical which fluoresces when struck by electrons.

An electron beam consists of a large number of electrons moving with high velocity and possessing considerable kinetic energy. This energy of motion is transformed into energy of other forms when the electron beam strikes some object. If the object is coated with a fluorescent chemical, part of the energy is transformed into light. Most of the energy, however, is dissipated in heat. If the electron beam is concentrated in one spot for a considerable length of time, it will destroy the fluorescent chemical and possibly even melt the glass tube. The operator is cautioned to guard against this condition.

SECTION II—GENERAL DESCRIPTION, FUNCTION, AND PRINCIPLES OF OPERATION OF A/N APQ 13-2 & 23-2

1. FUNCTION OF BASIC RADAR SET APQ-13

The primary purpose of the AN APQ-13 is to serve as a high-altitude bombing set during overcast weather conditions. Because of insufficient definition, its results cannot be classified as precision bombing but rather as area or pattern bombing. When used in conjunction with the Norden bombsight, its accuracy is greatly improved.

In addition to its use as a bombing set, it is a valuable navigational aid. By observing the PPI scope, it is possible to determine the direction and velocity of the wind, and the speed and altitude of the plane. In operating the set with azimuth stabilization (the output of the flux-gate compass system of the plane is fed to the APQ-13), true north appears at the top of the scope at all times regardless of the plane's movement.

Navigation is also aided by the set's ability to trigger off a beacon up to 300 miles distance enabling the navigator to take a fix or home on the beacon.

In addition to all these uses, it can be used as a conventional sea-search set to detect targets.

It can be readily seen that the AN APQ-13 is an all-round radar set and not exclusively a bombardment set.

2. FACTORS INFLUENCING FALL OF BOMB

If a bomb were released from a plane and no air resistance existed, it would fall at the same forward velocity as the speed of the plane and be directly below the plane at the moment of impact. But since air resistance does exist, holding the bomb in the air longer (vertical lag), and reducing its forward speed (horizontal lag), the plane may be a considerable distance ahead of the point of impact. This distance is called trail.

From this very brief discussion, it is obvious that the altitude of the aircraft will affect the vertical lag in the fall of the bomb, that the speed of the plane will affect the horizontal lag, and that the particular type of bomb will affect the air resistance. Therefore, the three factors influencing the fall of a bomb are altitude, speed, and bomb-type.

Crosswind will also alter the path of the falling bomb—the point of impact will be either to the left or right of the plane's track. The distance from the track to this point is called crosstrail. No correction is made for crosstrail on this equipment. It should be remembered that all computers must take altitude, speed, and bomb-type into consideration.

3. BOMBING TECHNIQUES

There are three methods of sighting: optical sighting with the telescope in the Norden bombsight, radar sighting by observing the target on the scope, and synchronous sighting with the radar set supplying the sighting information to the Norden computer. (This also is called coordinated visual sighting.)

Optical Sighting (Norden Bombsight)

Two indexes appear on the Norden bombsight. One represents a predetermined dropping angle (angle made between a perpendicular and the telescope pointing to the target). The other index represents the instantaneous sighting angle. As the plane approaches the target, the sighting angle should keep decreasing at a rate proportional to the speed of the aircraft until the sighting angle equals the dropping angle. When the sighting angle equals the dropping angle, the bombs are released.

Figure 6—6. Plan Position Indicator (PPI).

The rate of closure (closing in on target) is determined by the movement of the telescope. A motor turns the telescope at a speed decided upon by the bombardier as he keeps the target on the telescope crosshairs.

Radar Sighting (AN/APQ-13)

In radar-sighting, release-line method, a slant-range bomb-release chart is used. The primary function of this chart is to determine the instant the bombs should be released so that they will hit the target. In addition to the horizontal lines representing altitude are the vertical lines representing various true ground speeds.

To determine the point of bomb release, the operator goes through the following procedure:

By rotating the altitude knob, the operator will set the horizontal crosshair of the slide directly on the plane's radar altitude, as indicated on the altitude scale of the chart. He will then rotate the range knob until the intersections of the crosshair on the slide lie directly over the ground-speed line corresponding to the true ground speed of the plane. These two adjustments of the computer predetermine the position of the bomb-release circle on the face of the PPI. The proper instant to release the bombs will come when the target to be bombed just passes under the bomb release circle.

Synchronous Sighting (Norden and Radar). (Coordinated Visual)

A synchronous bomb-release chart is used. The primary function of this chart is to determine specific sighting angles, ranging from 70 to 21 degrees, from the plane to the target. It is used also to determine the slant range of any target. It is used also to determine the slant range of any target within 15 miles and to determine radar altitude as with the slant-

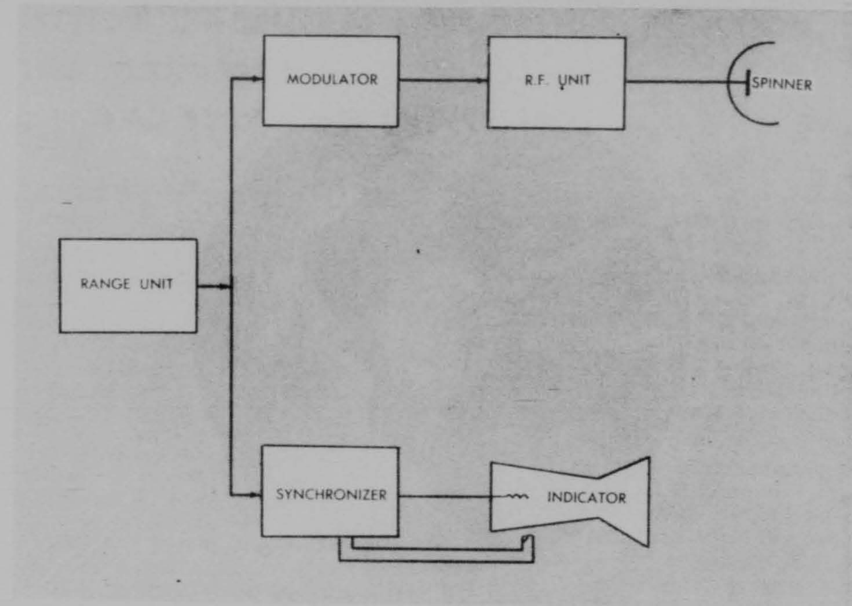

Figure 6–7. Block Diagram, Radar Set.

range bomb-release chart. In addition to horizontal lines representing altitude and vertical lines representing slant range, there is a group of eleven diagonal lines representing various sighting angles from 70 to 21 degrees.

In practice, the radar operator sets up the bomb-release circle by setting the computer drum at the intersection of the appropriate horizontal altitude line and the largest sight-angle line appearing on the altitude line. He notifies the bombardier, via interphone, what that sighting angle is. The bombardier has already preset his dropping angle form rate, trail, disc speed, etc., and he now sets in the sighting angle supplied by the radar operator.

When the target coincides with the bomb-release circle at this setting, the radar operator informs the bombardier, who starts his rate motor (motor-driving telescope). In the meantime the operator has reset his computer to the next lowest sighting angle and as the target approaches coincidence with the new setting of the bomb-release circle, the radar operator calls to the bombardier, e.g. "68 degrees—now!" As this signal is given, the bombardier notes the angle to which the sight has moved at this instant, and if it varies from the value given by the radar operator, he makes an appropriate change in the rate and displacement of the bombsight. This process is continued for other angles as the release point is synchronized for rate and range.

As in normal visual bombing, the bombs are released automatically by the sight when the release point is reached. As an added precaution, the radar operator sets up his equipment for slant-range bombing and follows through on the run so as to be able to take over in case of bombsight failure. It is necessary, as in release-line bombing, for the radar operator to supply the pilot with appropriate course corrections during the bomb run.

Overall Operation of Radar Set

The radar set begins with a master timer (in range unit) which simultaneously trig-

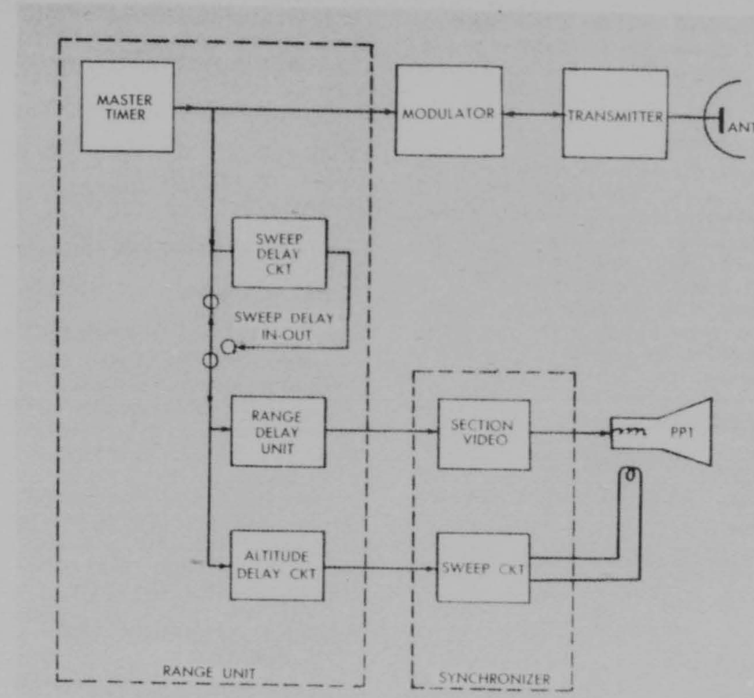

Figure 6–8. Block Diagram, Timing CKT.

gers the transmitter through the modulator and RF unit and starts the sweep in the synchronizer unit. The received signal comes from the antenna (spinner) through the preamplifiers in the RF unit and receiver (in synchronizer) to the PPI (in indicator). Figure 6-6 shows this simple basic function. (See Figure 6-7.)

4. PRINCIPAL CHANNELS OF RADAR SETS

Every radar set can be broken down into a minimum of five channels, namely: transmitter, receiver, sweep, Selsyn and power-supply channels. For simplification in study and rapid trouble shooting, the set will be presented by channels rather than by units. Thus the continuity of the electrical circuits will be maintained regardless of the number of units involved. (See Figure 6-8.)

Transmitter Channel

The pulse which eventually triggers the transmitter magnetron comes from the master timer circuit located in the range unit. The modulator simplifies and shapes the pulse and feeds it to the magnetron transmitting tube. An intense pulse of high frequency is then transmitted to the antenna (spinner) through a flexible waveguide.

Receiver Channel

The reflected energy is picked up by the same antenna and returned to the converter in the RF unit (which includes the beating oscillator and two stages of IF preamplifica-

THIS PAGE IS DECLASSIFIED IAW EO 13526

tion). The signal from the IF preamplifier is then fed through the remainder of the receiver located in the synchronizer unit and finally to the CRT in the indicator unit.

Sweep Channel

The master timer in the range unit which triggers the transmitter also initiates the sweep. However, the pulse must pass through the altitude-delay circuit and possibly through the sweep-delay circuit (depending upon whether sweep delay is being used) all in the range unit. From the range unit, the pulse starts the sweep circuit in the synchronizer unit. The sweep then appears on the CRT in the indicator.

Selsyn Channel

The Selsyn system must convert a physical rotation of the antenna into electrical energy and transmit this energy to the point desired (indicator) and reconvert it to a physical rotation of the sweep. The Selsyn phasing units, torque amplifier, and the azimuth control box aid in orienting the sweep and antenna position.

Power Supplies

No central power supply exists for this set. In addition to the low-voltage rectifier and high-voltage rectifier, the range unit, modulator and torque amplifier have additional power supplies.

Set Characteristics

Transmitter frequency: 9375
Wavelength: 3 cm.
Intermediate frequency: 60 mc.
PRF on 4-, 10-, 20-mile radar: 1350 C.P.S.
PRF on 50-, 100-mile radar: 675
PRF on all beacon ranges: 270
Pulse width on 4-, 10-, 20-mile radar:
MD-12 MD-38
½ ms ½ ms.
Pulse width on 50-, 100-mile radar:
1⅛ ms ¾ ms.
Pulse width on all beacon ranges:
2¼ ms 2¼ ms.
Peak Power output: 40 KW Average Power output—30 Watts.
Beacon frequency: 9310 mc.
Altitude limits: 15,000 to 35,000 feet.
Tx radiation width in degrees: 3.
Antenna tilt limits: Plus 10 degrees, minus 30 degrees.
Sector scan limits in degrees: 50° plus or minus 10°.
Spinner speeds: continuous 20 to 27 RPM cw-ccw 13 to 21 RPM
Sector scan 13 to 21 RPM, or 50-60 scans per minute.
Units that are pressurized: R.F., Top Hat, wave guide.
Amount of pressure: 5 to 7 pounds per sq. in. —med. to RF unit.
Range mark spacing: 1 and 5 miles.
Crystal current: .5 to 1.2 ma.
Transmitter current: 6 to 8 ma.
Approximate weight of equipment: 630 lbs.
Altitude delay limits: 3 to 5 miles.
Range delay limits: .5 to 15 miles.
Sweep delay limits: 0 to 200 miles.
Antenna radiation pattern: Cosecant Sq.
Average power used: 8 amps, 27½ volts DC; 10.4 amps, 115 volts AC.
Average inverter drain: 100 amps at 27.5 volts DC with a starting drain of 700 amps.

5. APQ-23 COMPUTER AND ITS PURPOSE

To understand the bombing equations solved by the APQ-23 computer, it is necessary to recall a few of the basic mathematical operations. In this chapter, the principles of algebra, geometry, and trigonometry, which are pertinent to offset bombing are reviewed and explained. A careful study of this material will help follow the development of the bombing equations and their application.

Algebraic Manipulations

An algebraic expression is one that expresses or represents a number by signs, numerals, letters, and exponents. It may consist of a single letter, such as E (for voltage); it may be two letters, such as IR (I times R, or current times resistance); it may contain an exponent, as in I^2R (I squared times R, or current squared times resistance); or it may contain a variety of factors, such as $5x^2Y$ (5 times x squared times y). The value of the number represented depends on the value of the letters. Thus, if I is 5 and R is 100, IR is

500; while if I is 2 and R is 50, IR is 100. The arrangement of the numerals and the letters indicates whether they are to be multiplied or divided; for example, ab means a times b, $\frac{a}{b}$ means a divided by b. The sign indicates whether the number is to be added or subtracted. Sometimes, of course, the final product has a negative sign when there is nothing from which to subtract. One should not be disturbed by that fact. It merely indicates a negative reference such as one encounters in a negative voltage.

Algebraic Expressions

Algebraic expressions can be treated as numbers, that is, they can be added, subtracted, multiplied, and divided. Two or more expressions can be multiplied by writing them as one expression; for example, ab times cd is written abcd. Similarly, abcd divided by bc equals ad. Two or more expressions may be added or subtracted only if they are like quantities, that is, have the same letters raised to the same powers. Thus, 5x plus 6x equals 11x. However, 5x plus 6y cannot be combined in one term because they have different letters. Enclosing expressions with parentheses ( ), brackets [ ], or braces { }, means that the enclosed terms are to be considered as one quantity; for example, the expression 16 − (12 − 6) means that the quantity (12 − 6) is to be subtracted from 16; the result is 10.

6. ALGEBRAIC OPERATIONS AND THEIR ORDER

In performing a series of different operations, some order must be followed. It has been agreed that multiplication and division must be performed first, and then addition and subtraction.

Example

$16 \div 4 + 8 + 4 \times 5 - 3$
$= 4 + 8 + 20 - 3$ (dividing and multiplying)
$= 32 - 3 = 29$ (adding and subtracting)

Addition

To add quantities with like signs, add their absolute values and prefix the common sign.

Example

Addition of Numbers

+6	+3	−6	−3
+3	+2	−3	−2
+9	+5	−9	−5
	+10		−10

Addition of Like Terms

+4Ra	+2Ra	−4Ra	−2Ra
+2Ra	+5Ra	−2Ra	−5Ra
+6Ra	+Ra	−6Ra	−Ra
	+8Ra		−8Ra

Addition of Unlike Terms

+4Ra	−3H
+6H	−6Ra
+3Rn	−4Rn
+4Ra +6H +3Rn	−3H −6Ra −4Rn

Addition of Polynomials

(Expressions of 2 or more terms)

+4Ra +6H +3Rn	−4Ra −6H −3Rn
+6Ra +2Rn	−6Ra −2Rn
+2H +7Rn	−2H −7Rn
+10Ra +8H +12Rn	−10Ra −8H −12Rn

To add quantities with unlike signs, find the differences of their absolute values and prefix to the result the sign of the one that has the greater absolute value.

Example

Addition of Numbers

+6	+3	−6	−3
−3	−2	+3	+2
	+5		−5
+3		−3	
	+6		−6

Addition of Like Terms

+4Ra	+6H	−4Ra	−6H
−2Ra	−2H	+2Ra	+2H
	−3H		+H
+2Ra		−2Ra	
	+H		−3H

Note that in the second example, the result is written as +H (not +1H). The numeral 1 is never written in front of an algebraic expression.

Addition of Unlike Terms

$-4Ra$	$+4Ra$
$+6H$	$-6H$
$-3Rn$	$+\ Rn$
$-4Ra+6H-3Rn$	$Rn-6H+4Ra$

Note that there is no sign in front of Rn in the second example. No sign is put in front of the first term of a series unless the term is negative, as in the first example.

Addition of Polynomials

$-4Ra+6H-3Rn$	$+4Ra-6H+3Rn$
$-2H+2Rn$	$+2H-2Rn$
$+6Ra-6Rn$	$-6Ra+5Rn$
$2Ra+4H-7Rn$	$-2Ra-4H+6Rn$

Subtraction

To subtract quantities from each other, change the sign of the quantities to be subtracted and add all the quantities in accordance with the rules of addition.

Example

$+8-(+3)=8-3=5$

$+8-(-3)=8+3=11$

The rule for this procedure is sometimes put as the following rule of grouping: to remove parentheses or other symbols of grouping preceded by a minus sign, change the sign of every term that was included in the group.

Example

$(-9a+5b)-(-10b+6a-3b)$

$=-9a+5b+10b-6a+3b$

$=-15a+18b$

Parentheses or other symbols of grouping preceded by a plus sign may be removed without any other change.

Example

$(x+y)+(2x-4y)$

$=x+y+2x-4y$

$=3x-3y$

Multiplication

Two or more expressions may be multiplied by writing them as one expression; for example, ab times cd is written as abcd. When either of the expressions to be multiplied contains more than one term, multiplication is indicated by putting expressions in parentheses next to each other; for example, ab times c + d is written as (ab) (c + d).

In multiplying expressions with different signs, determine the sign of the product by the number of negative factors. If there is an even number of negative factors, the product is positive; if there is an odd number of negative factors, the product is negative.

Example

$(-a)\ (-b)=ab$

Even number of negative factors.

$(-a)\ (+b)=-ab$

Odd number of negative factors.

$(a)\ (-b)=-ab$

Odd number of negative factors.

$(-a)\ (-b)\ (-c)=-abc$

Odd number of negative factors.

$(-a)\ (-b)\ (-c)\ (-d)=abcd$

Even number of negative factors.

Division

When quantities are divided, the quotient is positive if the numbers have like signs and negative if the numbers have unlike signs.

Examples

$\frac{6}{3}=2 \qquad \frac{-6}{-3}=2 \qquad \frac{-6}{3}=-2 \qquad \frac{6}{-3}=-2$

Equations

An equation is a mathematical statement that two or more expressions are equal to each other; for example, the equation e + 3 = 7 states that when 3 is added to e, the total is 7. Solving an equation is finding the value of the literal numbers in the equation. In the equation just given, it is easy to see that e equals 4. However, there are many equations which are far more difficult to solve. These require various types of manipulation for their solution. These manipulations are based chiefly on axioms. An axiom is a statement which is obviously true and is accepted without proof. The following axioms will help solve equations: If equal numbers are added to or subtracted from both sides of an equation, its equality is not destroyed.

Example

If $x=y$

Then $x+2=y+2$ and $x-2=y-2$.

Both sides of an equation may be multiplied or divided by the same number without destroying the equality.

Example

If $x=y$

Then $5x=5y$ and $\frac{x}{5}=\frac{y}{5}$

Numbers that are equal to the same numbers are equal to each other.

Example

If $x=a$ and $y=a$

Then $x=y$

A few other rules and processes which have grown out of axioms are helpful in solving equations. These include transposition, changing signs, and cancellation.

A term may be transposed from one side of an equation to the other, provided its sign is changed.

Example

Solve for x in the following equation:

$x-3=2;\ x=2+3=5$

(The 3 was transposed from the left side to the right side of the equation and its sign was changed.)

If the same term with the same sign occurs on both sides of the equation it may be eliminated from both sides.

Example

Solve for x in the following equation:

$x+y=2+y$

Cancelling y, $x=2$

The signs of all the terms of an equation may be changed without destroying equality.

Example

Solve the equation	$8-x=3$
Transposing:	$-x=3-8$
Changing signs	$x=-3+8=5$

Transposition may also be accomplished by multiplication and division.

Examples

Solve for R in the equation $E=IR$

Dividing both sides by I, $\frac{E}{I}=\frac{IR}{I}$

$R=\frac{E}{I}$

Solve for c by multiplying both sides by c:

$1=\frac{1}{2ac} \qquad c=\frac{c}{2ac} \qquad c=\frac{1}{2a}$

If there is any doubt about the solution of the equation, the solution may be checked by substituting the values in the original equation. If the equation holds true, the solution is correct.

Examples

$3x+14+2x=x+26$

Transposing: $3x+2x-x=26-14$

Adding terms: $4x=12$

$x=3$

Test by substituting 3 for I in the original equation.

$3x+14+2x=x+26$

$(3\times3)+14+(2\times3)=3+26$

$9+14+6=29$

$29=29$

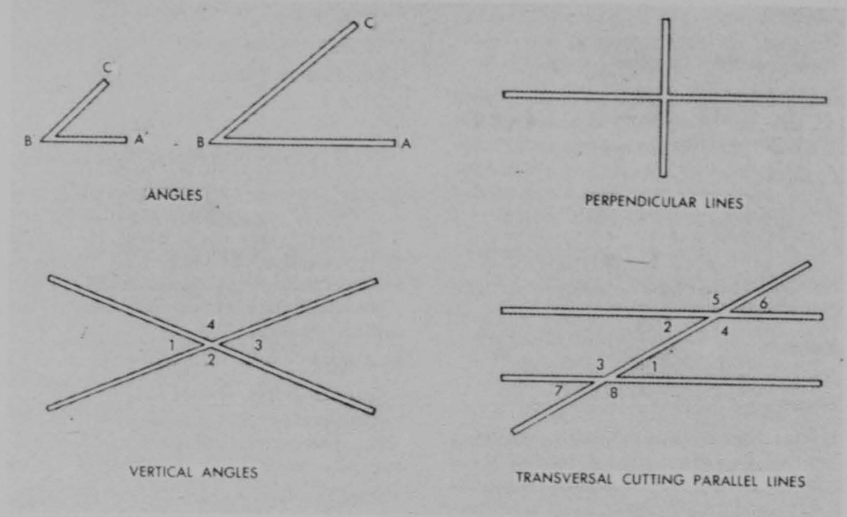
The equation is checked and the solution is correct.

7. PLANE GEOMETRY

A review of the basic concepts of plane geometry that apply to the various bombing problems will help understand the solution of these problems. Since most of the problems deal with right triangles and parallel lines they are reviewed here.

One of the basic elements of geometry is the angle. An angle is the figure formed by two straight lines drawn from the same point. The size of an angle depends upon the amount one of the lines must rotate about the point to coincide with the other line. In the illustration of angles, the size of the angle depends upon the amount the line AB must revolve about B to take the position CB. The size of the angle does not depend on the length of the sides. The two angles in the drawing are the same size even though their sides differ in length.

THIS PAGE IS DECLASSIFIED IAW EO 13526



Some Basic Elements of Plane Geometry

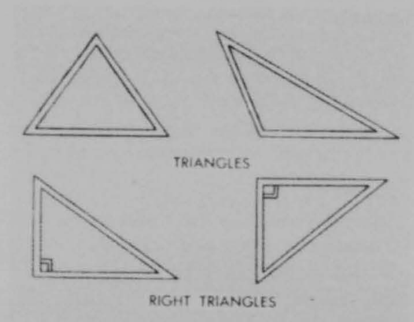
If four equal angles are formed when one straight line intersects another, the angles are called right angles. Because one complete revolution of a line about a point is equal to 360 degrees, the sum of four right angles is equal to 360 degrees and each right angle is equal to 90 degrees. The two lines forming the right angles are called perpendicular lines.

The two pairs of opposite angles formed by the intersection of two straight lines are called vertical angles. Thus, angles 1 and 3 and 2 and 4 in the diagram are vertical angles. Geometry proves that vertical angles are equal. Remember this fact, for it will be helpful in understanding the drift angle in bombing problems.

Parallel lines are lines that do not meet, no matter how far they are extended. If parallel lines are cut by a transversal (a straight line across them), they form alternate interior angles on opposite sides of the transversal between the parallel lines. It is proven by geometry that alternate interior angles are equal. Thus, in the drawing, angle 1 is equal to angle 2, and angle 3 is equal to angle 4. This relationship is useful in understanding angle Dc in the bombing problem. The angles formed on the outside of parallel lines cut by a transversal are called alternate exterior angles. Alternate exterior angles are also equal. Thus, angle 5 is equal to angle 8, and angle 6 is equal to angle 7.

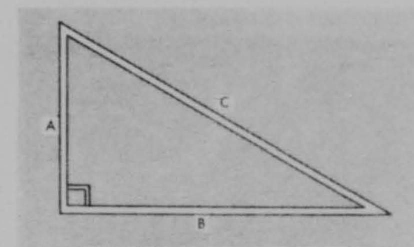
8. TRIANGLES

A figure bounded by three straight lines is called a triangle. A triangle that contains a right angle is a right triangle. The side opposite the right angle is called the hypotenuse.



Pythagoras, a famous Greek philosopher and mathematician who lived about 540 B.C., proved that in any right triangle, regardless of size, the square of the hypotenuse is equal to the sum of the squares of the other two sides. This is known as the Pythagorean theorem, and in mathematics is usually written as follows:

$a^2 + b^2 = c^2$



PYTHAGOREAN THEOREM: A² B² C²

This theorem has many uses in the bombing problem. It is used, for example, to find the straight-line distance from the plane to the target when the altitude and ground range are known. Consider a situation where the altitude is 4 miles and the ground range is 3 miles. The straight-line distance from the plane to the target forms the hypotenuse of the triangle. According to the Pythagorean theorem:

$c^2 = a^2 + b^2$

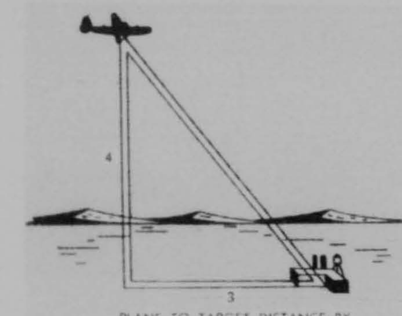
Substituting the values in the equation, it becomes:

$$c^2 = 4^2 + 3^2$$
$$= 16 + 9$$
$$= 25$$
$$c = 5$$

The straight-line distance from the plane to the target is 5 miles.

9. TRIGONOMETRIC FUNCTIONS

In any right triangle there is a definite relationship between the size of the acute angles (the angles that are not right angles), and the length of the sides. This relationship forms the foundation of trigonometry. There are three relationships between the size of an angle and the size of the sides of the triangle which one will find particularly important in



PLANE TO TARGET DISTANCE BY PYTH. THEO. √4² 3²

study of the bombing problems. These are the sine, the cosine, and the tangent. They are known as trigonometric functions.

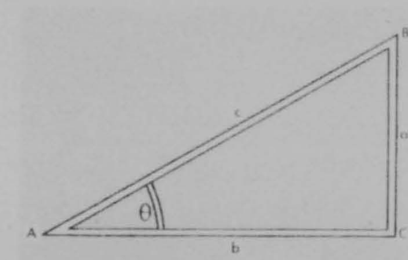
In the triangle shown, the relationships are as follows:

The sine of angle θ (written sin θ) $= \frac{a}{c} = \frac{\text{opposite side}}{\text{hypotenuse}}$

The cosine of angle θ (written cos θ) $= \frac{b}{c} = \frac{\text{adjacent side}}{\text{hypotenuse}}$

The tangent of angle θ (written tan θ) $= \frac{a}{b} = \frac{\text{opposite side}}{\text{adjacent side}}$

The value of the trigonometric functions can be calculated when needed. However, to speed up computation, mathematicians have calculated the values and have prepared tables



Illustrating the Trigonometric Functions

THIS PAGE IS DECLASSIFIED IAW EO 13526

of these functions. These tables are known as tables of natural functions to distinguish from tables of the logarithms of the functions.

Here are a few problems to illustrate the use of trigonometric functions:

The hypotenuse of a right triangle is 10 inches long, and one side is 5 inches. Find the size of the angles and the length of the other side of the triangle.

To find angle θ, the sine function can be used.

$$\text{Sin } \theta = \frac{\text{opposite side}}{\text{hypotenuse}}$$

Substituting: $\text{Sin } \theta = \frac{5}{10} = .500$

Referring to the tables, you find that the angle whose sine is .500 is 30°.

Therefore, $\theta = 30°$

To find angle ⌀, the cosine function can be used.

$$\text{Cos } \emptyset = \frac{\text{adjacent side}}{\text{hypotenuse}}$$

Substituting: $\text{Cos } \emptyset = \frac{5}{10} = .500$

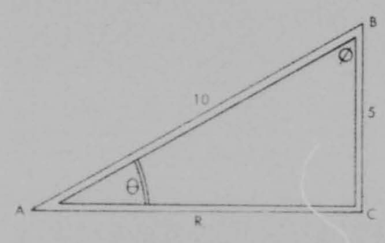
From the trigonometric tables you will find that an angle whose cosine is .500 is 60°. Therefore, ⌀ = 60°. To find the other side (Ra), the cosine function can be used.

$$\text{Cos } \theta = \frac{\text{adjacent side}}{\text{hypotenuse}}$$

Substituting: $\text{Cos } \theta = \frac{\text{Ra}}{10}$

Cross-multiplying: $\text{Ra} = 10 \text{ Cos } \theta$

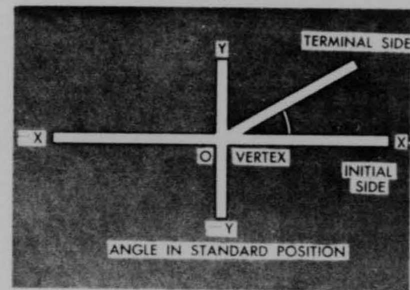
From the trigonometric tables, you will find that the cosine of a 30° angle is .866; therefore, Ra = (10) (.866) = 8.66 inches.



Use of the Trigonometric Functions

Functions of Angles Larger Than 90 Degrees

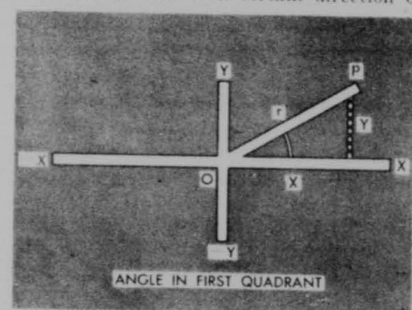
An angle can be considered as generated by a line that starts in a certain initial position and rotates about a point until it stops at its final position. The point is called the vertex of the angle. The original position of the rotating line is called the initial side of the angle, and the final position is called the terminal side of the angle.



ANGLE IN STANDARD POSITION

An angle is said to be in standard position when its vertex is at the origin of a system of rectangular coordinates and its initial side extends in the positive direction along the x axis. Angle θ in the drawing of an angle in the first quadrant is in standard position.

In trigonometry, an angle is called a positive angle if it is generated by a line revolving counterclockwise. If the generating line revolves clockwise, the angle is called a negative angle. In the computer, positive angles are generated by rotating a potentiometer arm counterclockwise and negative angles by rotating it clockwise. The important point to remember is that if a certain direction of



ANGLE IN FIRST QUADRANT

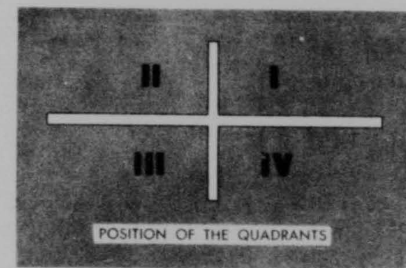
rotation generates positive angles, opposite rotation generates negative angles.

In the drawing, angle θ is generated by rotating vector OP from its original position, OX. If a perpendicular line is drawn from point P to the X axis, a right triangle is formed, and the function of angle θ can be given as follows:

$$\sin\theta = \frac{Y}{r} = \frac{\text{ordinate}}{\text{radius}}$$

$$\sin\theta = \frac{x}{r} = \frac{\text{abscissa}}{\text{radius}}$$

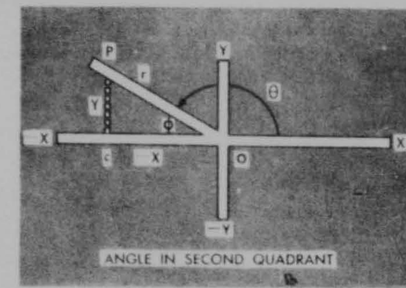
$$\tan\theta = \frac{Y}{x} = \frac{\text{ordinate}}{\text{abscissa}}$$



POSITION OF THE QUADRANTS

Beginning with the upper right quadrant (quarter of circle) and going on in a counterclockwise direction, the various quadrants are numbered as shown. Thus, positive angles from 0° to 90° are in the first quadrant, from 90° to 180° in the second quadrant, from 180° to 270° in the third quadrant, and from 270° to 360° in the fourth quadrant. Negative angles from 0° to 90° are in the fourth quadrant, from 90° to 180° in the third quadrant, and so on. Using the unit circle, the functions of angles in the various quadrants are obtained as follows:

The absolute value of the functions of angle θ in the second quadrant are obtained from the table by using the supplement of the angle (180° minus the angle). In the drawing, this is angle φ in the right triangle PCO. Consequently, the signs of the function can be obtained by using angle φ. In determining the signs, always consider r to be positive and determine the signs of the abscissa (x values) and the ordinates (y values) by the quadrants in which they are located.



ANGLE IN SECOND QUADRANT

$$\sin(180° - \theta) = \frac{Y}{r} = \sin\phi$$

$$\cos(180° - \theta) = \frac{-x}{r} = -\cos\phi$$

$$\tan(180° - \theta) = \frac{y}{-x} = -\tan\phi$$

Thus, in the second quadrant, the sine is positive while the cosine and tangent are negative.

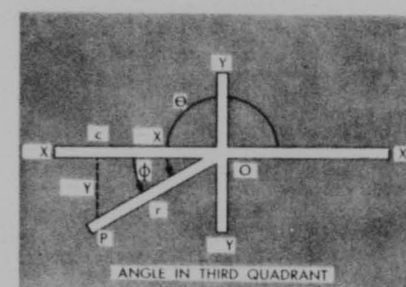
The absolute values of the functions of angle θ in the third quadrant are obtained from the tables by using the difference (angle φ) between angle θ and angle θ and 180°. Here, too, the signs of the functions are obtained by using angle φ in the right triangle PCO.

$$\sin(\theta - 180°) = \frac{-y}{r} = -\sin\phi$$

$$\cos(\theta - 180°) = \frac{-x}{r} = -\cos\phi$$

$$\tan(\theta - 180°) = \frac{-y}{-x} = \tan\phi$$

Thus, in the third quadrant, the sine and cosine are negative while the tangent is positive.



ANGLE IN THIRD QUADRANT

The absolute values of the functions of angle Θ in the fourth quadrant are obtained from the table by using the difference (angle ϕ) between 360° and angle Θ. The signs of the functions are again established by using angle ϕ in the right triangle PCO:

$$\sin(360 - \Theta) = \frac{-Y}{r} = -\sin\phi$$

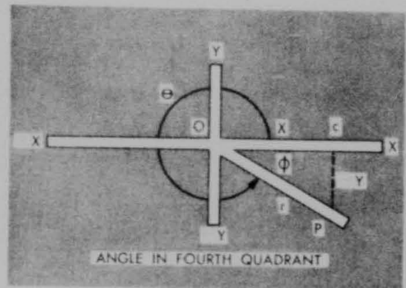
$$\cos(360 - \Theta) = \frac{x}{r} = \cos\phi$$

$$\tan(360 - \Theta) = \frac{-y}{x} = -\tan\phi$$

Thus, in the fourth quadrant, the sine and tangent are negative while the cosine is positive.

Summarizing, one can find the function, absolute value, and sign of any positive angle if one locates it in the proper quadrant according to its size and use the acute angle of the right triangle formed by a perpendicular from any point P on the rotating vector to the X axis. One must observe the sign of the x and y values in the various quadrants. The table summarizes the signs of the functions of positive angles.

FROM—To	SINE	COSINE	TANGENT
0°—90°	+	+	+
90°—180°	+	—	—
180°—270°	—	—	+
270°—360°	—	+	—



ANGLE IN FOURTH QUADRANT

In studying the computer of the **APQ-23**, one will deal also with negative angles. Remember that negative angles are caused by opposite rotation of the rotating vector. The functions of negative angles in the first quadrant are the same as those of positive angles in the fourth quadrant. Observe the signs of the x and y values.

$$\sin(-\Theta) = \frac{-y}{r} = -\sin\Theta$$

$$\cos(-\Theta) = \frac{x}{r} = \cos\Theta$$

$$\tan(-\Theta) = \frac{-y}{x} = -\tan\Theta$$

By comparing the signs of these functions with the signs of the functions of a positive angle in the first quadrant, one can see that the sign of the sine and tangent functions of negative angles is opposite to that of positive angles, while the sign of the cosine function is the same for both positive and negative angles. These relations are true for any value of $-\Theta$, regardless of the quadrant or magnitude of the angle. The table summarizes the signs of the functions of negative angles.

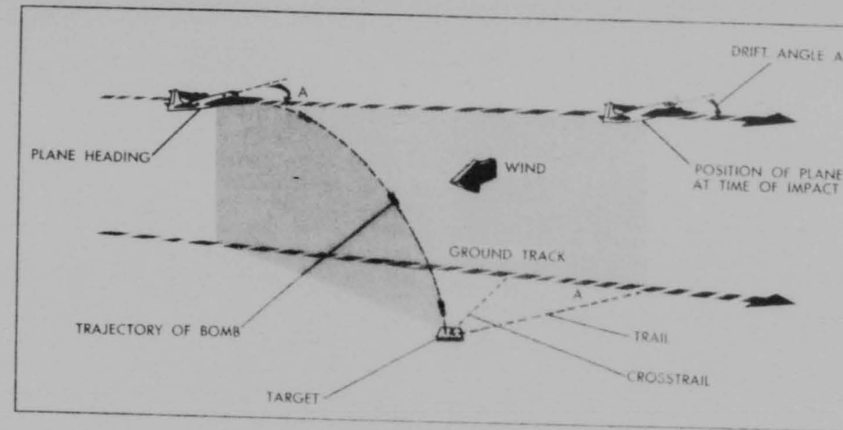
10. BASIC BOMBING GEOMETRY

The chief problem of bombing is to determine the exact point at which to release the bomb. Since the bomb has to cover both a horizontal and a vertical distance to reach the target, the problem resolves itself into a question of how long it takes the bomb to fall and the distance it covers in that time. The vertical distance is the altitude of the plane at release, and the time the bomb takes to cover it (the time of fall) is determined by gravity and the ballistics of the bomb. The horizontal distance traveled by the bomb in that time depends on the speed of the plane, the resistance of the air, the wind direction and speed, and the ballistics of the bomb.

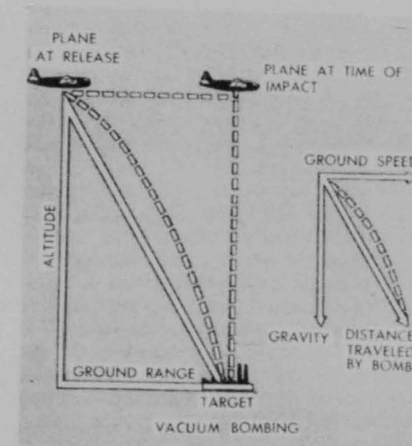
The simplest case of bombing would be one set up in a vacuum. In this set-up, only two factors would determine the distance traveled by the bomb—the altitude and the ground speed of the plane. At the moment of release, the bomb would be moving at the same speed as the plane, and since in a vacuum, there would be nothing to slow its speed, it would continue to travel at that speed as it fell. Consequently, it would be under the



Perspective View of Bombing Geometry.

plane at all times, and the plane would be directly over the target at the time the bomb hit. To figure out the release point of the bomb in this case, it would be necessary to consider only the altitude (to determine the time of fall) and the ground speed of the plane (to determine the horizontal speed of the bomb).

Since bombing isn't done in a vacuum, there are many other factors that affect the bombing problem besides altitude and ground speed. One considers the same problem as before but

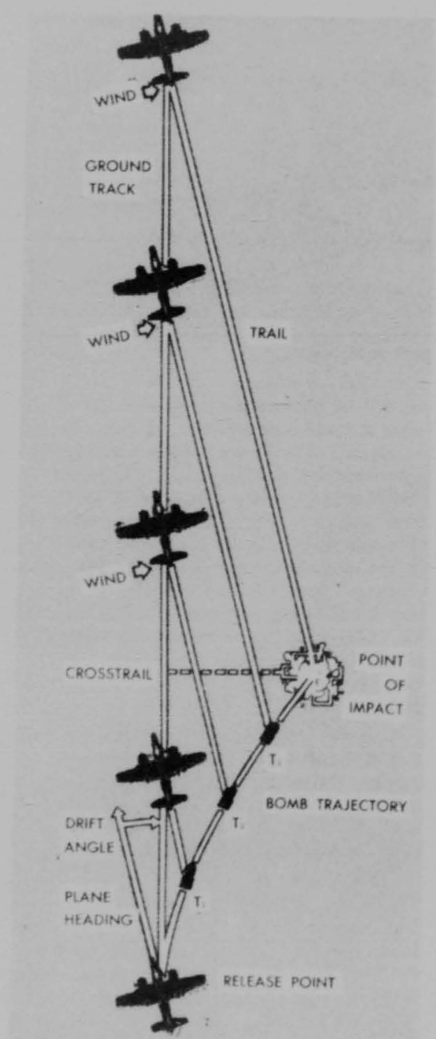


VACUUM BOMBING

in still air instead of a vacuum. Altitude and ground speed must still be considered, but the resistance of the air must also be taken into account. The air resistance continually reduces the forward velocity of the bomb so that it gradually lags farther behind the plane. The distance that the bomb lags behind the plane at the moment of impact is called trail. This distance depends on the altitude, the ground speed, and the type of bomb. In this case, the time of fall is still determined by altitude, but the distance covered by the bomb in that time depends on the type of bomb as well as the ground speed of the plane.

Now consider the same problem, not in still air, but with a headwind or a tail wind. One can readily see that the only difference is in the ground speed, and since the ground speed of the bomb and the plane are equally affected, the solution of the problem depends on the same things as in still air, namely the altitude, the ground speed, and the type of bomb.

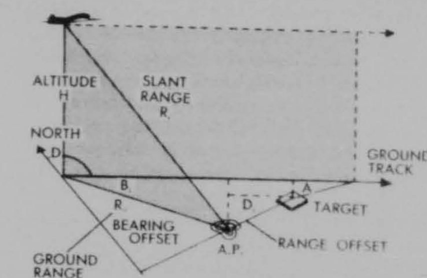
A crosswind presents a different problem. In a crosswind, the plane has to head into the wind to make good its ground track. The angle at which it heads into the wind, that is, the angle formed by the nose-to-tail line of the plane and the ground track, is called the drift angle. At release, the bomb is given a momentum along the ground track, but it does not make good the same track as the airplane



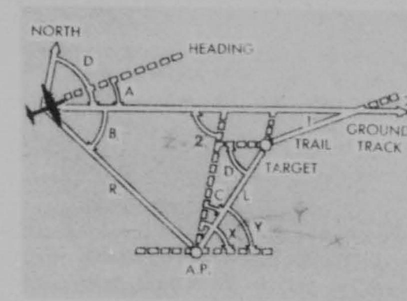
Horizontal Projection of Bombing Problem.

because its original momentum is gradually dissipated by the resistance of the air. Consequently, in a crosswind, the bomb only lags behind the plane, but it is also moved to the right or left of the ground track, depending on the direction of the wind. At the same time, because of the initial momentum given to it by the plane, the bomb lies underneath the extended nose-to-tail line of the plane, as shown in the illustration. Note that at each point, T-1, T-2, T-3, the bomb lies along the extended nose-to-tail line but lags behind and to the right of the plane. The distance it moves to the side is called crosstail. The size of this crosstail depends on the drift angle of the plane and the trail of the bomb. In this case, the time of fall is still determined by the altitude, but the distance covered by the bomb in that time depends on the drift angle as well as the type of bomb and the ground speed of the plane.

The bombing methods just discussed are called direct bombing because they involve aiming directly at the target. However, this is not always practical, for there are times when the target does not show up well on the radar scope. At such times offset bombing is used. In this method, some object that shows up well on the scope and is near the target is taken as the aiming point, and the calculations are based around that point instead of the target even though the bomb is still directed at the target. Offset bombing introduces new factors. Not only must the altitude, the ground speed of the plane, the drift angle, and the trail be considered, but the range offset (the distance between the aiming point and the target) and the bearing offset (the true bearing of the range offset line) must also be considered. These factors are shown in the offset bombing diagram. In the vertical triangle, that is the triangle formed by a line from the plane to the aiming point, a line from the plane to the ground directly below it, and a line from that point to the aiming point, the altitude is called H, the slant range, Rs, and the ground range, Ra. In the horizontal portion of the drawing, the drift angle is called angle A, the true bearing of the range offset line is called angle C, and the angle between the range offset line and the ground track is called angle Dc.



Offset Bombing.



Offset Bombing

Each of these terms is used by the computer in the solution of an offset bombing problem, as explained later. However, that explanation depends on the fact that angle Dc is equal to angle D minus angle C. This may well be proved here.

To make this proof, use the angle Dc and the drift angle diagram. Notice the two dashed lines constructed through the aiming point. One is parallel to the north-south line, and the other, parallel to the ground track, is called angle Dc.

	Reason
∠D = ∠Z = ∠Y	Alternate interior angles formed by a transversal cutting parallel lines are equal.
∠X = ∠Y − ∠C	By inspection.
∠X = ∠D − ∠C	Equals can be substituted for equals.
∠X = ∠Dc	Alternate interior angles formed by a transversal cutting parallel lines are equal.
∠Dc = ∠D − ∠C	Equals can be substituted for equals.

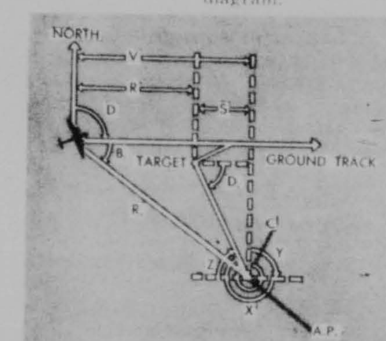
Another assumption made in the computer is that the drift angle A is equal to angle 2 in the diagram. That, too, can be proved here. Notice that the line from the target to the ground track (trail) is parallel to the heading line.

	Reason
∠A = ∠1	Alternate angles formed by a transversal cutting parallel lines are equal.
∠1 = ∠2	Vertical angles are equal.
∠A = ∠2	Things equal to the same things are equal to each other.

Sometimes, the diagram for an offset bombing problem is like the one shown below. In this case, angle Dc is still equal to angle D − c, although the signs of the trigonometric functions are not always the same for angle D − C as for angle Dc.

In the diagram, notice the two dashed lines constructed through the aiming point; one is parallel to the north-south line, and the other is parallel to the ground track. Also notice the dashed line constructed through the target parallel to the ground track.

	Reason
∠D = ∠Y	Same as in the previous proof for the previous diagram.



Offset Bombing

THIS PAGE IS DECLASSIFIED IAW EO 13526

$\angle Y - \angle C = -\angle X$	By inspection.
$-\angle X = \angle D - \angle C$	Equals can be substituted for equals.
$\angle X - 180° = \angle Z$	By inspection.
$\angle Dc = \angle Z$	Alternate interior angles formed by a transversal cutting parallel lines are equal.
$\angle Dc = \angle X - 180°$	Equals can be substituted for equals.

The trigonometric functions of angle Dc are the same as those of angle X.

To find the absolute value of the trigonometric functions of angles between 180° and 270°, the difference between the angle and 180 degrees is used.

Therefore, the absolute values of the functions of angle Dc are the same as those of angle X.

In this problem, you must establish the sign of the functions of D−C by dealing with the negative angle Dc. The sine function is positive and the cosine and tangent functions are negative, because the negative angle is between 180° and 270°. Remember this, as it will help you to understand certain applications of the bombing problems in the next chapter.

Another assumption made in the computer is that the distance R along the ground track is equal to Ra Cos Bc—L Cos Dc. This can be proved as follows:

	Reason
$R = V - S$	By inspection.
$CosBc = \frac{V}{Ra}$	Right triangle relationships.
$V = RaCosBc$	By multiplication.
$CosDc = \frac{S}{L}$	Right triangle relationships.
$L = S\,CosDc$	
$R = Ra\,Cos\,Bc - L\,Cos\,Dc$	Equals substituted for equals.

A thorough understanding of the problems discussed in this chapter will help to understand the development of the bombing equations in the following chapter. No attempt has been made to cover all the variations of the bombing problems. However, the principles discussed will apply to the geometry of any of the problems.

11. PROBLEMS SOLVED BY THE COMPUTER

The chief purpose of the computer is to determine the proper point at which to release the bombs in order to hit the desired target. To do this, the computer must solve a mathematical equation known as the "bomb-release equation." The computer can solve this equation properly if the proper information is set into it by the operator. This information consists partially of fixed factors, such as altitude, trail, and time of fall, and partially of variable factors, namely, ground range, ground speed, turn, and drift. By use of instruments and charts the operator can readily determine the fixed factors and set them in. However, he cannot accurately determine the variable factors without some check on his settings. For this reason, the computer solves two additional equations—the "variable range-circle equation" and the "steering equation"—which determine the position of reference lines on the scope and show the operator whether the continuously-variable information he set in was accurate, or, if not, how he must change it.

When the operator sets in altitude and ground range, the computer solves the variable range-circle equation, determines the slant range to the aiming point on the basis of the operator's settings, and puts a circle on the scope at this range. Since the position of the aiming point on the scope is an accurate indication of the slant range, the variable range circle should coincide with the aiming point. If it does, the operator knows that he has properly set the GROUND RANGE knob. If it does not, the operator can see that he must change the position of the GROUND RANGE knob until the variable range-circle coincides with the aiming point. The variable range circle also enables the operator to set the GROUND SPEED knob correctly, for if it

is at the correct setting, the variable range circle will move in at a rate proportional to the ground speed of the plane and will track the aiming point. If the variable range circle does not track the aiming point, the operator can adjust the GROUND SPEED knob until it does. In this way, the solution of the variable range-circle equation by the computer enables the operator to set accurate ground range and ground-speed information into the computer.

The solution of the steering equation by the computer positions a visual indicator—the azimuth marker—on the scope and enables the radar operator to determine whether the plane is being steered in the proper direction to permit the bombs to hit the target. This azimuth marker should always be on the aiming point. If it is not, the plane is off course, and the radar operator must adjust the TURN control to put the azimuth marker on the aiming point and the plane on course. (When control is at the pilot's position, adjustment of the TURN control does not actually change the plane's heading, for then the TURN control is not connected to the automatic pilot; it merely indicates to the pilot via the PILOT'S DIRECTION INDICATOR how he should change the heading). If the azimuth line is put on the aiming point, but does not stay on, it indicates that the plane is getting off course (presumably because of drift), and the radar operator can use the DRIFT control to correct the heading of the plane to compensate for drift and put the azimuth line back on the aiming point. In this way, the solution of the steering equation enables the radar operator to steer the plane properly, or, if the pilot is flying the plane, to give the proper corrections to the pilot on the PILOT'S DIRECTION INDICATOR.

Besides solving the variable range-circle equation, the steering equation, and the release equation, the computer also solves a fourth equation—the "sighting-angle equation." While the solution of this equation is not necessary for the actual bombing, it serves a valuable purpose in furnishing continuous information to the bombardier for synchronizing the optical bombsight with the radar so that he can make a visual assist if the opportunity occurs.

The exact nature of the four equations solved by the computer varies with the type of bombing problem encountered. To help understand these equations, they are developed in the following pages. The equations for the simplest case of bombing are considered first; then these equations are gradually broadened in logical sequence to cover more and more complicated situations, until a set of equations is developed to cover the most complicated problem, namely, offset bombing with drift. The final set of equations arrived at is applicable to all cases, and operation of the computer is based on these equations.

In the case of direct bombing without drift, the plane is flown directly over the target, the path of the bomb after release is the same as that of the plane, and there is no special problem of steering. Only the variable range-circle equation, the release equation, and the sighting-angle equation have to be solved.

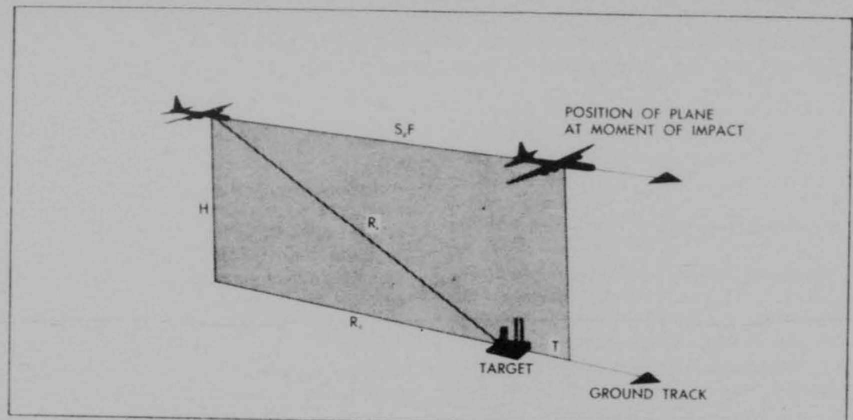
Variable Range-circle Equation

The variable range-circle equation solves for the slant range on the basis of the altitude and ground range set in by the operator. It is obtained from the vertical triangle, the three sides of which are: altitude (H), slant range (Rs), and ground range (Ra). The equation is based on the relationship that exists between the base, altitude, and hypotenuse of a right triangle, namely, $(Altitude)^2 + (Base)^2 = (Hypotenuse)^2$. Substituting from the vertical triangle: $H^2 + Ra^2 = Rs^2$

Transposing: $H^2 + Ra^2 - Rs^2 = 0$

This is the variable range circle equation. Note that the terms of the equation have been transposed and made equal to zero. This is done with all equations in this chapter, for that is the exact form in which the computer uses the equations. A signal voltage proportional to each term in the equation is produced, summed up, and the result applied to the grid of an amplifier. If the equation is satisfied, the sum of the terms is zero, and no signal is applied to the amplifier. If the equation is not satisfied, a signal is applied to the amplifier, and the amplifier-circuit output causes a motor to rotate and balance the equation or, in some cases, a meter to indicate the results of the signal. In the case of the vari-

THIS PAGE IS DECLASSIFIED IAW EO 13526



Direct Bombing without Drift.

able range circle equation, an unbalance is caused by a change in the ground range. The equation is balanced again by the automatic change in the Rs^2 signal. At the same time the variable range circle is repositioned. In the computer, two things cause a change in the ground range, a re-setting of the GROUND RANGE knob by the operator, and the progressive change in ground range by the rate motor. By continually checking the altitude, and by adjusting the GROUND RANGE and GROUND SPEED knobs to keep the variable range circle tracking the target, the operator can keep the ground range and slant range in the computer at an up-to-the-second accuracy.

Release Equation

If, after release, the bomb were to continue to travel at the same forward velocity as the plane, it would travel a ground distance equal to the ground range covered by the plane from the release point to the time of impact. Calling the ground speed of the plane Sg and the "time of fall" of the bomb F, the distance would be equal to SgF (the ground speed of the plane multiplied by the "time of fall"). However, because of air resistance, the bomb lags behind the plane a distance called trail (T), and the actual ground range from the plane at release to the target is SgF − T. That is also, by definition, the ground range Ra.

Therefore: $Ra = SgF - T$

Transposing: $Ra - SgF + T = 0$

Ra is the changing value of the equation. The result of the equation, that is, the difference between Ra and SgF − T is shown on the DISTANCE-TO-GO METER (distogometer). When Ra decreases to the point where the difference is equal to 0, the meter reads 0, and the bombs are released.

Sighting-angle Equation

In synchronous bombing, the problem is to compare the distance from the ground position of the plane to the target as determined by the APQ-23 to the distance as determined by the Norden bombsight. In the case of direct bombing without drift, the APQ-23 distance to the target is called RA, and the Norden distance to the target is called Rn. For the Norden to be synchronized with the APQ-23, the following equation must be satisfied:

$Ra = Rn$

Transposing: $Ra - Rn = 0$

This is the sighting-angle equation. The balance or unbalance of this equation is shown on the SA METER. If the Norden rate is properly synchronized with the APQ-23, Rn will change at the same rate as Ra, and the SA METER will indicate 0. If it does not change at the same rate, the bombardier has to change the rate of the Norden to bring the SA METER to 0 and keep it there.

By comparing the drawings for direct bombing without drift and with right drift, one will find that the vertical-triangle portion of the problem is the same for both. However, in the case of direct bombing with drift, because of crosstail, additional information is needed to establish the correct ground course. The pilot must know just how far the plane must be flown upward from the target. In this case, RA is still the ground range to the target, but it is not along the ground track. Also, angle Bc and angle A enter the picture. Angle Bc is the angle between the ground track and the line drawn through the target. Angle A is the drift angle, that is the angle between the nose-to-tail line of the plane and the ground track.

Variable Range-circle Equation

This equation is the same as in the previous case. $H^2 + Ra^2 + Rs^2 = 0$

Steering Equation

A course must be steered to compensate for drift and for the resulting crosstail. In the diagram, x (the crosstail) is common to both horizontal triangles. T (trail) is a fixed distance and is set into the computer from a prepared chart. Assume that the rate has been killed and that Ra is correctly set. Assume also that drift has been killed, and the proper course established. Angle A and angle Bc will then be correctly set in the computer. Then applying trigonometry: $x = Ra \sin Bc$ and $x = T \sin A$

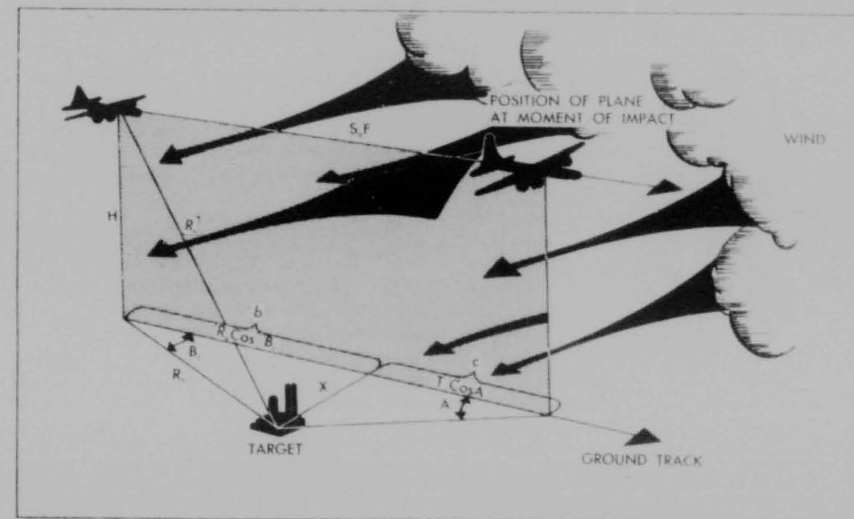
Therefore: $Ra \sin Bc = T \sin A$

Transposing: $Ra \sin Bc - T \sin A = 0$

This is the steering equation for the case of direct bombing with right drift. When the proper course is established, this equation will balance and the target will move down the azimuth marker. If the plane is not steered along the correct course, the equation will be unbalanced, and the azimuth marker will be off the target. It will then be possible to place the azimuth marker through the target by adjusting turn and drift to the point where the azimuth marker and the target coincide. It is possible also to overcompensate the turn and drift and momentarily make the target and marker coincide, but this will not establish the correct course, and the target will continually move away from the marker.

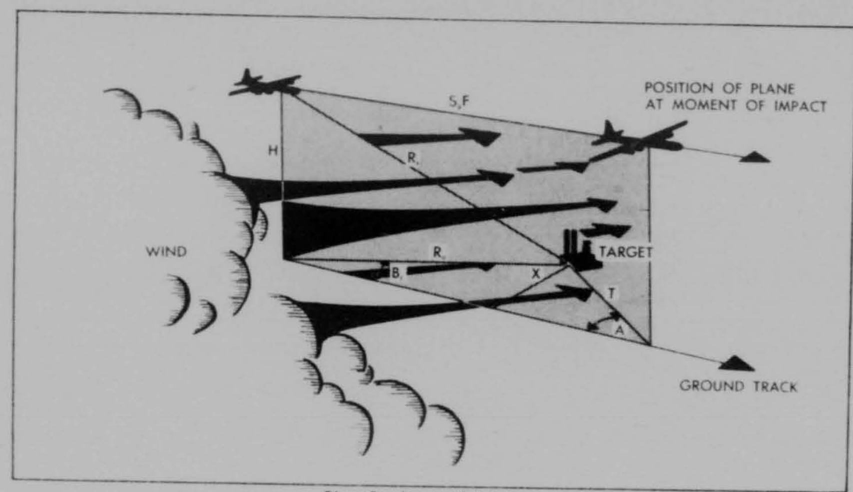
Release Equation

In the problem of direct bombing with no



Direct Bombing with Right Drift.

THIS PAGE IS DECLASSIFIED IAW EO 13526



Direct Bombing with Left Drift.

drift the release equation was established as follows: Ra − SgF + T = 0. Where there is drift, Ra no longer lies along the ground track, and is not used directly in the release equation. Instead, the distance along the ground track must be used.

As can be seen from the diagram in direct bombing with right drift, SgF is equal to b + c. By trigonometry, one can see that b equals Ra Cos Bc and c = T Cos A. In other words:

Ra Cos Bc + T Cos A = SgF

Transposing:

Ra Cos Bc − SgF + T Cos A = 0

In the actual release equation, T (trail) is substituted for T Cos A. The error caused by the difference in the length of the hypotenuse (T) and the base of the right angles (T Cos A) is very minor. This error, referred to as the "range component of crosstail error", is ignored in the release equation. Therefore the release equation for direct bombing with right drift is: Ra Cos Bc − SgF + T = 0

Ra and Bc are the changing values in this equation, and the computer continually solves for the value Ra Cos Bc, and indicates the difference between Ra Cos Bc and SgF − T on the distogometer. When this difference reaches 0, the bombs are released.

Sighting-angle Equation

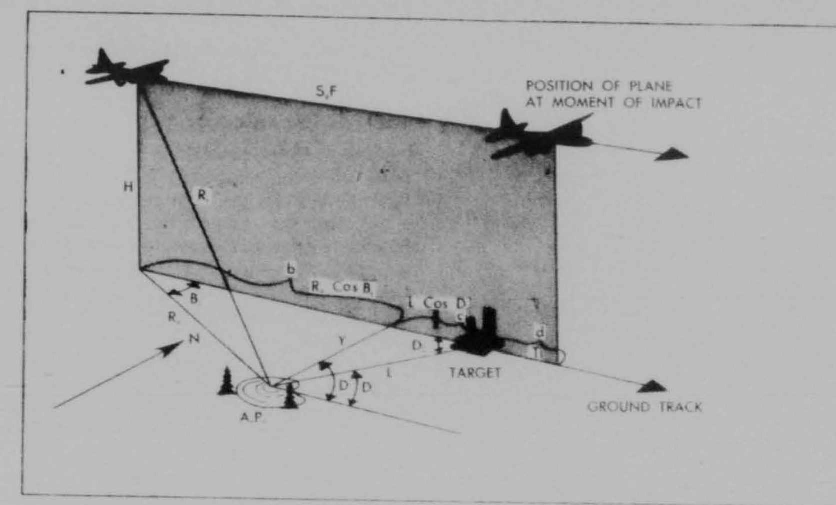
The problem that exists here is similar to the previous case of direct bombing without drift. In that case, the APQ-23 ground range (Ra) to the target was compared with the ground range of the Norden (Rn). However, in this as well as in all following cases in this chapter, the APG-23 distance that is compared with the ground range of the Norden bombsight is not the ground range to the target itself but to a point on the ground track that is opposite the target. The APQ-23 distance now becomes Ra Cos Bc. Therefore, Ra Cos Bc = Rn.

Transposing, the Sighting Angle Equation becomes: Ra Cos Bc − Rn = 0.

In comparing the left- and right-drift drawings, one can readily see that the terms in each are identical, but that some change must be made in the steering equation because the plane is flown on opposite sides of the target in the two cases.

Variable Range-circle Equation

The vertical triangle remains the same, and the equation is still $H^2 + Ra^2 - Rs^2 = 0$



Offset Bombing without Drift, Aiming Point before Target

Steering Equation

As in the steering equation for direct bombing with drift, two adjacent horizontal right triangles exist. The side y is common to both. Assuming that the proper course has been established, angle Bc, angle Dc, L, and Ra are all accurately set into the computer. Under these circumstances, the following equations are true:

Y = Ra Sin Bc and y = L Sin Dc

Combining these: Ra Sin Bc = L Sin Dc

Transposing: Ra Sin Bc − L Sin Dc = 0

This is the steering equation for offset bombing without drift, aiming point before the target. If this equation is satisfied, the azimuth marker extends through the aiming point during the entire approach of the plane. However, since in this case without drift, the equation is based on the proper setting of the TURN control, the equation is not satisfied until the control is properly set. For this reason, if the azimuth marker does not extend through the aiming point, the TURN control must be adjusted by the operator until the aiming point tracks down the azimuth marker.

Release Equation

As in the previous bomb release situation, the distance along the ground track of the airplane is the important consideration. Note from the diagram that, in this case, this distance is made up of three segments, b, c, and d. From the diagram one can also see that b is equal to Ra Cos Bc, c is equal to L Cos Dc, and d is equal to T. One can see, too, that the sum of these segments is equal to SgF, the total distance traveled by the bomb from the moment of release to the time of impact. In the form of an equation, this is:

Ra Cos Bc + L Cos Dc − SgF + T = 0

The distance Ra Cos Bc is continually decreased as the airplane approaches along the ground track. Consequently, the sum of the three terms Ra Cos Bc, L Cos Dc and T is continually decreasing. The difference between the sum of these terms and SgF is shown on the DISTANCE-TO-GO METER, and when it reaches 0, the bombs are automatically released.

Sighting-angle Equation

The APQ-23 ground range, as can be seen

THIS PAGE IS DECLASSIFIED IAW EO 13526

from the diagram, is Ra Cos Bc + L Cos Dc. To keep the Norden bombsight synchronized with the APQ-23, the ground range of the Norden (Rn) must be equal to this ground range. The sighting angle equation is therefore:

$Ra \text{ Cos } Bc - L \text{ Cos } Dc = Rn$

Transposing:

$Ra \text{ Cos } Bc + L \text{ Cos } Dc - Rn = 0$

As long as this equation is satisfied, the Norden bombsight is synchronized with the radar.

Changing the offset-bombing problem from aiming point before target to aiming point after target changes the ground-track distances and therefore changes the release and sighting angle equations. This does not affect the variable range circle equation or the steering equation.

Variable Range-circle Equation

The variable range circle equation is, as before: $H^2 + Ra^2 - Rs^2 = 0$

Steering Equation

The steering equation is, as in the case of offset bombing without drift, aiming point before target: $Ra \text{ Sin } Bc - L \text{ Sin } Dc = 0$

Note the angles around the aiming point. Angle Dc is still equal to the angle D—C but it is in the opposite quadrant than it was in the previous case. However, since the sine of a negative angle is the same in the third quadrant as in the fourth, the steering equation is unchanged.

Release Equation

As before, the problem is to find the distance along the ground track that is equal to SgF. As one can see from the drawing, b — c + d along the ground track is equal to SgF. Since b is equal to Ra Cos Bc, c is equal to L Cos Dc, and d is equal to T, the following equation is true:

$Ra \text{ Cos } Bc - L \text{ Cos } Dc + T = SgF$

Transposing:

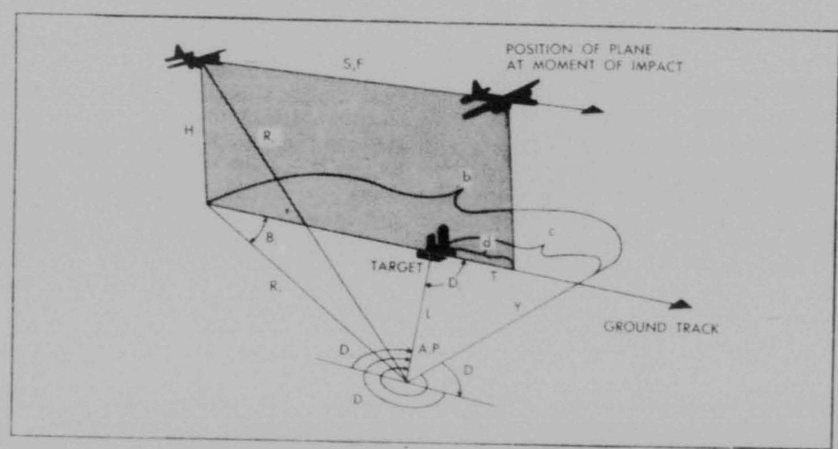
$Ra \text{ Cos } Bc - L \text{ Cos } Dc - SgF + T = 0$

This is the release equation for offset bombing without drift, target before aiming point. The only change from the previous case is the sign of L Cos Dc, which is now minus. This is due to the fact that the Dc angle is in the third quadrant.

Sighting Angle Equation

From the drawing one can see that the APQ-23 ground range is equal to b — c, or Ra Cos Bc — L Cos Dc. For synchronization of the Norden with the radar, this must be equal to the Norden range, Rn.

$Ra \text{ Cos } Bc - L \text{ Cos } Bc = Rn$



Offset Bombing without Drift, Target before Aiming Point.

Transposing:

$Ra \text{ Cos } Bc - L \text{ Cos } Dc - Rn = 0$

This is the sighting-angle equation for offset bombing without drift, target before aiming point. As in the release equation, the only change from the sighting-angle equation for offset bombing without drift, target after aiming point, is in the sign of L Cos Dc from plus to minus.

In offset bombing without drift, the ground track of the plane was far enough to one side of the aiming point to enable the plane to pass over the target. This is the distance y in the diagram. In case of offset bombing with right drift, the ground track of the plane must be flown and additional distance to the left of the aiming point to compensate for crosstail. This is the distance z; thus the total distance between the ground track and the aiming point is equal to y + z. This affects the steering equation. The distance along the ground track is very similar to that previously discussed in cases of offset bombing.

Variable Range-circle Equation

Again the variable range circle equation is $H^2 + Ra^2 - Rs^2 = 0$

Steering Equation

The distance between the aiming point and the ground track (x) is equal to y + z, as one can see from the diagram. One can also see that z = Ra Sin Bc, y = L Sin Dc, and z = T Sin A. Therefore, substituting in the equation x = y + z, it becomes Ra Sin Bc = L Sin Dc + T Sin A. Transposing: $Ra \text{ Sin } Bc - L \text{ Sin } Dc - T \text{ Sin } A = 0$

When this equation is satisfied, the azimuth marker extends through the aiming point. As before, the distance Ra is correctly checked by the variable range-circle. The satisfying of this equation depends on the angle Dc which in turn depends on the correct setting of the TURN and DRIFT controls.

Release Equation

Comparing the drawing of this problem to the drawing for offset bombing with no drift, aiming point before target, as for offset bombing without drift, aiming point before target. This equation is:

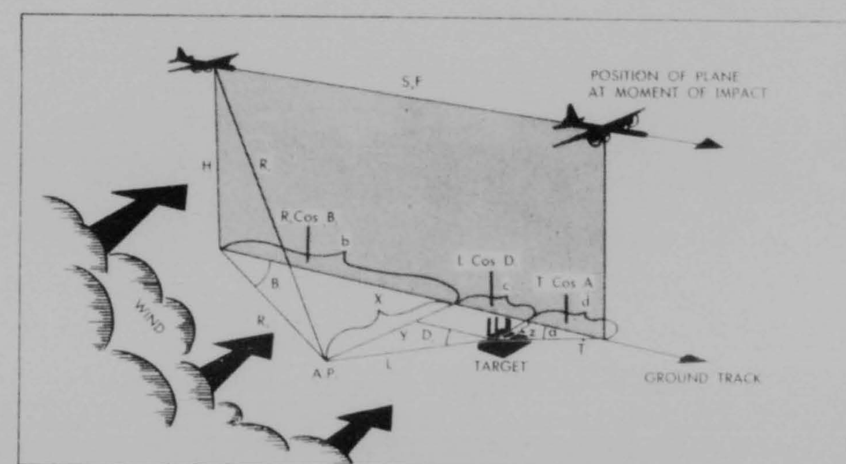
$Ra \text{ Cos } Bc + L \text{ Cos } Dc - SgF + T = 0$

Sighting-angle Equation

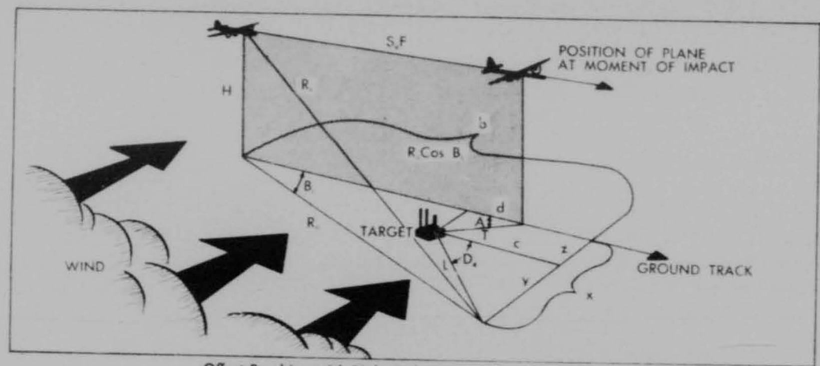
The sighting-angle equation is the same as for offset bombing without drift, aiming point before target. This equation is:

$Ra \text{ Cos } Bc + L \text{ Cos } Dc - Rn = 0$

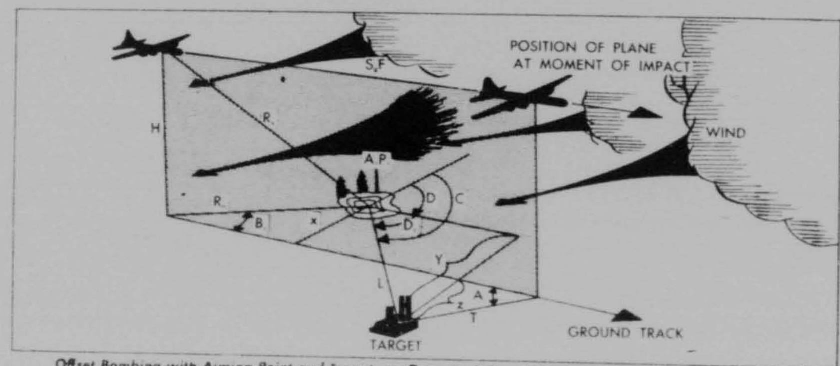
As usual, the Variable Range Circle Equation is the same as in all previous cases. If



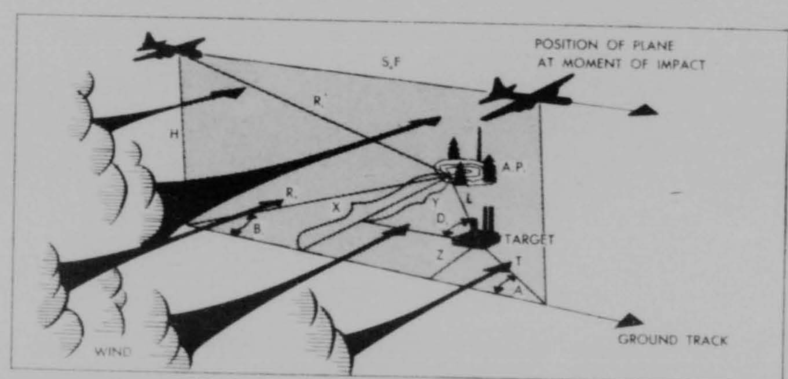
Offset Bombing with Right Drift, Aiming Point before Target.



Offset Bombing with Right Drift, Target Before Aiming Point.



Offset Bombing with Aiming Point and Target on Opposite Sides of Ground Track and with Right Drift.



Offset Bombing with Left Drift, Aiming Point before Target.

one develops the steering equation in the same way as it was developed in the case of offset bombing with right drift, aiming point before target, one will see that the steering equation here is the same as for that case. (Ra Sin Bc — L Sin Dc — T Sin A = 0.) Developing the release equation and the sighting-angle equation as in the case of offset bombing without drift, target before aiming point, one finds that these equations are the same here as in that case.

Release Equation:

Ra Cos Bc — L Cos Dc — SgF + T = 0

Sighting Angle Equation:

Ra Cos Bc — L Cos Dc — Rn = 0

The drawing for this case will strike one at first as being entirely different from those for the previous cases. However, if one derives the equations as was done in the previous cases, one finds that the variable range circle equation, release equation, and the sighting-angle equation are identical to those for offset bombing with right drift, aiming point before target. The steering equation, however, is different.

Steering Equation

One can develop the steering equation here as before. Since the aiming point and the target are on opposite sides of the ground track, one can see that the basic equation changes from x = y + z, which was used in the previous case, to y — z = x. As before x = Ra Sin Bc, y = L Sin Dc, and z = T Sin A. Substituting these terms in the equation y — z = x, one has:

L Sin Dc — T Sin A = Ra Sin Bc

Transposing:

If one develops the variable range circle, the release, and the sighting-angle equation, one will see that these three equations are the same as in the case of offset bombing with right drift, aiming point before target. Only the Steering Equation is revised.

Steering Equation

One can develop the steering equation as in the previous examples. By inspection one can see that y + z = x and that x = Ra Sin Bc, y = L Sin Dc, and z = T Sin A.

Substituting:

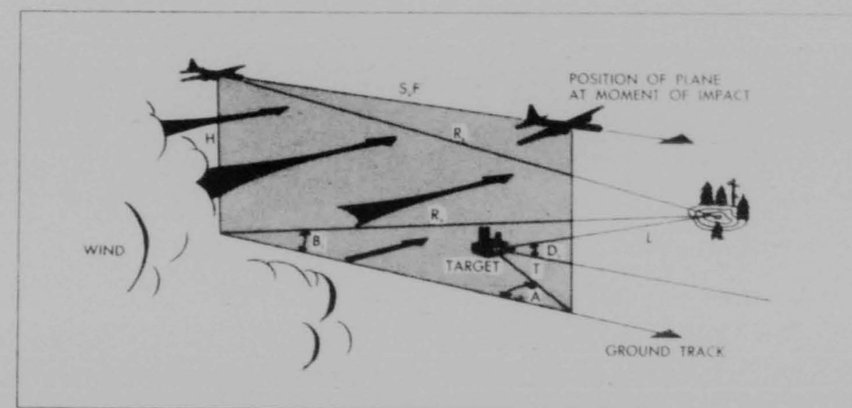
L Sin Dc + T Sin A = Ra Sin Bc

Transposing:

— Ra Sin Bc + L Sin Dc + T Sin A = 0

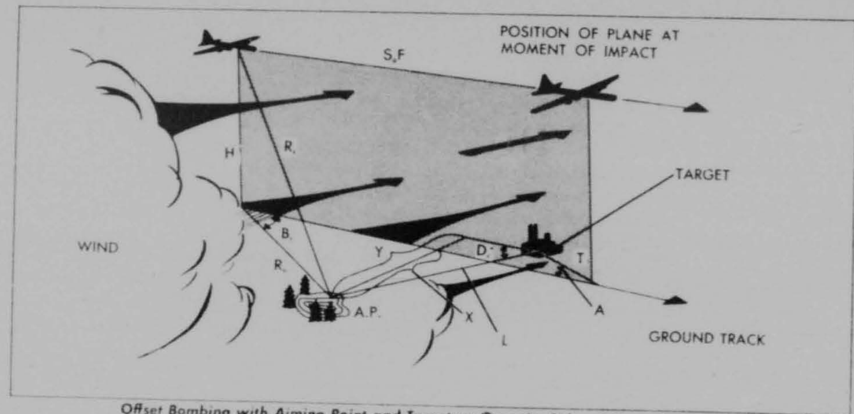
Developing the equations for this case, one can see that the variable range circle-equation is the same as in all previous cases, the steering equation is the same as for offset bombing with left drift, aiming point before target

(— Ra Sin Bc — L Sin Dc — T Sin A = 0), the release equation is the same as for offset bombing with right drift, target before aiming point



Offset Bombing with Left Drift, Target before Aiming Point.

THIS PAGE IS DECLASSIFIED IAW EO 13526



Offset Bombing with Aiming Point and Target on Opposite Sides of Ground Track and with Left Drift.

(Ra Cos Bc + L Cos Dc — SgF + T = 0), and the sighting-angle equation is the same as for offset bombing with right drift, target before aiming point (Ra Cos Bc − L Cos Dc − Rn = 0).

Except for the steering equation, the equations are the same as for the same problem with right drift.

Steering Equation

By examining the drawing one sees that the factors on the steering equation are the same as for the same problem with right drift except that they are on opposite sides of the ground track. In this case, therefore, the equation is x − y = z. Again, x = Ra Sin Bc, y = L Sin Bc, and y = L Sin Dc, and y = T Sin A

Substituting:

Ra Sin Bc − L Sin Dc = T Sin A

Transposing:

Ra Sin Bc − L Sin Dc − T Sin A = 0

Summary

Only a few of the many different bombing possibilities have been discussed in this chapter. However, by examining the table of the equations that have been developed, it is readily seen that the same pattern exists throughout.

One finds, for example, that the same terms are used in the equations for all cases where they apply. Thus, Ra Sin Bc, L Sin Dc, and T Sin A are the terms in the steering equation in all cases except direct bombing and offset bombing without drift. In the case of direct bombing, L Sin Dc does not apply, for there is no offset and the term is 0. In the case of offset bombing without drift, T Sin A does not apply, for the drift angle is 0 and T Sin A is 0. In the release equation, the terms are Ra Cos Bc, L Cos Dc, SgF, and T in all cases except direct bombing where, again, L Cos Dc does not apply, for there is no offset, and L Cos Dc is 0. There is a pattern also for the signs of the terms. Notice, for example, that T Sin A is positive in the steering equation whenever there is left drift and negative in the steering equation whenever there is right drift. Similarly, L Cos Dc is positive in the release and sighting-angle equations when the aiming point is before the target and negative in these equations when the target is before the aiming point.

Because of this consistent pattern for all cases, the one set of controls on the computer can be used to set in all problems, and the mechanism can automatically arrive at the desired results. Take, for example, a case of direct bombing without drift. The release equation for this situation (Ra − SgF + T = 0) differs from the release equation for other situations in that it shows Ra instead of Ra Cos Bc and does not show L Cos Dc at all. The computer automatically takes care of the situations as follows: Since the drift angle

Condition	Variable Range Circle Equation	Steering Equation	Bomb Release Equation	Sighting Angle Equation
Direct bombing without drift	H² + Ra² − Rs² = 0	None	Ra − SgF + T = 0	Ra − Rn = 0
Direct bombing with right drift	H² + Ra² − Rs² = 0	Ra Sin Bc − T Sin A = 0	Ra Cos Bc − SgF + T = 0	Ra Cos Bc − Rn = 0
Direct bombing with left drift	H² + Ra² − Rs² = 0	−Ra Sin Bc + T Sin A = 0	Ra Cos Bc − SgF + T = 0	Ra Cos Bc − Rn = 0
Offset bombing without drift, A. P. before target	H² + Ra² − Rs² = 0	Ra Sin Bc − L Sin Dc = 0	Ra Cos Bc + L Cos Dc − SgF + T = 0	Ra Cos Bc + L Cos Dc − Rn = 0
Offset bombing without drift, target before A. P.	H² + Ra² − Rs² = 0	Ra Sin Bc − L Sin Dc = 0	Ra Cos Bc − L Cos Dc − SgF + T = 0	Ra Cos Bc − L Cos Dc − Rn = 0
Offset bombing with right drift, A. P. before target	H² + Ra² − Rs² = 0	Ra Sin Bc − L Sin Dc − T Sin A = 0	Ra Cos Bc + L Cos Dc − SgF + T = 0	Ra Cos Bc + L Cos Dc − Rn = 0
Offset bombing with right drift, target before A. P.	H² + Ra² − Rs² = 0	Ra Sin Bc − L Sin Dc − T Sin A = 0	Ra Cos Bc − L Cos Dc − SgF + T = 0	Ra Cos Bc − L Cos Dc − Rn = 0
Offset bombing with right drift, A. P. before target on opposite sides of ground track	H² + Ra² − Rs² = 0	Ra Sin Bc + L Sin Dc − T Sin A = 0	Ra Cos Bc + L Cos Dc − SgF + T = 0	Ra Cos Bc + L Cos Dc − Rn = 0
Offset bombing with left drift, A. P. before target	H² + Ra² − Rs² = 0	−Ra Sin Bc + L Sin Dc + T Sin A = 0	Ra Cos Bc + L Cos Dc − SgF + T = 0	Ra Cos Bc + L Cos Dc − Rn = 0
Offset bombing with left drift, target before A. P.	H² + Ra² − Rs² = 0	Ra Sin Bc + L Sin Dc + T Sin A = 0	Ra Cos Bc − L Cos Dc − SgF + T = 0	Ra Cos Bc − L Cos Dc − Rn = 0
Offset bombing with left drift, A. P. before target on opposite side of ground track	H² + Ra² − Rs² = 0	Ra Sin Bc − L Sin Dc + T Sin A = 0	Ra Cos Bc + L Cos Dc − SgF + T = 0	Ra Cos Bc + L Cos Dc − Rn = 0

Bombing Equations

set in by the operator for this case is 0 and the Cos for an angle of 0° is 1, Cos Bc is 1, and Ra Cos Bc is exactly the same as Ra. Since the range offset put in by the operator is 0, L is 0, the term L Cos Dc is 0, and that term drops out of the computation. In this way, the computer automatically eliminates terms that do not apply.

The computer provides for a change in the signs of terms through the setting of the dials. Where the drift and bearing offset angles are such that the terms should be minus in the equation, the mechanism is so designed that, when the controls are set at those angles, a minus voltage is derived from the potentiometer. Where the angles are such that the terms should be plus in the equations, the mechanism is so designed that, when the controls are set for such angles, the potentiometer gives a plus voltage. The precise manner in which this is accomplished within the computer is explained in the following chapters.

THIS MANUAL SUPERSEDES ConAC Manual 50-100-1, 50-200-2 Vol. II, Part 9.

Preface

THIS textbook has been prepared specifically for the college or university student who is participating in the Air Force ROTC program. It is one volume of a series designed to qualify him as an officer specialist in the United States Air Force.

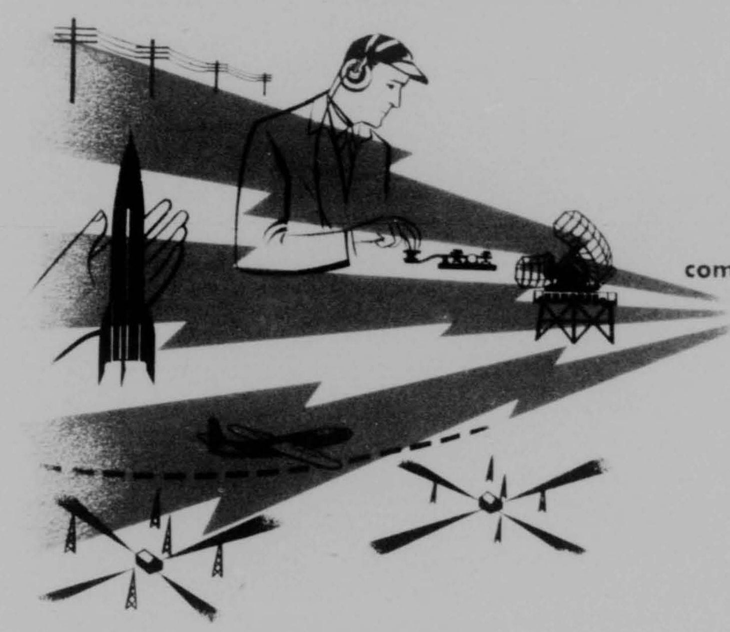
The text is planned to indoctrinate the officer candidate in the fundamental principles of Air Force Communications, rather than to present a detailed treatise of the entire complex field.

In order to achieve maximum efficiency and effectiveness in the performance of his duties, the Air Force officer must be constantly aware of new developments in his specialty and its allied fields. A receptive mind, nurtured by supplementary research and reading, can be a vital force in the personal and professional development of the officer specialist throughout his career.

THIS PAGE IS DECLASSIFIED IAW EO 13526

TABLE OF CONTENTS

CHAPTER 1 - INTRODUCTION



communications and electronics

SECTION 1 - BACKGROUND

Effective control over the composite elements of a military force is imperative to successful military action. This control depends almost entirely upon the ability of the commander to make his will known to his subordinates, which, in turn, obviously involves some sort of communications. When military operations were relatively primitive, the commander shouted his orders. At a later period as armies grew in size and operations became more involved, the commander's voice was wholly inadequate, and his decisions were made known by prearranged signals, such as the sound of a bugle, the roll of a drum, or the firing of a flare. These simple communications served fairly well when the field was limited, but they too became hopelessly obsolete as battles and battle areas grew in magnitude.

As late as the American Civil War the orders of commanding generals were conveyed to subordinate commanders by mounted couriers. This system of combat communications, while colorful, was at best highly vulnerable. Often, and at critical times, the courier failed to reach his destination and failure to do so often resulted in defeat.

Warfare in the twentieth century is bewildering in its complexity. Advances in technology have produced weapons which compel total mobilization of the nation's manpower, materiels, and productive capacity. Armies once composed of thousands are now composed of millions. Each soldier has become a trained specialist and numerous activities must be precisely coordinated in order to accomplish the over-all mission. This welding of many parts into an organic

THIS PAGE IS DECLASSIFIED IAW EO 13526

whole is achieved by means of unobstructed communications. Destroy these lines of communication and the efficient army becomes a chaotic mob. Open lines of communications provide the means for effective control; impaired or imperiled lines endanger control; disrupted or destroyed lines lead to military defeat.

Think of the United States Air Force as you would think of your body. Think of the numerous parts of the Air Force as you would think of the parts of your body. Hundreds of thousands of cells unite to form your little finger. You can move your little finger up and down and sideways, and you can coordinate it with other bodily actions by means of the will of your brain. Your will is transmitted by your body's lines of communication (your nervous system) to the cells composing your finger. This illustration is analogous to military operations. One man in Washington, the brain or Chief of Staff, can direct global warfare and control the action of every man in his gigantic striking force by means of the military **nervous system**—the lines of communications.

During World War II, command from remote locations was the rule rather than the exception. The activities of the tactical air forces were closely coordinated with the movements of the allied armies. The units of the Twentieth Air Force were based in the Mariana Islands of the Pacific, while the operations of those units were the result of directives from their headquarters in Washington, D. C. In both of these types of operation, the need for centralized headquarters was imperative, and contact with the widely spread units was accomplished chiefly by radio.

In task force organization, hundreds of organizational units, each responsible for a separate and special assignment, were brought into concerted action as a great team and an irresistible task force by means of remote control was made possible by communications. General Eisenhower was able to command hundreds of ships and thousands of men on D-Day in Europe because of the channels of communications which reached every ship and every soldier participating in the invasion.

As the war progressed, this trend toward remote control and dependency upon communications became more marked. The Combined Chiefs of Staff and the Joint Chiefs of Staff, along with subordinate agencies, planned the grand strategy of the war in Washington and projected it by means of a world communciations network to the distant fighting fronts. This point is well illustrated in the case of the Twentieth Air Force.

Remote control is likely to become increasingly pronounced in the atomic and rocket age. The technological revolution in warfare is well under way. Weapons are reaching toward the ultimate in range, power, and speed. These developments are not to be dismissed as fantastic impossibilities, for they now exist as the grimmest of realities. Atomic bombs, approximating the absolute in destructive power; supersonic guided missiles; high speed submersibles equipped with rocket-firing facilities; these, along with other awe-inspiring innovations have heralded the pattern of future warfare. Should this country be forced into another conflict, the United States, by the new concept of war now evolving, will tend to become the main operating base, regardless of the disposition of the country's armed forces.

Discussion so far in this chapter has been limited to communications, which implies the

transference of intelligence from one human to another. This restricted concept is no longer in order. It is now improper to consider communications as a separate and distinct field from electronics. With the development of new weapons and new ideas of strategy, communications and electronics become more intimately related and interdependent. One must think of messages not only in the conventional manner, but also in terms of "impulses" sent out through space to provide remote control to a missile speeding toward a predetermined target at 2,000 miles per hour.

It becomes apparent that the field of communications and electronics must keep pace

and even anticipate other scientific advances. Failure in the field could and would result, in the final analysis, in general collapse of offensive and defensive action.

Never before has such a burden of responsibility rested upon the communications officer. In a very literal sense, the safety of the United States depends upon him. He must warn of the approach of a hostile force; he must guide the retaliating missile to its destination; he must keep the sea lanes free from hidden "schnorkels," and he must provide the means for the remote control of our armed forces all over the earth.

Proficiency in the field of communications and electronics requires considerable exacting application. There are compensations, however, for the officer with initiative and vision. He will soon realize that his opportunities for professional growth are very good and that he has an opportunity to make valuable contributions in this field.

SECTION 2 - DEFINITIONS

1. GENERAL

Communications and Electronics

The field of **communications and electronics** comprises all radio, wire, and other means for electrical transmission or reception of intelligence and all radar, radiation aids to aircraft and navigation, including control of guided missiles, radiation aids to fire control and bombing, radiation countermeasures and related radiation, and reradiation and all ancillary equipment. Specifically exempt from this field are nonradiating electrical devices, such as autopilots, fluxgate compasses, and kindred apparatus.

In a broad military sense, communications may be redefined as the means provided to extend the senses of the commander in terms of time and space. These means include all electrical, electronic, aural and visual media which, when assembled and integrated into an overall system, provide the required degree of operational and administrative control within the command.

Strictly speaking, this should be known as the **field of communications and electronics**; however, it has been abbreviated by general usage to **communications**.

Communication

Communication is the transmission of any messages except those sent by mail. The term message includes all oral, written, and pictorial communications, along with orders, reports, and instructions in plain language or encrypted.

Agency of Communications

Agency of communications embraces the personnel and equipment necessary to operate message centers, communication intelligence, communication supply, communication repair, and messenger, pigeon, radio, visual, sound, and wire communications.

Means of Communications

Means of communications indicates an agency of communications capable of transmitting messages. The following agencies are means of communication: messenger, pigeon, radio, semaphore, whistle, telephone, and telegraph.

2. AGENCIES OF COMMUNICATIONS

The following agencies of communication may be employed in the United States Air Force.

Message centers

Messenger communications, including:
- Air messenger
- Motor messenger
- Foot messenger (runner)

Radio communications, including:
- Radiotelegraph
- Radiotelephone
- Radioteletypewriter
- Radio facsimile

Wire communications, including:
- Telephone
- Telegraph
- Teletypewriter
- Facsimile

Visual communications, including:
- Lamps
- Flags
- Panels
- Pyrotechnics
- Smoke
- Hand and arms signals
- Maneuvers of aircraft

Sound communications

Radar installations, including:
- Ground radar installations
- Airborne radar installations

Electronic aids to navigation, including:
- Radio ranges
- Instrument landing devices
- Direction finding systems
- Loran
- Radio beacons
- Radio compass
- Radio altimeter
- Homing stations

Communications supply

Communications maintenance

DEPENDENT UPON SITUATION INVOLVED

3. MEANS OF COMMUNICATIONS

The communication systems within organizations of the United States Air Force generally employ one or more of the following means of communications: radio, wire, or messenger. Sound and visual communications are employed for special purposes. Choice of the means to be employed in every instance is dependent upon the situation involved as well as the suitability and availability of the means. In many instances, means are combined, i.e., radio links are used with wire communications. Exclusive reliance upon any one means is unwise since special and unforeseen circumstances may render that means inoperative or unsuitable when most needed. Plans of all commanders should make advance provision for the employment of as many different means as are regarded necessary to insure continuous communications and should include reliable alternate means. Simultaneous operation of several means minimizes the effect of complete interruption of any one. Generally, the principal means used for tactical purposes will be that which provides greatest facility and speed of installation and operation while insuring the necessary security and dependability.

Teamwork

To insure successful communication, the communications troops must work as a team regardless of unit, arm, or service. There must exist a spirit of mutual helpfulness and cooperation. The communications personnel at any headquarters should become acquainted with personnel at other headquarters with whom they communicate directly. This includes units in all relationships (supported, supporting, superior, subordinate, adjacent, and attached), and is true regardless of the point at which the responsibility for communication is fixed. Personal contact promotes a better understanding of the special problems and conditions which exist at each headquarters, and permits full assistance and cooperation in the installation, operation, and maintenance of communication. Coordination and cooperation are mandatory. This is especially true in joint operations with the Army, the Navy, and other air forces.

THIS PAGE IS DECLASSIFIED IAW EO 13526

SECTION 3 - COMMUNICATION DOCTRINE AND BASIC PRINCIPLES

1. GENERAL

In the design, construction, operation, and maintenance of communication systems, there are six basic principles upon which the systems must be founded. These are:

Principle of Reliability
Principle of Security
Principle of Speed
Principle of Economy
Principle of Flexibility
Principle of System Integration

Each of these principles must be carefully considered and assigned its proper weight. For example, in aircraft control communications speed may be of primary importance while security may be of only minor concern. On the other hand, certain command channels require the highest degree of security, while speed is secondary in importance. A full discussion of the application and balance of these factors is beyond the scope of this paragraph. Suffice to state that the balancing of these principles in the design and operation of a communication system is one of the most important decisions which can be made concerning the system.

2. PRINCIPLE OF RELIABILITY

Communications are vital to the proper control of military operations, and, to perform their proper role, must be available in its various forms when required by the commander.

Application of the principle of reliability of communications may consist of:

Engineering and building reliability factors into communications equipment. This includes specifying military characteristics so that the equipment will be sufficiently rugged to withstand the abuse of weather, transportation, and diversified operating conditions.

Engineering and building reliability factors into communications systems. This means the planning of alternate routes for communications channels to follow and the provision of alternate means of communications. In the latter, systems must be designed so that there will always be a standby means for handling traffic. For example, there must be radio channels to replace telephone channels, and there must be a courier, or messenger service to relieve some of the load placed on the electrical means. Additionally, this principle requires that the equipment selected be capable of handling the volume of message traffic which is anticipated and that it require a minimum of maintenance. Such other matters as the allocation of proper radio frequencies to the various nets so as to obtain maximum efficiency must be included in the planning of reliable communications.

Establishing adequate personnel programs and projects, including training programs and schedules, which produce personnel, as individuals or units, who are trained to meet unusual as well as routine problems. The morale of communications personnel has a major effect on the reliability of communications. In order to build and maintain this morale, there must be stated policies concerning training, assignment, and promotion. The individual is entitled to know the basis on which he will be promoted, that he will be assigned to the work for which he is best suited, and that he may expect to advance in his specialty.

Establishing adequate supply and maintenance programs and projects, including those for the welfare of personnel. A thorough maintenance program, especially preventive maintenance, is a major factor in insuring reliability of communications.

3. PRINCIPLE OF SECURITY

Proper application of this principle insures that the enemy is denied useful military information which he might otherwise obtain from friendly military communications. Security is of varying degrees. The design and operation of a communications system should provide the necessary degree of security consistent with the necessity for speed, reliability, and other military considerations.

Application of the principle of security to military communications consists of strict compliance with the provisions of AFR 205-1 **Safeguarding Military Information,** and strict application of principles and procedures as established in other appropriate documents.

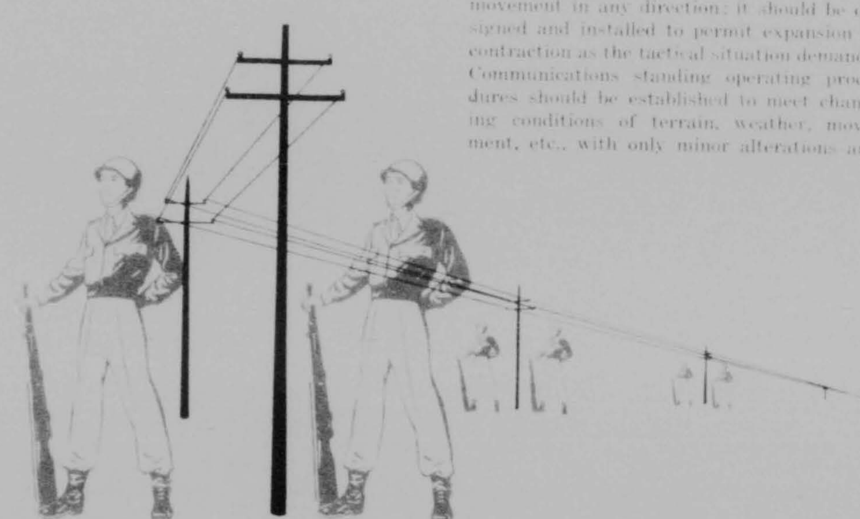
4. PRINCIPLE OF SPEED

The principle of speed of communications requires that systems be designed and operated so that information may be transmitted quickly enough to be useful in modern, high-speed warfare. While the need for speed has its greatest manifestation among the combat elements, the effect is felt even in the rearmost support elements; the requirement for speed in communications is present throughout the military establishment. The application of the principle of speed must be consistent with the necessity for security, reliability, and other military considerations.

Application of the principle of speed of communications may consist of:

Installation of direct, private, telephone, and teletypewriter facilities.

Application of privacy equipment to eliminate the necessity for a separate cryptographic process.



Use of carrier equipment to increase telecommunication channel availability.

Use of radio links in telecommunications to speed installation of networks.

Use of voice radio for such purposes as control of aircraft.

High standards of such personnel factors as operator training and morale.

5. PRINCIPLE OF ECONOMY

The principle of economy, as applied to communications, requires that the scale of communications be not more than that required to accomplish the mission successfully. This principle is an extension of one of the basic principles of warfare, **economy of force.** The application of this principle should be consistent with the necessity for reliability, security, flexibility, speed, and other military considerations.

6. PRINCIPLE OF FLEXIBILITY

The principle of flexibility of communications requires that communications systems be able to meet changing and diversified situations with only minor adjustments to the systems. Thus, a system should be designed and installed so as to permit freedom of movement in any direction; it should be designed and installed to permit expansion or contraction as the tactical situation demands. Communications standing operating procedures should be established to meet changing conditions of terrain, weather, movement, etc., with only minor alterations and

THIS PAGE IS DECLASSIFIED IAW EO 13526

modifications. Commanders must be free to act as the tactical situation demands without restrictions imposed by an inflexible communications system.

7. PRINCIPLE OF SYSTEM INTEGRATION

At first glance, it may seem that system integration should be a subdivision of other principles, such as flexibility, economy, and reliability. Such a surmise is partially correct, yet this principle is of such vital importance as to warrant separate consideration.

System integration includes: the blending of the separate communications nets, or systems, of subordinate units into the over-all communications system of the superior unit to produce one integrated system, and the adoption of common procedures throughout the integrated system.

SECTION 4 - THE USAF COMMUNICATIONS OFFICER

1. GENERAL

Normally, tactical unit commanders (and many service unit commanders) down to squadron level, are provided with a special staff officer trained in the tactics and techniques of communications. This office is charged, under the direction of the commander, with the exercise of tactical supervision of communications for the command. He is further charged with the duty of initiating, by means of proper recommendations, the necessary measures for the training of personnel and or subordinate units in communications for combat.

Channels of Supervision

Orders affecting the tactical employment of communications are issued through normal command channels (i.e., from the commander to a subordinate commander), and are coordinated with orders issued to other tactical or technical agencies by the appropriate staff section before issue. Orders pertaining to routine matters issued for the technical control of any agency of communications, and which need not be coordinated with orders issued to other elements of the command, may be issued (in the name of the commander) by the communications officer of the superior unit to the communications officer of a subordinate unit.

2. THE COMMUNICATIONS OFFICER (0200)

The following is a quotation from **AF Manual 35-1, Military Personnel Classification and Duty Assignment** (terminology used herein is that employed prior to National Defense Act of 1947):

Qualifications and Duties

Specification Serial Number (SSN) 0200

Directs or supervises the installation, operation, and maintenance of the signal communication agencies of a unit other than Signal Corps. Trains unit personnel in use of communication equipment; maintains efficient communication within a unit and with attached and supported units; establishes communications agencies as wire communications, radio communications, visual signaling, message centers, and messengers; supervises the enforcement of radio silence when in effect and provides for the use of runners and mounted messengers; supervises training of personnel in radio operation and maintenance; use of codes, construction, and maintenance of wire circuits, use of visual signals such as flags, flares and rockets, and message center operation and maintenance.

Must have thorough tactical and technical knowledge to insure establishment of necessary signal communication agencies according to tactical plans. Must be a specialist in Army signal communications systems.

Military experience essential and should include graduation from an officers' communication school.

Trade school or college training in electrical engineering desirable.

The above is a description of the duties of a communications officer (0200) plus the general qualities which must be present in an individual who would be one. From this, it must be obvious that the communications officer must be fully and carefully trained.

Staff Duties

As a member of the commander's staff, the communications officer is technical advisor to the commander and others on the staff on communications matters; he bears a staff responsibility for technical inspection of the communication systems of the command and subordinate units; he advises the commander and staff on matters of communications training and prepares the necessary training program under the general training policy as laid down by the commander and by higher authority; he takes steps to secure the required equipment throughout the command, and makes training inspections to insure proper progress in communications training.

SECTION 5 - NOMENCLATURE SYSTEM FOR COMMUNICATIONS EQUIPMENT

1. GENERAL

A supply system of so vast a scale as that required by the several parts of the national defense organization must have a system of item identification. Such a system must be both exact and brief. For supply purposes, the simple combination of stock number and nomenclature (one serving as a check on the other) fulfills both the requirements of exactness and brevity.

For other purposes (such as operations, planning, orders, and instruction), item identification is established by nomenclature alone. Therefore, nomenclature must be brief and specific. Each item, set, or group of equipment must be given a name which will serve to identify that particular article and nothing else. The "Dictionary of United States Army Terms" defines nomenclature as a "set or system of official names or titles given to items of material and equipment."

Communications and associated equipment of the Army, Navy, and Air Force is assigned its proper nomenclature under the Army-Navy Nomenclature System. This system was secured through joint agreement.

Prior to the adoption of this system in January, 1943, each service had its own system of nomenclature. The old system still exists since many of the items that were named in this manner are still in use. Therefore, it is well that the communications officer understand something about the use of both systems employed in the naming of the equipment.

2. ARMY-NAVY NOMENCLATURE SYSTEM

Development of AN System

The Army-Navy (AN) Nomenclature System was developed to establish a standard plan of naming communications and associated equipment of the two services in order to eliminate delays in interservice supply occurring when identical equipment of the Army and Navy differed in name. The same plan applies to the communications equipment used by the now autonomous Air Force.

THIS PAGE IS DECLASSIFIED IAW EO 13526

In developing the system, it was considered that it should:

Facilitate the operation of the Army and Navy supply services as well as speed inter-service supply.

Be logical in principle and easily understood.

Be flexible and broad enough in scope to cover all present types of equipment and new types to be developed in the future.

Avoid conflict with any then existing nomenclature systems.

Provide adequate identification on name plates without requiring the full name to be stated.

Provide a ready means of identifying equipments standardized for use by the Army and/or Navy and other United Nations.

Nomenclature Assignment Policy

The nomenclature system described pertains only to communications and associated equipment of the Army, Navy, and Air Force. The expression **associated equipment** extends the scope of the system to include many items essential to the proper operation or functioning of communications equipment such as power units, batteries, cases for equipment, and shelters or housing for equipment. Likewise, because of their long-standing associations with the Signal Corps, meteorological apparatus and photographic equipment receive AN nomenclature.

Communications equipment, which had been assigned nomenclature in the Signal Corps system prior to the adoption of the AN system in January, 1943, has not been redesignated. To avoid confusion, the AN System has been applied only to equipment developed since adoption of the system. Equipment formerly designated by Signal Corps nomenclature will continue to be so designed unless specifically changed by official order.

Army-Navy Nomenclature has been and will be assigned to: **complete sets of equipment** and **major components** of special design by or for the Army and Navy groups of items, of either commercial or military design, which are grouped for a special military communications purpose; **major units of equipment** of military design which are not part of or used with sets; and **commercial articles** when nomenclature will facilitate military identification and/or procedures.

A complete set is a complete group of equipment or major components, deriving power from outside or one or more included sources, which is capable of operating by itself and independently of other sets or accessories in performing its intended purpose. A major component is an item of a set which, when connected with associated equipment, will perform a major function.

Army-Navy Nomenclature is not assigned to:

Articles cataloged commercially except when nomenclature will facilitate military identification and/or procedures.

Minor components of special military design that can be identified in the stock number description by specification number, standard number, manufacturer's code number, or nomenclature of some other government agency.

Small parts such as condensers, resistors, etc., which continue to be identified by Army stock numbers or Navy type numbers.

Articles having other adequate identification in American War Standard or Joint Army-Navy Specifications.

The assignment of an AN Nomenclature is centrally controlled by the Joint Army-Navy Air Force Nomenclature Committee. Under no circumstances may other personnel or agencies originate or change any part of any AN Nomenclature assignment, including modification letters, unless the nomenclature previously has been approved and assigned by the aforementioned committee. Agencies performing authorized equipment modifications in the field may not add modification letters without authorization. Requests for new nomenclature assignments or changes are sent to the Joint Army-Navy Air Force Nomenclature Committee for action.

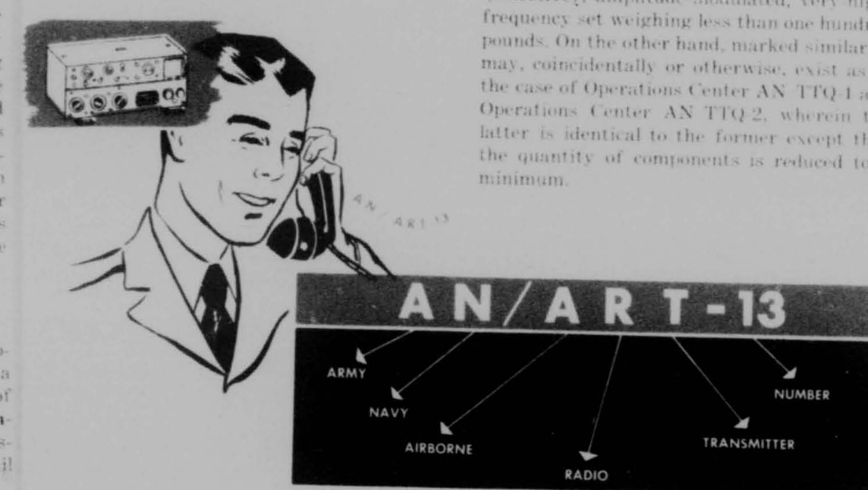
Composition of AN Nomenclature

In the AN system, (see Appendix) nomenclature consists of a name followed by a type number. The **name** is terminology of standard engineering usage. The **type number**, variable in composition, is characteristic of the system and is explained in detail

below. Some examples of complete nomenclature are as follows: Radio Set AN/ARC-3; Radio Transmitting Set AN/AR T-13; Telegraph Terminal TH-1/TCC-1; and Switchboard SB-5/PT. In the last example, switchboard is the **name;** SB-5/PT is the **type number.** Type numbers are composed as follows:

Type Numbers for Complete Sets. The type number for a complete set always contains the AN system indicator "AN" followed by a slant bar, indicator letter, and an assigned number. Example: AN/TRC-7. When applicable, modification letters and additional indicators are appended. The system indicator "AN", which is used only with type numbers for complete sets, does not mean that both the Army and Navy use the equipment but simply that the type number was assigned in the AN System and distinguishes it from similar type numbers in the Navy Model Letter System. The slant bar (/) serves only to separate the system indicator and the set or equipment indicator letters. The combination of indicator letters immediately following the slant bar is derived from, and interpreted by, the Table of Set or Equipment Indicator Letters in Appendix III. For complete sets, the type number always contains three of these indicator letters; the first letter indicating the type of installation, the second letter the general type of equipment, and the third letter the general purpose for which the set is used.

The number following the set or equipment indicator letters designates a specific complete set. It is an assigned number, a **model** number. Except in instances where suffix letters X, Y, and Z are applied as explained in Table I, or where letters are used to indicate functional interchangeability, different numbers are assigned to sets or equipment not electrically and mechanically interchangeable as a whole. As used in the type number AN/TRC-7, the number "7" indicates the seventh ground transportable radio communications set to which nomenclature has been assigned. The fact that two sets or equipments possess type numbers differing only in this assigned number, whether consecutive or not, does not imply any similarity of equipment other than that denoted by the set or equipment indicator letters. Thus, Radio Set AN/TRC-6 and Radio Set AN/TRC-7 are necessarily similar only in that each is a ground transportable radio communication set. No further similarity is implied. Radio Set AN/TRC-6 is an eight-channel (simultaneous), pulse-modulated, super-high frequency set weighing approximately five tons. Radio Set AN/TRC-7, however, is a two-channel (selective), amplitude modulated, very high-frequency set weighing less than one hundred pounds. On the other hand, marked similarity may, coincidentally or otherwise, exist as in the case of Operations Center AN/TTQ-1 and Operations Center AN/TTQ-2, wherein the latter is identical to the former except that the quantity of components is reduced to a minimum.



THIS PAGE IS DECLASSIFIED IAW EO 13526

When a set is modified for the first time, producing a minor variation in the functioning but not affecting interchangeability of the original and modified set of components, the basic nomenclature assignment is changed by the addition of the letter "A". Example: Radio Set AN ARC-7A indicates the first such modification of Radio Set AN ARC-7B, and so forth.

The use of modification letters, additional indicators for experimental sets and training sets, and the star (*) for United Nations Standardization is explained in Appendix III.

The reader should note that Appendix III presents an example of nomenclature for a complete set at the top of the table. Immediately under the example, the type number is expanded across the entire page. Under each letter or figure of the type number appears an explanation of that particular element of that type number. Additional examples of type numbers, with their meanings, appear at the lower left of the table.

Type Numbers for Components. Where only a component of a set is to be indicated, the letters "AN" in the prefix are replaced by a component indicator of one or two letters, followed by an assigned number for that component, a modification letter (if applicable), a slant bar, and the set or equipment indicator letters, assigned number, and modification letters of the set for which the component was originally designed. Examples: Radio Receiver R-89A ARN-5A; Radio Transmitter T-47 ART-13. The component indicator is derived from, and interpreted by, the Table of Component Indicators in Appendix III.

The meaning of the various elements of a component type number is explained in a manner similar to that used to explain the type number of a complete set.

In case a component developed for one set is later used in another set, the component will continue to bear its original nomenclature assignment, thus indicating the purpose for which it was originally developed and avoiding more than one nomenclature for a given component. Example: Radio Transmitter T-47 ART-13. The type number indicates that it is the forty seventh radio transmitter (disregarding lettered modifications of preceding transmitters) to be assigned nomenclature in the AN system and is a part of or is used with Radio Transmitting Set AN ART-13. However, Radio Transmitter T-47 ART-13 is also a part of Radio Set AN ARC-8, yet it retains its original nomenclature.

In cases where a component is generally employed with several sets, only such of the set or equipment indicator letters will follow the slant bar as are necessary to indicate the extent of use. Examples: Assume that a headset is designed so that it is suitable for use in several types of installations and can be used for radio telephone, and telegraph. Such an item might be indicated as follows: Headset H-16 U. A motor generator designed to be used with several airborne radar sets is designated Motor Generator PU-7 AP. A test set designed to be used with several airborne radar navigation sets would be indicated as follows: Test Set TS-10 APN. A test set designed to work specifically with a certain airborne radar navigation set would be indicated as follows: Test Set TS-477 APN-19, which would indicate that the equipment was originally designed to be used with Radar Beacon AN APN-19.

Type Numbers for Major Units. The type number for an independent major unit (equipment of military design which is not part of nor necessarily used with a set) or a group of items when less complete than a set, consists of a component indicator; a number; modification letter, if any; the slant bar; and such of the set or equipment indicator letters as apply. Example: Switchboard SB-5 PT would be the type number of a portable telephone switchboard for independent use. SB is the component indicator for a switchboard and PT indicates that it is a ground portable telephone equipment.

In any combination of set or equipment indicator letters, whether it consists of one, two, or three letters, the letters always indicate information in the standard sequence; installation, type of equipment, and purpose. If only one letter is used, it indicates installation. Two letters indicate installation and type of equipment.

Parentheses Indicator. A type number with parentheses, ( ), following the basic type

number is used to identify an article generally, when the need exists for a more general identification than that provided by nomenclatures assigned to specific designs of the article. Example: AN GRC-5 ( ), AM-6 ( ) GRC-5, SB-9 ( ) CG. A specific design is identified by the plain basic type number, the basic type number with a suffix letter, or the basic type number with an experimental indicator in parentheses: Examples: AN GRC-5, AN GRC-5A, AN GRC-5 (C-1), AM-6B GRC-5, SB-9 (XO-3) GG.

3. SIGNAL CORPS NOMENCLATURE SYSTEM

Composition

The old Signal Corps Nomenclature System likewise adhered to the principle that nomenclature consists of a name followed by a type number. Again, the name portion is terminology of standard engineering usage. Examples: Radio Set SCR-522, Radio Set SCR-399, Telegraph Terminal Set TC-22, Telephone EE-8-A, Radio Transmitter BC-375.

The type number consists of one, two, or three letters followed by a number. In general, the letters are abbreviations. Thus, SCR for Signal Corps Radio, BC for Basic Component, and LS for Loudspeakers. This is by no means always true and a thorough familiarity with the system is gained only through long association. No attempt is made to describe the system thoroughly, but rather to present a brief description of it.

Some of the more frequently encountered indicators or letter designators used in the Signal Corps System are interpreted below.

A complete list of such designators and their meanings, appears in AF Technical Order T.O. 16-50-13. A cross index of type numbers, item names, and stock numbers appears in SIG 5-1 section of the Department of the Army Signal Supply Catalog.

The reader may note that in some instances the designators used in the Signal Corps system are identical with some component indicators in the AN system, indicating an apparent source of conflict. This is an apparent contradiction of one of the requirements of the AN system as stated in paragraph 3, a, (4) above. Actually, no confliction exists, due to one or more of the following considerations:

Any type number in the AN system always contains a slant bar ( ) with at least one letter following it. No slant bar is used in type numbers in the Signal Corps system.

In cases where the names of the items differ widely, conflict is avoided by the name. Thus in the Signal Corps system, "C" indicates Coil (induction) and the name associated therewith may be "Coil" or "Transformer"; in the AN system "C" indicates Control Articles which are never of such a nature to be confused with a coil.

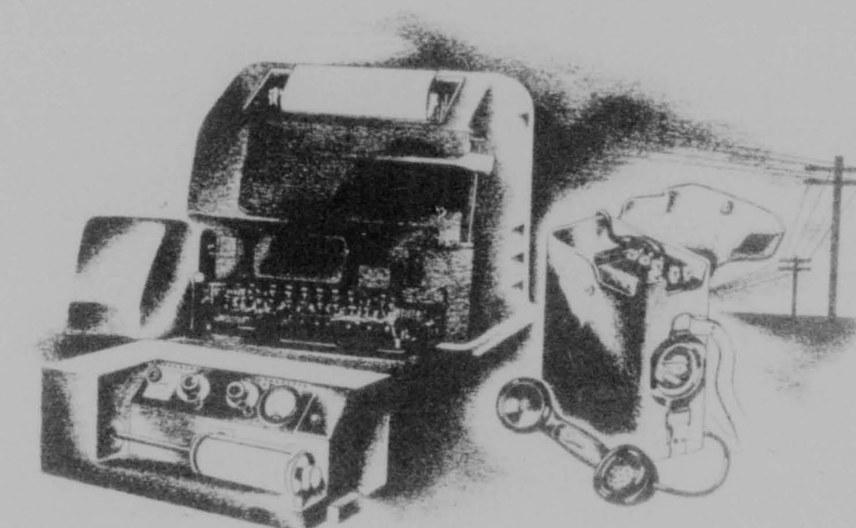
If the names are identical, or likely to be similar, a new block of nonconflicting numbers is used in the AN System. Thus, for the indicator "BA", Battery BA-1 through Battery BA-149 are common to the old Signal Corps System; whereas Battery BA-200 U was the first such battery to be assigned nomenclature in the AN system.

As in the AN system, a type number with parentheses, ( ), is used to identify an article generally. Thus, Radio Set SCR-399 refers to a specific set, as does Radio Set SCR-399-A; whereas, Radio Set SCR-399- ( ) refers to all models of the set.

SIGNAL CORPS NOMENCLATURE

BA — Primary batteries (dry)
BB — Storage batteries
BC — Receivers, transmitters, control boxes, etc. (Radio)
EE — Telephone, Telegraph and Signal Lamp Sets
FT — Fittings, mountings, clamps, etc.
HO — Shelters
HS — Headsets
LS — Loudspeakers
P — Headsets
R — Telephone receivers
RL — Reel Mechanism
SCR — Radio Sets and complete assemblies
SCS — Extensive Communication Systems
TC — Central Office Sets (wire)
TG — Telegraph Instruments
TC — Transmitter Tuning Units

CHAPTER 2 - WIRE COMMUNICATIONS



SECTION 1 - PRINCIPLES OF TELEPHONY

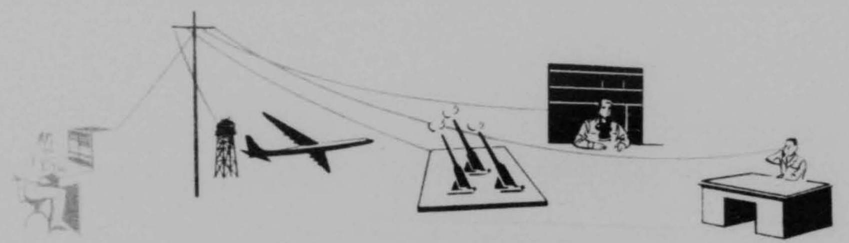
1. GENERAL

Wire telephone communications became an actuality when electrical impulses created by the human voice were first transmitted over a metallic circuit between two distant points. Today, as a result of constant research and development, wire communication has become a primary means of binding the civilized world together.

Likewise, wire communication has become a necessary implement for the successful accomplishment of military operations. When telephone and telegraph were first adopted in military communications systems to meet the requirements of existing tactical conditions, they were restricted to short-range facilities, requiring minimum equipment designed for small combat units. Today, however, as the tactics and techniques of modern warfare have changed, so have the military practices in the employment of wire communications. Present military wire systems are closely patterned after those of commercial companies with modifications and revisions in wire and wire equipment designed to meet the requirements of varying combat conditions. Wire lines used in conjunction with radio links will meet the communications requirements of most tactical situations.

In comparing wire with radio, advantages common to both are found. Technically, the principle of transmission is the same, except for the medium of the transmission path. Tactically, they differ in their employment. However, it is well to remember that wire and radio employed together form the basis of military communications systems.

While wire communications may not have the glamor which is associated with radio, it plays an extremely important part in any



system of military communications. It requires considerable time and planning by the communications officer to make the best use of the facilities available.

Proper employment of these facilities will increase communications security, relieve a great part of the traffic load from the radio system, and permit a more rapid handling of messages.

2. CAPABILITIES AND LIMITATIONS

The quality of service rendered an organization is governed by the capabilities and limitations of wire lines and equipment. Like radio, there are numerous factors which permit or restrict the use of short or long distance wire communications. The more important factors which affect the employment of wire lines are the following:

First, consideration must be given to the electrical characteristics of metallic conductors. There are electrical properties which exist in all conductors when an electromotive force is impressed on them. These properties tend to resist or impede the passage of a message over them, and therefore must be given consideration when planning the use of wire.

Second, consideration must be given to the physical and mechanical characteristics of the wire. These characteristics are also related to the electrical characteristics of the wire. In this category are included the size of the conductor and its mechanical strength.

Third, consideration must be given to the type and size of the tactical organizations to be served by the installation. This consideration, although nontechnical, does affect the type of wire to be employed and the number of circuits that will be installed.

The final consideration is that of personnel. Satisfactory and reliable service can be provided only if the installing, operating, and maintaining personnel know their work. The solution then, is to employ well-trained and experienced personnel. The communications officer must bear this consideration in mind in facing any one of the many communications problems.

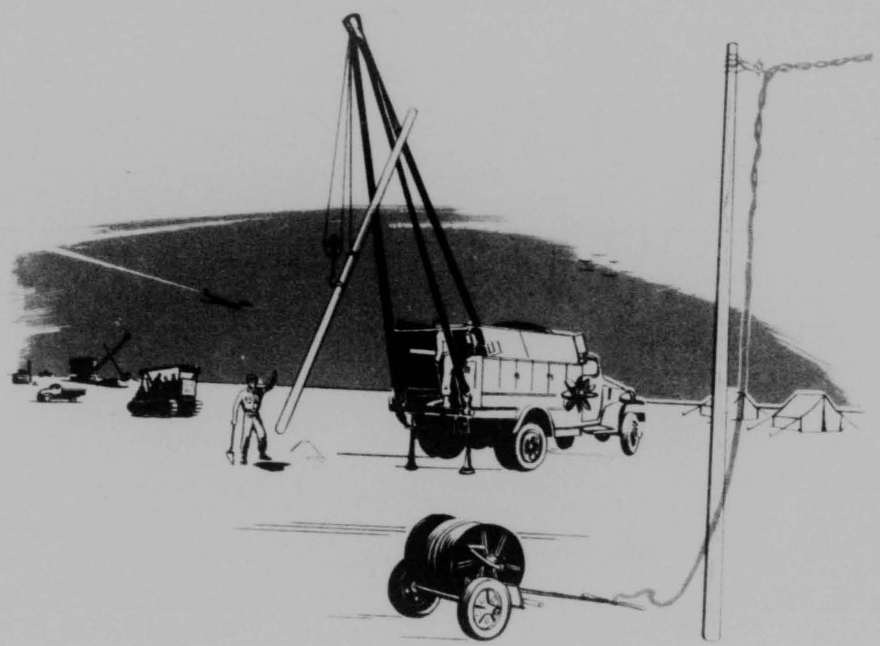
It is these factors which have been briefly discussed that determine the technical capabilities and limitations of wire communications. To these must be added consideration of the principles of communication.

Of the electrical means of communication, wire is generally the simplest since the medium of transmission is physical. Telephone and related systems employed tactically are basically simple circuits; the equipment is not complex.

Well-constructed wire communications facilities are reliable. They are not affected by climatic conditions, nor are they subject to mechanical or electrical failure to any great extent.

Wire is considered as the most secure means of communication. Security is here used in a relative sense. As long as wire lines and terminal equipment are located in friendly territory, there is little danger of interception of messages by an enemy. Traffic is not broadcast as it is when certain types of radio are employed, and, as a result, the only possibility of intercepting messages transmitted over wire comes from enemy agents who may be able to gain access to transmission lines.

The wire systems installed determine the degree of flexibility of the medium. Adequate advance planning will usually provide for



flexibility. Line construction will follow the axis of communication, and will, normally, satisfy military needs. Terminal equipment may be installed which will be adequate even after the original using unit moves away. The medium may be used for voice, telegraph, teletypewriter, or facsimile transmission, or for combinations of several or all of these.

In many respects, wire may be considered to satisfy the principle of mobility since any military wire equipment may be installed in trucks or trailers. Transmission lines such as field wire, rubber-covered cable, and spiral-four cable can be constructed rapidly. While wire cannot match radio as a communication means for mobile units, such as aircraft or tanks, for headquarters which may move from time to time, it is possible to install wire facilities rapidly enough to consider that it is a mobile means of communication.

3. TELEPHONE TRANSMISSION OF SPEECH

General

Because of the small amount of energy contained in the normal talking voice, the distance of satisfactory reception between the individual to whom communication is directed and the speaker is restricted. When the intervening distance becomes too great for face to face conversation, the telephone supplies the simplest medium of transmission for voice communication. The purpose of a telephone, like that of radio, is to extend the range of voice communication between individuals. To accomplish this, the telephone system must first convert the energy of the speech sound wave in air to a corresponding electrical wave which may be transmitted over the intervening wires, and then to reconvert the electrical energy into sound energy so that it may be understood. The tele-

THIS PAGE IS DECLASSIFIED IAW EO 13526

phone transmitter is the device which converts the sound wave energy into electrical energy and back again to sound energy. Other essential parts of modern telephone sets are the induction coils, capacitors, the hook switch, signaling equipment, and a ringer. These will be described in turn in succeeding paragraphs.

The original telephone, invented by Alexander Graham Bell in 1876, consisted of a carefully constructed instrument which was used both as a transmitter and as a receiver. Neither a battery, nor signalling equipment was employed. Figure 2-1 illustrates the circuit of two such units.

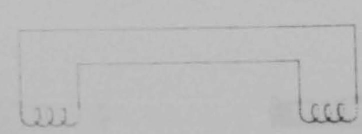


Figure 2-1 Simple Telephone Circuit

At the speaker's station, the sound waves of the voice strike the metal diaphragm of one unit; the alternate condensations and rarefactions of the air set the diaphragm in vibration. Behind the diaphragm is a permanent magnet, the lines of force leaving the north pole of the magnet pass through the winding, through the diaphragm, and return to the south pole of the magnet. A review of magnetism reveals that the number of lines of force depends upon the width of the air gap as well as the metal in the magnetic path. As the diaphragm moves in and out under the influence of the sound waves, it varies the length of the air gap between the diaphragm and the permanent magnet. The vibration of the diaphragm causes corresponding changes in the number of lines of force which pass through the receiver winding; this results in the winding being cut by a varying magnetic field, or an increasing or decreasing number of lines of force. The changing magnetic field establishes a varying electromagnetic force in the winding. This induced voltage has wave characteristics that correspond to the impressed sound wave.

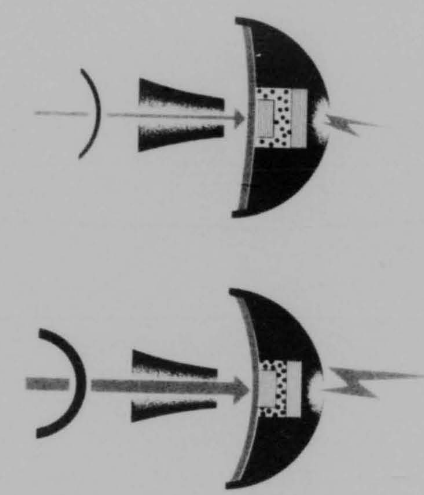
Figure 2-1 shows that the windings of both units are connected in series so that any current which flows through one winding must flow through the other winding.

The varying current which has been generated at the speaker's end of the circuit will pass through the winding at the distant end of the line. In so doing, it will set up a field that alternately strengthens and weakens the field of the permanent magnet at the distant end. The varying magnetic field exerts a varying pull upon the receiving diaphragm with the result that the receiving diaphragm will vibrate in unison with the diaphragm at the transmitting end, and thereby reproduce the original sound. Because of the losses in the transmission line and in the telephone units, the receiving diaphragm will vibrate with less amplitude, and produce a less intense sound than was originally put in at the sending end.

This discussion of the Bell instrument has been included because the principle of operation applies to modern telephone receivers and to the sound-powered telephone discussed in paragraph 6. Modern telephone transmitters are described below.

Telephone Transmitters

In the early stages of telephone development, it was found that electrical energy generated by a diaphragm moving in a comparatively weak magnetic field was insufficient for the transmission of speech over any great distance. Even by using stronger magnets, the best possible diaphragms, and louder sounds, voice transmission was limited to rather short distances. One year after the invention of the original telephone, the Blake transmitter was introduced. It worked on the principle of a diaphragm varying the strength of an already established electrical current, in contrast to the generation of electrical energy by means of electromagnetic induction. This type of transmitter is very similar to a valve, since it regulates the flow of current from some external source.



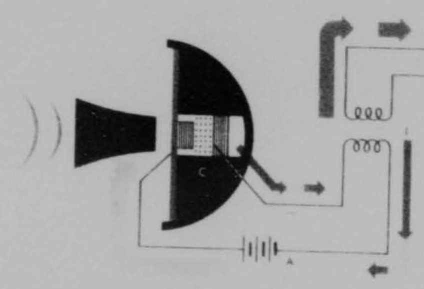


Figure 2-2 Simple Telephone Transmitter Circuit

The principle of the transmitter may be better understood by referring to Figure 2-2. Direct current from battery A flows first through a cup of carbon granules C, then through the primary winding of an induction coil I, and back to the negative terminal of the battery. The function of the induction coil will be discussed at a later time.

One side of the cup C rests against a small carbon disk, which is rigidly connected to the transmitter diaphragm. As the diaphragm vibrates, it varies the pressure upon the carbon granules, causing them to make better or poorer contact with each other. This causes fluctuations in the value of the direct current maintained in the circuit by a battery. These varying fluctuations, even though they are represented by varying values of direct current, establish, by transformer action, an induced alternating electromotive force in the secondary of the induction coil. The alternating electromotive force in turn causes an alternating current to flow in the series circuit consisting of the line and the two receivers. Figure 2-3 illustrates transmitters used at the ends of a simple telephone circuit.

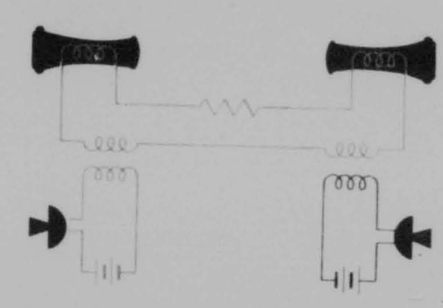

Figure 2-3 Use of Transmitters in Simple Telephone Circuit

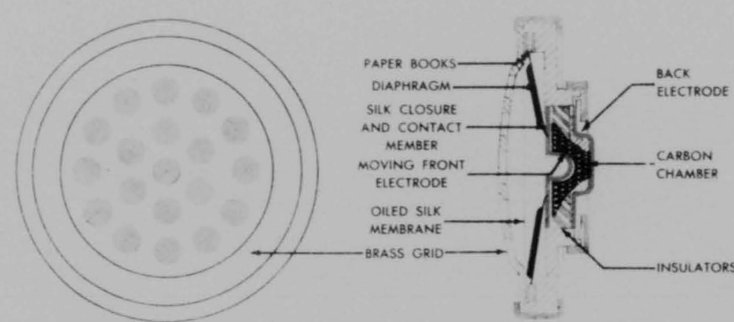

Figure 2-4 Modern Transmitter Unit

It can be seen from Figure 2-3 that when a person speaks into a transmitter, the voice currents which result must pass through the windings of his own receiver. This sound heard in the receiver (caused by vibrations picked up from the transmitter of the same telephone unit) is called "sidetone."

The operation of a telephone transmitter depends upon the vibration of the diaphragm. The vibration of the diaphragm is caused by the variation in the pressure of the sound wave striking it. Figure 2-4 illustrates a cross section of a transmitter unit which is widely employed in current telephone practice.

The electrical circuit passes from the moving front electrode, through the carbon chamber, to the back electrode. The conical bell-shaped carbon chamber is used so that sufficient contact force exists between the carbon granules and the electrodes, regardless of the position in which the transmitter is held. For this reason, the transmitter will ngnt magnet; the lines of magnetic force operate satisfactorily in any position. Transmitters possessing this feature are called "nonpositional." The transmitter is also of the direct action type; that is, the movable element is attached to the diaphragm, and in addition to exerting the variable pressure, also serves as an electrode. As the drawing shows, this curved electrode is attached to the center of a conical diaphragm, forming the front center surface of the bell-shaped carbon chamber. The diaphragm is made of an aluminum alloy 0.003 inch thick and has ridges to increase its stiffness. Paper books, which consist of a number of thin paper rings, support the diaphragm at its edges without restricting its movement. The carbon chamber is closed on the front side by a silk covering clamped upon the flange of the front electrode. A light, spoked copper contact member, also clamped under the front electrode, provides a flexible connection between the front electrode and the metal frame. The fixed back electrode is held in place in the frame by a threaded ring; it is insulated from the frame by a fiber washer and a ceramic insulator, which also forms part of the surface of the carbon chamber. The surfaces of both front and back electrodes are gold plated where they make contact with the carbon granules. The perforated brass plate, or grid, in Figure 2-4 protects the vibrating parts from mechanical injury. Moisture is kept out of the working parts by an oiled silk membrane placed between the brass grid and the diaphragm. When new, the transmitter unit has a resistance of about 35 ohms.

Figure 2-5 illustrates the manner in which the transmitter unit is mounted in a shell when used as part of a modern telephone

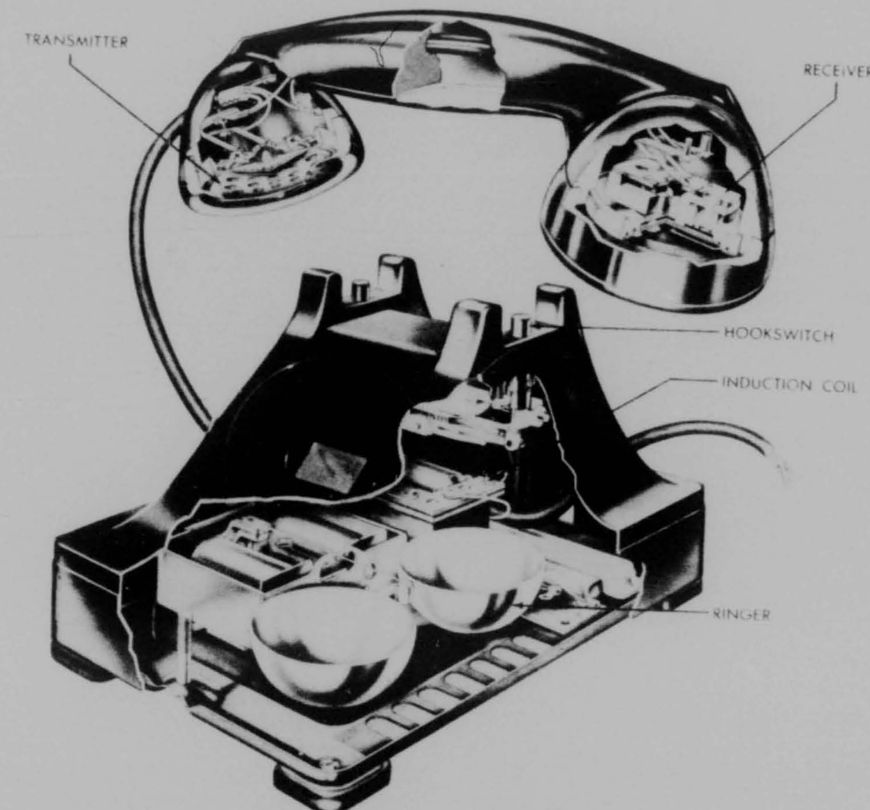

Figure 2-5 Cutaway of Telephone Desk Set

handset. The transmitter unit may be removed by unscrewing the transmitter cap or mouthpiece. This figure also shows how the contact springs press against the contacts of the transmitter unit. The transmitter mouthpiece is made of the same plastic material as that of the receiver shell and case.

Telephone Receivers

There has been no fundamental change in telephone receivers comparable to that which has been made in transmitters. Consequently, the theory of the operation of the original Bell instrument applies to present day equipment.

The earlier forms of the telephone receiver were equipped with a permanent bar magnet as illustrated in Figure 2-6.

The efficiency of this instrument was greatly increased by the use of the horseshoe magnet, as illustrated in Figure 2-7. Here the length of the magnetic path is greatly shortened, since the magnetic lines of force, after passing through the airgap, pass from one pole to the other through the diaphragm only.

THIS PAGE IS DECLASSIFIED IAW EO 13526

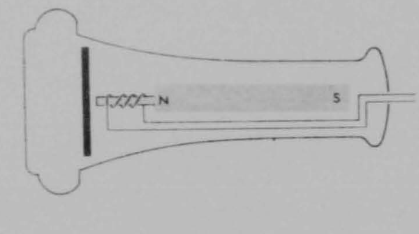

Figure 2-6 Telephone Receiver

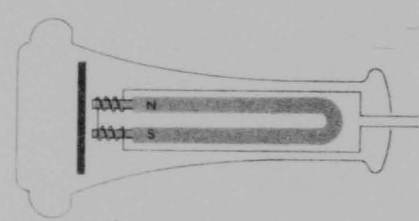

Figure 2-7 Telephone Receiver with Horseshoe Magnet

Modern telephone receivers are equipped with permanent magnets which normally are not impaired by jarring or other abuse. A permanent magnet not only increases the amplitude or vibration when voice currents are flowing in the windings, but also prevents the diaphragm from vibrating at twice the voice frequency. This principle is illustrated in Figure 2-8.

When a diaphragm is held near an electromagnet consisting of a soft iron core and a winding, the diaphragm is attracted by the electromagnet regardless of the direction of the current in the windings. If, as in Figure 2-8, an alternating current were passed through a coil wound around a soft iron core, the diaphragm would be attracted during each half cycle. Such a receiver would be useless, since the sound wave produced obviously would not be identical with the electric wave that produces it. But if, as in Figure 2-8, a permanent magnet is used as the core, the electromagnet merely increases or decreases the pull of the permanent magnet. The permanent magnet exerts a constant pull upon the diaphragm, when the current through the receiver winding is in such a direction as to set up a magnetic field that will aid the magnetic field of the permanent magnet, the diaphragm moves inward toward the magnet. Conversely, when the direction of the current is reversed, the diaphragm moves outward. The diaphragm then moves both inward and outward from its neutral position, and produces a sound wave corresponding in frequency and amplitude to the impressed electrical wave.

Remember that if it is necessary to permit the flow of direct current through a receiver winding, the receiver should be connected in such a manner that the field produced by the direct current will aid the field of the permanent magnet. Such a process is called "poling." The word "poling" is also used when other types of connections are made; for example, "poling the batteries in a series connection" so that their voltage will be additive.

One of the latest receiver unit types is shown in Figure 2-9. Three comparatively new magnetic alloys are used in its construction; the receiver unit is designed so that it can be mounted in several different types of telephone instrument. The receiver winding

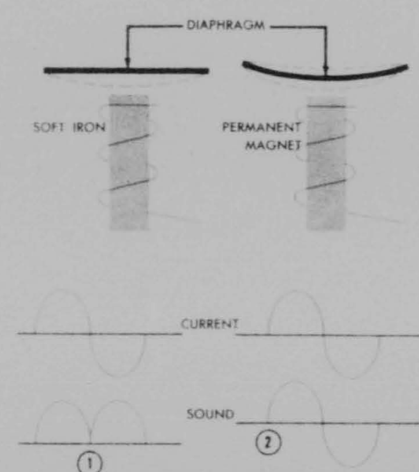

Figure 2-8 Operation of Telephone Receiver

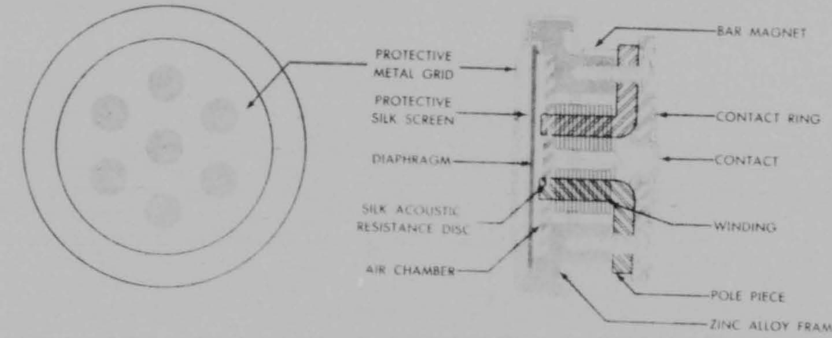

Figure 2-9 Modern Handset Receiver

is wound around two permalloy pole pieces, shown in Figure 2-9. The pole pieces are welded to a pair of very strong, cobalt-steel bar magnets. The whole assembly is fastened to a zinc-alloy frame.

The diaphragm, which is made of special steel alloy, is unclamped, and, as can be seen from Figure 2-9, rests upon a ring-shaped ridge. The whole unit is held together by a brass clamping ring. Upon the back of the unit are mounted two silver-plated contacts for electrical connections. Figure 2-5 illustrates how this receiver unit rests in the receiver shell when used with a standard desk-stand. If trouble develops, or when necessary for testing purposes, the receiver unit may be removed by merely unscrewing the receiver cap. When the receiver cap is screwed on tight, it exerts a pressure on the receiving unit, forcing the two silver-plated contacts against two contact springs which are connected to the external wiring. The receiver and transmitter described are of recent design; however, many of the older types are still in everyday use. Different designs are used for operators' chest sets and linemen's test sets. The principles involved, though, are essentially the same in all cases.

Telephone Induction Coils

A telephone induction coil is a transformer which is efficient over a wide range of voice frequencies. The discussion in this text will be limited to the types of induction coils which are commonly employed in military communications.

There are two general types of induction coil: the closed-core type and the open-core type. The closed-core type is more efficient because the iron core forms a closed loop around the coil. It provides a better magnetic return for the lines of force than does the open-core type, which requires that the lines of force complete their circuit through the long air gap between the ends of the magnet. The coil consists of insulated copper wire wound around a laminated silicon-steel core. The employment of a laminated core minimizes power losses caused by eddy currents in the core. Most induction coils used in telephones have either two or three windings, the ends of which are brought out to terminals mounted over the core.

Induction coils are used in telephone systems to separate physically, and, at the same time, to couple inductively two electrical circuits. The manner in which a telephone transmitter causes a variation in the value of a steady direct current already has been explained. The variation in current may be considered as two separate currents. The first of these is the steady value of the current supplied by the battery, and the second is the fluctuating current caused by the voice which is superimposed upon the steady value of the direct current. Since the induction coil is a transformer, a steady current flowing in its primary will not cause a voltage to be induced in its secondary. The superimposed voice currents, since they are changing in value, will induce corresponding voltages in the secondary. The transmission efficiency of

THIS PAGE IS DECLASSIFIED IAW EO 13526

the telephone set is also increased by stepping up, through transformer action, the voice frequency voltages originating in the transmitter circuit. These factors will be discussed more fully in the study of telephone station circuits.

Telephone Capacitors

A capacitor may be described briefly as a device which acts like an open circuit to direct current, but which permits the passage of alternating current. With a fixed capacitor in a circuit in which an alternating current of varying frequency is flowing, the impedance of the circuit varies inversely with the frequency. In other words, as the frequency of the applied alternating voltage increases, the impedance of the capacitance decreases and as the frequency of the alternating voltage decreases, the impedance will increase. Voice frequency currents transmitted over a telephone system are considered to be essentially between 200 and 2,700 cycles per second; the ringing currents used by the operator to operate the signaling device are in the neighborhood of 20 cycles. A given capacitor will offer much more impedance to the low frequency ringing current than to the high frequency voice currents. If it is remembered that a larger capacitor is required to pass ringing currents, it will be much easier to trace the separate paths of ringing and voice currents in circuits to be encountered in later sections of this book.

The two general types of capacitors used extensively in telephone practice are either paper or mica capacitors. The terms "paper" and "mica" are derived from the type of separator employed in the construction of the capacitor. The separator is called the "dielectric."

Telephone Hookswitch

The telephone hookswitch is a device that will break or open the circuit when the telephone is not in use. Its purpose is to prevent any unnecessary drain on the power supply. The hookswitch is simple and automatic in its operation since merely lifting the receiver from its hook or cradle closes the contacts. In addition, in common-battery telephone circuits, closing or opening the hookswitch contacts automatically signals the operator that a call is to be placed or has been completed. There are several types of hookswitch and numerous spring arrangements sometimes referred to as "pile-ups;" the different arrangements are used for extra features in telephone circuits. A type of hookswitch in common use is the plunger type. (See Figure 2-5). This hookswitch depends upon the weight of the handset to depress two plungers that push against the springs, thereby opening the circuit in the manner previously described.

Signaling

Telephone systems must provide some means whereby a telephone subscriber may call or signal the operator when it is desired to make a call. The signaling equipment is in addition to the equipment required to transmit the voice signals. Signaling equipment is also required by the operator when it is necessary to call a subscriber. In order to accomplish signaling, a generator capable of providing the ringing current and a ringer assembly must be added to the system. For local battery systems a hand-cranked generator, described below, is used in telephones and small switchboards. Larger local-battery switchboards are provided with a reed vibrator. Common-battery systems employ a 20-cycle rotary inverter.

The magnetic field of a hand generator is supplied by a combination of two to five U-shaped steel permanent magnets arranged with like poles on the same side. These magnets are provided with cast-iron pole pieces (Figure 2-10). End plates which contain bearings are secured across the ends of the pole pieces and in these bearings an armature is mounted.

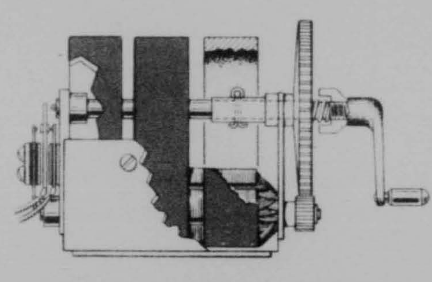

Figure 2-10 Gear & Crank for Hand Generator

The fewer the bars in the permanent magnet, the greater will be the number of turns in the armature winding, which range from about 3,000 turns for a three-bar generator, to 1,700 turns for a five-bar generator. In a particular type of generator, one end of the winding is connected to the armature core, and the other end connected to a pin set in the axis of the armature shaft. This pin is insulated from the rest of the shaft. A flat spring presses against the pin and completes the armature circuit to one terminal of the generator, while a connection to the generator frame acts as the other terminal.

Telephone Ringers

Figure 2-11 illustrates a common type of telephone ringer.

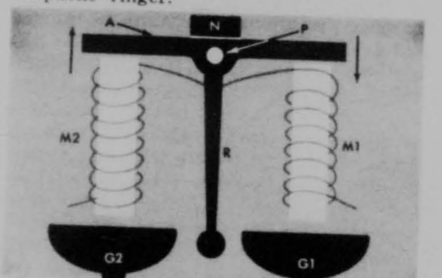

Figure 2-11 Telephone Ringer Circuit

This device operates on the 20-cycle ringing current generated either by a hand generator or a ringing machine.

The theory of the ringer can be more readily understood by referring to Figure 2-11. N represents the north pole of the permanent magnet. The permanent magnet is mounted very close to the center of the armature, and induces a south pole at the center of the armature. Assume that the 20-cycle ringing current is passing through the windings and that its direction during a half-cycle is as illustrated. This makes the upper end of M1 a south pole and the upper end of M2 a north pole. The armature will rotate in the direction indicated about its pivot P, striking the tapper against G2. During the next half-cycle of the ringing current, the direction of current flow is reversed, reversing the direction of rotation of the armature, so that the tapper strikes G1. This action is repeated with subsequent cycles of the ringing current. The name of "polarized ringer" is applied to this type of ringer, since it has a permanent magnet. Windings with resistances ranging from 250 to 2,500 ohms are constructed, with a 1,000-ohm ringer being the most common. The impedance of a 1,000-ohm ringer to average voice current frequencies is approximately 30,000 ohms, and the presence of a ringer across the line during normal conversation does not cause appreciable transmission loss. However, some telephone circuits provide for removing the ringer from the line during the period of conversation by employing the action of contacts in the hookswitch.

SECTION - 2 TELEPHONE SYSTEMS

1. IDENTIFICATION OF TELEPHONE SYSTEMS

There are two types of military telephone systems: the **local-battery** and the **common-battery systems.** The common-battery system may be either manual or automatic. These systems plus the sound-powered telephone will be described in this section.

To identify local-battery and common-battery telephone systems, the distinguishing features of each type of system must be kept in mind.

In **local-battery telephone systems,** the electrical energy for the operation of the transmitters is furnished by dry cells located within each telephone instrument. Signaling is accomplished by cranking a hand generator

THIS PAGE IS DECLASSIFIED IAW EO 13526

which provides an alternating current to operate the ringers and drops. When the telephone is not in use, no voltage is applied to the line. For this reason, local-battery lines are said to be dry.

On the other hand, in **common-battery systems** all DC voltages are supplied by a large storage battery located at the common-battery switchboard. For the purpose of this textbook, it is sufficient to say that a battery of 24-volt potential is applied at all times to each individual line. It is used to furnish current for the operation of the transmitters, for signaling purposes, and for supervision. Common-battery lines are said to be wet because there is a voltage applied to them at all times.

2. CAPABILITIES OF TELEPHONE SYSTEMS

The current required from each battery in a local-battery telephone is slight and intermittent, hence dry cells are as well suited for this duty as any other type of cell. But from an economic standpoint, dry cells are one of the most expensive sources of electrical energy. Furthermore, their life is short, they deteriorate while idle, and their voltage is not constant. When used in telephones, their maintenance requires frequent visits to each instrument to test the battery and replace exhausted cells. The service between stations in the local-battery system is not uniform, since a station with a partially exhausted battery may be connected with one having a fresh battery. The inclusion of batteries and a hand generator in each telephone results in an instrument which is bulky and complex. The turning of the hand generator to signal the operator requires conscious effort on the part of the subscriber. Failure on the part of the subscriber to signal the switchboard operator that his call is completed (ring-off) increases the work of the operator. The restoration of the drops and the necessity for cutting in to supervise also add to the operator's work.

However, in spite of these disadvantages there are certain advantages that make this system very usable in military communications systems. There are many instances where this equipment may be used to much greater advantage than common-battery systems. Since a common-battery system requires a higher voltage battery to supply sufficient current for transmitter operation, a better quality of outside plant construction is required to minimize leakage and subsequent loss of power. Furthermore, common-battery switchboard equipment is far more complex and delicate than is the local-battery equipment. Local-battery transmission is superior to that of common-battery over long lines having relatively high resistance. From the standpoint of condition of outside plant, reliability of switchboard equipment, and volume of transmission, common-battery equipment is not well suited for military field telephone systems, which are more or less temporary. However, local-battery equipment is well suited for this type of operation.

The use of the common-battery system overcomes some of the objections to local-battery equipment. By furnishing all current used in the system from a centrally located battery, the drain is sufficient to warrant the use of storage batteries, which are efficient when properly maintained. The cost of the energy to recharge the storage battery is a great deal less than the cost of the purchase of dry cells to give the same service. In addition, it does not require that each station be visited periodically by a maintenance man and thereby effects a consideration saving in man-hours. Since automatic signaling of the operator is inherent in the common-battery system, the magneto is not required in the common-battery telephone. With the removal of the magneto and battery from the telephone instrument a simpler, smaller, and neater instrument results. As the operation of the common-battery telephone will be explained more fully in a later section, it is sufficient to say that lifting the handset will complete a signaling circuit notifying the operator that the subscriber desires to place a call. Returning the handset to the hook signals that the call has been completed. Automatic signaling and supervision not only simplify the routine for persons using the telephone, but they reduce the operating work to such an extent that a signal operator can handle many more lines on a common-battery switchboard and still furnish better service.

Post installations are of more permanent nature and are better suited for the application of the common-battery equipment than are most of the field installations.

3. LOCAL-BATTERY TELEPHONE SYSTEM

General

Local-battery telephone systems consist of telephone instruments, switchboards, and transmission lines. The most commonly used local-battery telephone, EE-8-( ) and representative local-battery switchboards will be described in the following paragraphs. Transmission lines will be included in a later paragraph.

Local battery antisidetone telephones such as the EE-8-( ) are used on point-to-point circuits and on loops to magneto switchboards. They are also used on long loops to common-battery switchboards where, because of the high resistance in the transmission line, an adequate amount of direct current does not reach the microphone. They also may be used on short loops to common-battery switchboards if common-battery telephones are not available.

Telephone EE-8-( )

With good batteries, the direct current through the microphone in the EE-8-( ) telephone will be in the vicinity of 0.06 to 0.07 ampere. A satisfactory grade of transmission will be obtained between two such telephones connected by lines having transmission losses of not more than 30 db.*

(*Transmission losses and gains are expressed in terms of the unit called the "decibel," abbreviated as db. This will be further explained in Section IV.)

Handset TS-9-( ) which is furnished as part of Telephone EE-8-( ) contains a compensated magnetic-type receiver in which the diaphragm is damped and free to move at the edge. This type of receiver produces equally well in all frequencies of the speech transmission band which are important from the standpoint of intelligibility (200 to 3,000 cycles).

The speech transmission loss is caused by bridging a Telephone EE-8-( ) across a 600-ohm line is about 3 db. However, because of resonance between the capacitance and induction elements in the telephone, the impedance of the telephone is very low at 500 cycles and the bridging loss at this frequency may under some conditions be as much as 15 db. It is therefore important to avoid bringing this telephone equipment across circuits using 500-cycle ringing.

Figure 2-12 illustrates the Telephone EE-8-(B).

Transmitting Circuit. The transmitter, receiver, induction coil, and the 0.3-mf capacitor are connected in an antisidetone circuit in which the impedance of these elements and the characteristic impedance of the average line (Wire W-110-B) are so balanced as to reduce the sidetone in the receiver to the proper level. This results in an effective gain since the effect of noise in the vicinity of the transmitter of the receiving telephone is reduced. The user also unconsciously speaks more loudly into the transmitter. This results in effective transmitting gain. On lines shorter than the average, the sidetone is more pronounced and the antisidetone effect is lessened.

Operating the handset switch closes the circuit consisting of the switch, battery, transmitter, and 2-3 section of the induction coil. Since this circuit has a relatively low impedance, large current changes are produced by the transmitter when it is activated by the sound of a voice. These current changes induce relatively high voltages in the entire 1-4 winding of the induction coil and across terminals **L1** and **L2** to which the line is connected.

The antisidetone operation of the circuit results from the electrical balance between the impedance of the 3-4 section of the induction coil in series with the 0.3 mf capacitor, and the impedance of the line circuit consisting of four miles or more of Wire W-110-B connected to terminals **L1** and **L2**. On shorter lines the antisidetone is less pronounced, although still effective.

Receiving Circuit. The induction coil, 0.3-mf capacitor, and receiver are so designed

THIS PAGE IS DECLASSIFIED IAW EO 13526

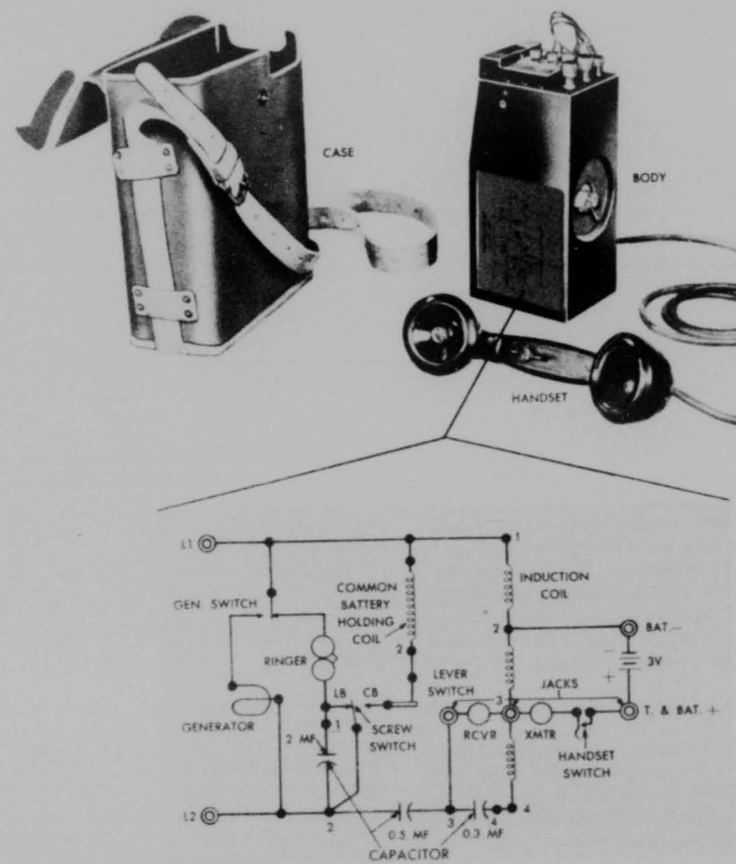

Figure 2-12 Telephone EE-8-B plus schematic

that the greater portion of the incoming line current will flow through the receiver over the voice-frequency range. This results in a maximum signal output.

The 0.5-mf capacitor is placed in series with the receiver to prevent the flow of direct current through the receiver, either from the batteries in the telephone or from the central office battery, when the telephone is connected to a common-battery system. This capacitor also limits 16-cycle ringing current through the receiving circuit and permits the permanent connection of the listening circuit across the line.

The transmission loss through the ringer, or the ringer and the capacitor in series, and the holding coil is negligible because of the high impedance to voice-frequency currents of these elements.

Signaling Circuit. The 1.9-mf capacitor in Telephone EE-8, or the 2.0-mf capacitor in Telephone EE-8-A and EE-8-B, is in series

with the ringer when the screw switch is in the CB (common-battery) position. This capacitor prevents direct current from biasing the ringer and also prevents the ringer from interfering with DC signaling or supervision when the telephone is connected to a common-battery system. The capacitor is short-circuited when the screw switch is turned to the LB (local-battery) position.

Telephone TP-9

This telephone combines the functions of Telephone EE-8-( ) and transmitting and receiving amplifiers which are located in the base of the unit, as shown in Figure 2-13. It is equipped with a transmitting amplifier which gives a fixed gain of 17 db compared with Telephone EE-8-( ) and is capable of providing a maximum power output of 15 db above one milliwatt. Because of this limitation on power output, the maximum gain of 17 db will be available only with talkers whose speech volume is below average. The receiving amplifier provides a variable gain up to about 55 db. The direction of transmission is controlled by the push-to-talk

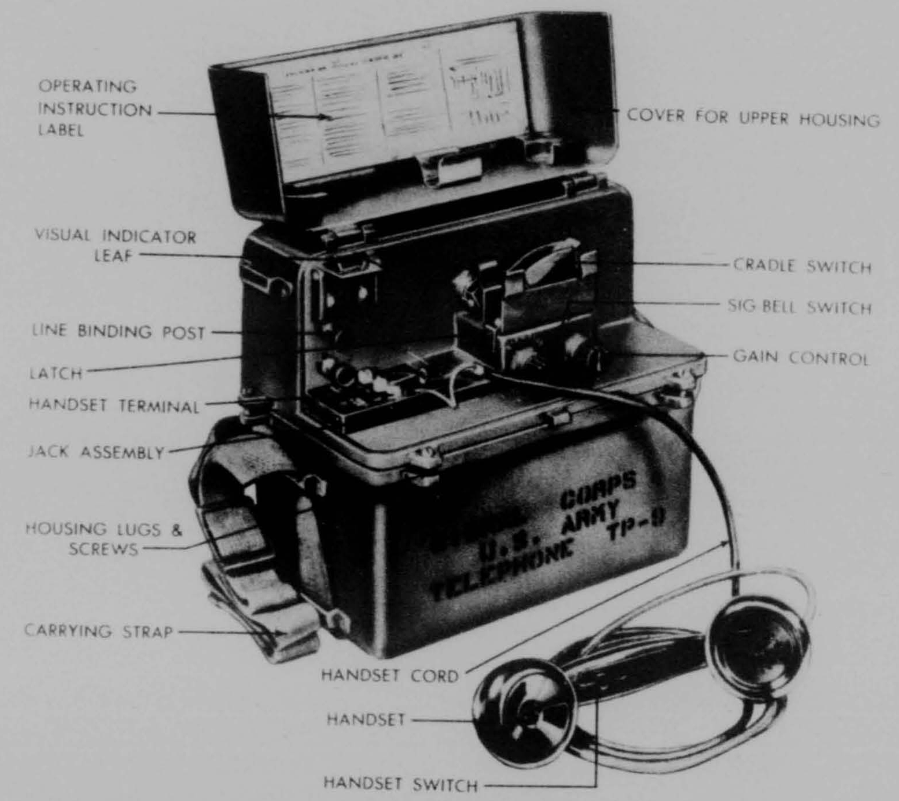

Figure 2-13 Telephone TP-9

THIS PAGE IS DECLASSIFIED IAW EO 13526

switch in the handset handle. While talking, the receiver circuit is open and the talker neither hears sidetone nor can he hear the distant party if he attempts to interrupt. This telephone cannot be used on common-battery loops since no coil is provided to complete the DC signaling path.

This telephone is intended for use where line losses are so great that transmission with Telephone EE-8-( ) is unsatisfactory. Since it has a power output which is approximately 15 db greater than that of the EE-8-( ), the probability of introducing cross-talk into other telephone circuits and overloading telephone repeaters is materially increased.

The large gains in receiving efficiency which are available will be effective in improving transmission on loops having high attenuation losses, and which are not subject to interference from power circuits or other extraneous sources, and in locations where ambient (acoustic) noise is high.

The high receiving gain of this telephone suggests the possibility of using it for listening in on enemy circuits either through a direct high impedance bridge or through crosstalk in a coupled path.

Local-Battery Switchboards

Switchboard Functions. The necessity of incorporating a switchboard in a telephone system is obvious. It is readily seen that it would be impossible to connect the subscriber's telephone to every other telephone subscriber that he might have occasion to call. This discussion will be limited to the switchboards which are employed in the military communications system. The functions which a local-battery switchboard must perform may be summarized as follows:

Provide a means of interconnecting the local loops and trunks terminated on the switchboard.

Provide a means whereby the operator can be signaled on all lines and trunks terminated on the switchboard.

Provide a means where the operator may talk and listen to the telephone subscribers who are connected to the switchboard.

Provide a means whereby the operator can signal on all lines and trunks terminated on the switchboard.

Provide the operator with a means of supervising calls.

Local-Battery Line Circuits. Each telephone line brought to a switchboard is connected to a separate jack. In order that the operator may be signaled, a line drop is provided in the local-battery switchboard for each line. The electrical circuit composed of the telephone line, the switchboard jack, and the line drop is called the line circuit. One type of line circuit is illustrated in Figure 2-14.

Turning the generator crank of the subscriber's telephone bridges the hand generator across the line, completing a circuit from the hand generator through the winding of the line drop. The ringing current from the generator passes through the winding of the drop, causing the armature to be attracted to the core or the winding. Since the armature is pivoted at point P, the shutter rod will raise and release the shutter. The falling of the shutter, or "line drop", as it is frequently called, provides a visual indication to the operator that the subscriber desires to place a call.

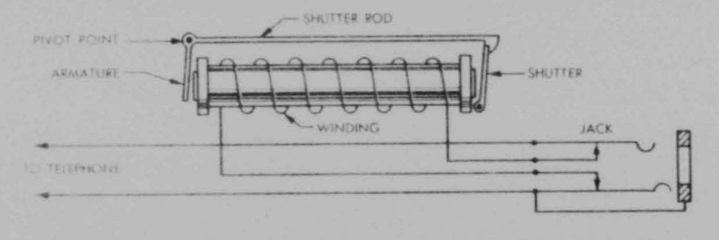

Figure 2-14 Local Battery Line Circuit

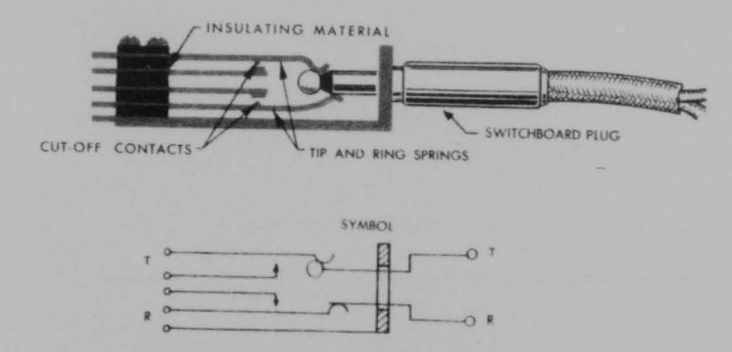

Figure 2-15 Local Battery Switchboard Jacks

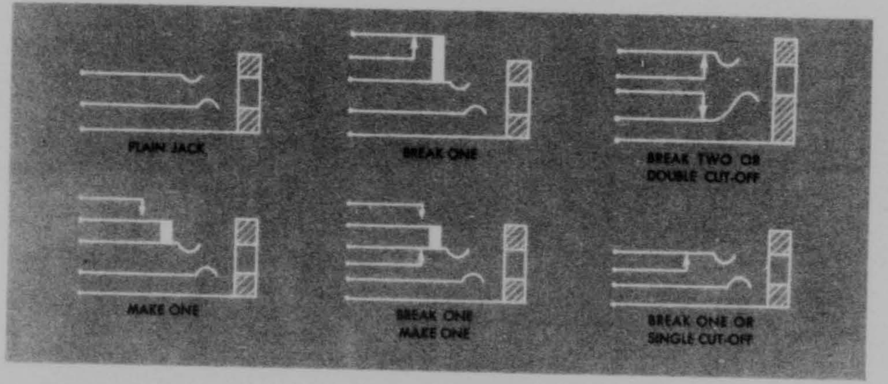

Figure 2-16 Types of Jacks

Drops are made with windings, having several different resistance values. This resistance varies from 80 to 1,600 ohms, with a value of 350 ohms being the most common. The windings do not offer a high impedance to voice currents. Consequently, if they are allowed to remain bridged across the line during conversation a considerable transmission loss would result, since the voice currents would be shunted through the winding. In order to prevent this loss, the circuit to the line drop is opened during the conversation as shown in Figure 2-15. When a switchboard plug is inserted in a jack, the tip and ring springs of the jack are forced apart, breaking the contacts between them and the cutoff springs. Jacks are made with several different combinations, depending upon the circuit in which they will be used. Some of these combinations are illustrated in Figure 2-16.

Types of Local-Battery Switchboards. The smallest switchboards are of the magneto-monocord type. These switchboards are available in capacities from six loops as provided by Switchboard BD-71 up to 12 loops as provided by Switchboard BD-72. The latter switchboard is illustrated in Figure 2-17. The equipment for each loop or trunk is principally a cord, a jack, a drop, and a two-way lever-type key. Ringing from the distant end of the loop operates the drop. The operator's

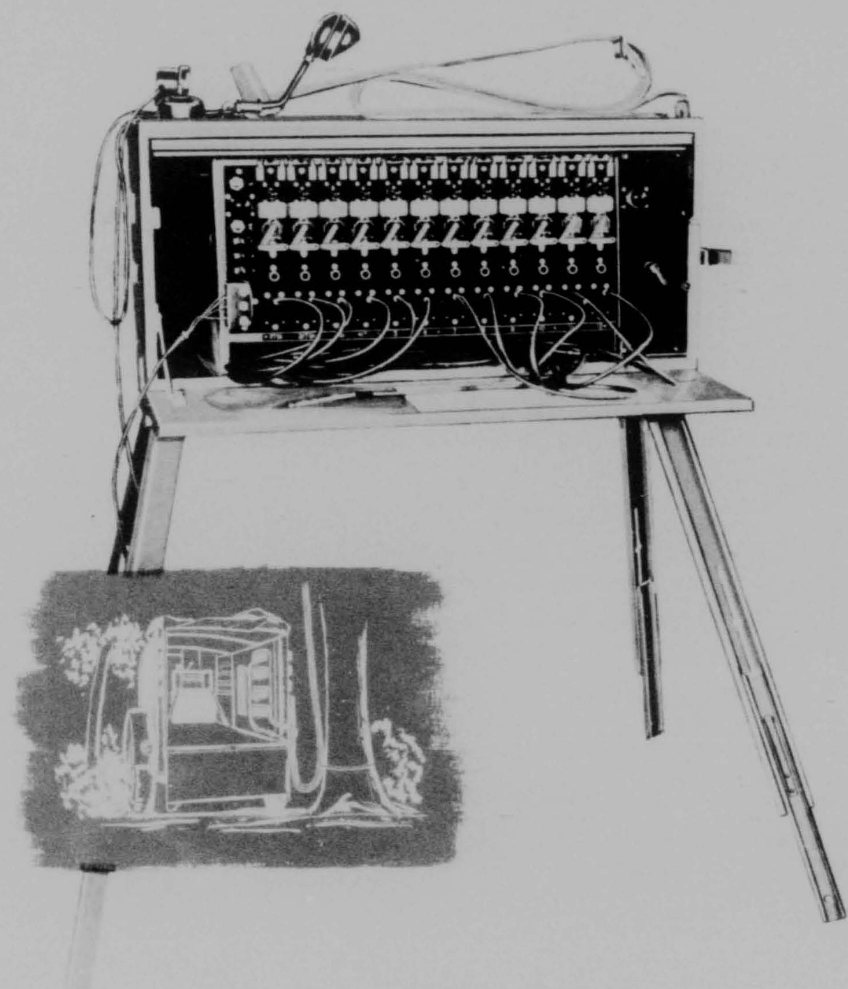

Figure 2-17 Local Battery Switchboard, BD-72

telephone is connected to the loop by the operation of the key switch in one direction. The key switch will remain in this position as long as the operator permits. Operation of this key in the opposite direction permits the operator to transmit a ringing current from his hand generator. The key must be held in the ringing position since it will return automatically to the neutral position. A connection between two loops is established

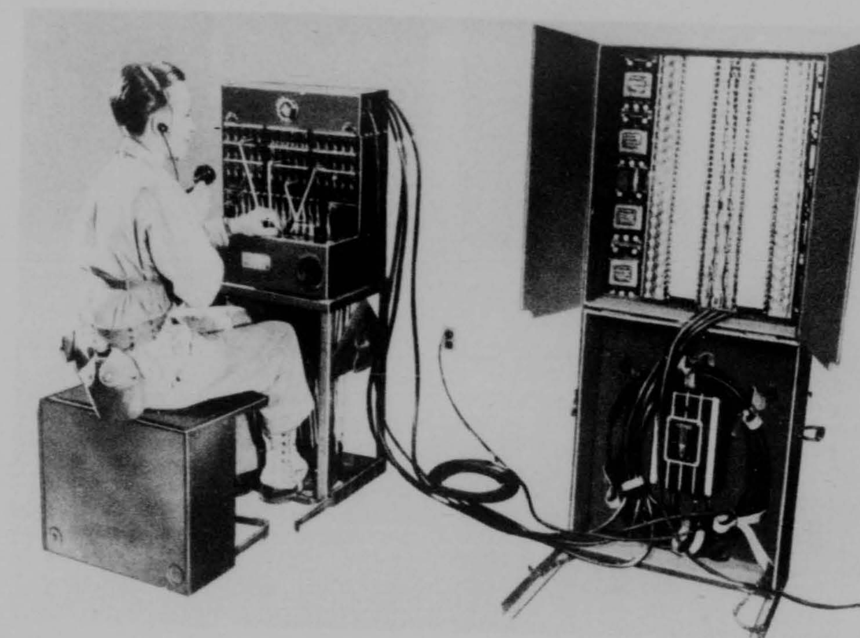

Figure 2-18 Telephone Central Office Set, TC-4

by connecting the cord associated with one circuit to the jack of the other loop.

The switchboards larger than those of the monocord types are of the cord type. Connections through these switchboards are established by cord circuits, terminated in pairs of cords. To establish a connection, one cord of a pair is connected to the jack of the called loop or trunk. Supervisory signals during connections over the cord circuit are indicated by drops or lamps associated with the cords. Signals on loops or trunks, while the cords are disconnected, are indicated by drops or lamps associated with the jacks. Connections to the operator's telephone are established through cord circuit keys. Similar keys are provided in the cord circuits for ringing on the loops and trunks.

The Switchboard BD-96, part of Telephone Control Office Set, TC-4, shown in Figure 2-18 is a local-battery cord switchboard with 40 loops and 12 cord circuits.

4. COMMON-BATTERY TELEPHONE SYSTEM

General

The circuit to be discussed in this paragraph is basic to all common-battery telephones. The circuits used in actual practice may be modifications of this circuit but essentially they remain the same in function. The components of the common-battery telephone are: transmitter, receiver, induction coils, capacitors, hookswitch, and ringer. The hookswitch, transmitter, receiver, and ringer are similar to those employed in the local-battery telephone.

Basic Circuit. The basic common-battery telephone circuit may be developed in a logical manner. Current for talking purposes is fed to the telephone from a central source so that it may be assumed that a battery is connected in some way to the terminals L1 and L2 of the subset. This circuit is called

THIS PAGE IS DECLASSIFIED IAW EO 13526

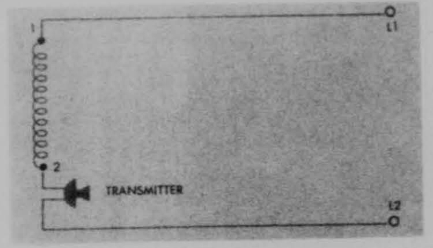

Figure 2-19 Primary Circuit of Telephone

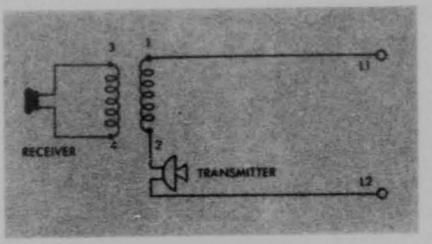

Figure 2-20 Primary & Secondary Circuits of Telephone

the "transmitter" or primary circuit and is illustrated in Figure 2-19. The receiver is coupled to the primary circuit by means of the secondary winding of the induction coil. This circuit is called the "receiver" or secondary circuit.

Since there is a direct current flowing in the primary of the induction coil and through the transmitter which is connected in series, the transmitter is able to vary the amount of the current in the same manner as previously described. The effect of this variable current in the primary is to produce an induced current in the secondary which permits the speaker to hear his own conversation as a sidetone. Sidetone is defined as that sound heard in the receiver caused by vibrations picked from the transmitter of the same telephone.

An incoming varying current from a transmitter at the distant point of the line passes through the primary of the induction coil, the transmitter, and back to its source. This current in turn induces a current into the secondary which is converted into sound energy by the receiver. Therefore, it is possible to transmit and receive signals using the circuit illustrated in Figure 2-20.

Transmitter, Receiver, and Ringer. Note that there are three distinct circuits in this telephone instead of four as there are in a local-battery telephone circuit. The transmitter or primary circuit includes the primary of the induction coil and the transmitter and is one complete circuit. The second circuit consists of the secondary of the induction coil and the receiver. The third circuit is composed of the ringer and its series capacitor.

Hookswitch. Signaling the operator in common-battery telephone operation is done by completing the DC path through the line and transmitter. In the circuit illustrated in Figure 2-21, the path of the direct current is always completed through the primary of the induction coil and the transmitter. In order to open this path when the telephone is not in use, it is necessary to insert a hook-

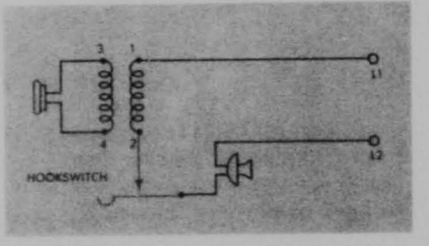

Figure 2-21 Hookswitch in Telephone Circuit

switch in the circuit. The closing of the hookswitch causes a signal to appear on the switchboard and indicates to the operator that a call is to be placed. So far as signaling the operator is concerned, it is not necessary to open the receiver circuit with hookswitch contacts so long as the receiver remains connected to a separate circuit. Figure 2-21 illustrates the circuit with the hookswitch added.

Ringer Circuit. There is but one circuit which remains to be added to complete the telephone for operational purposes and that is the ringer. This circuit enables the switch-

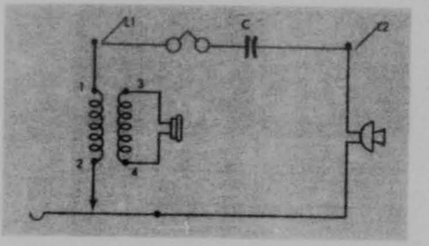

Figure 2-22 Capacitor & Ringer in Telephone Circuit

board operator to signal the subscriber that there is a call for him. The ringer must be across the line but must not allow the direct current to pass through it. To accomplish this a capacitor is connected in series with the ringer; this permits the ringing current to pass but blocks the passage of the direct current. Figure 2-22 illustrates the circuit with the ringing circuit added. This is a complete basic common-battery telephone circuit.

Common-Battery Telephone, TP-6. Common-battery antisidetone telephones such as Telephone TP-6 shown in cutaway form in Figure 2-5 are used on loops to common-battery switchboards, and the direct current for the microphone (transmitter) is obtained over the loop. The transmitting efficiency of these telephones is therefore not as high when connected to a short loop. On very short loops the transmitting efficiency is about the same as that of a local-battery telephone.

The microphone and receiver used in the handset which is a part of the TP-6 are similar in their performance to those in Handset TS-9.

The transmitting loss of the common-battery antisidetone telephone for different loops, compared with that of the local-battery telephone, is given by the empirical formula: $L = \frac{R}{4E} - 4$ db, where L is the amount in db by which the transmitting loss of the local-battery set, "R" is the total circuit resistance, and "E" is the voltage of the common-battery supply.

The various elements of a typical loop which contribute to the total circuit resistance and consequently to the amount of direct current which flows through the circuit are shown in Figure 2-23.

Figure 2-24 shows approximate transmitting losses of common-battery telephone TP-6 compared with local-battery telephone EE-8-( ).

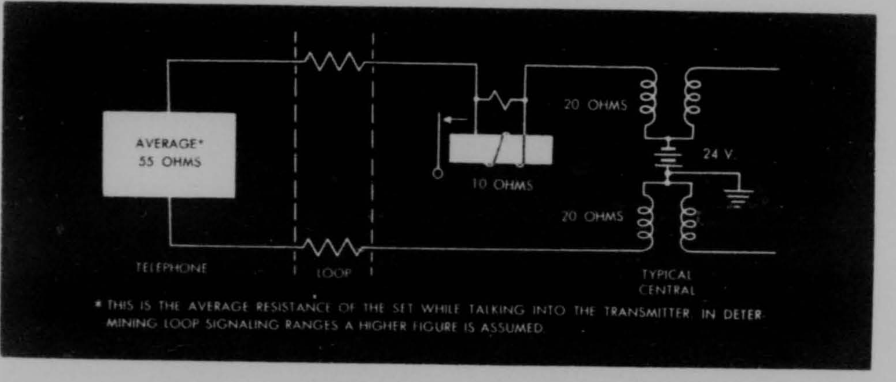

Figure 2-23 Typical Common Battery Loop Circuit

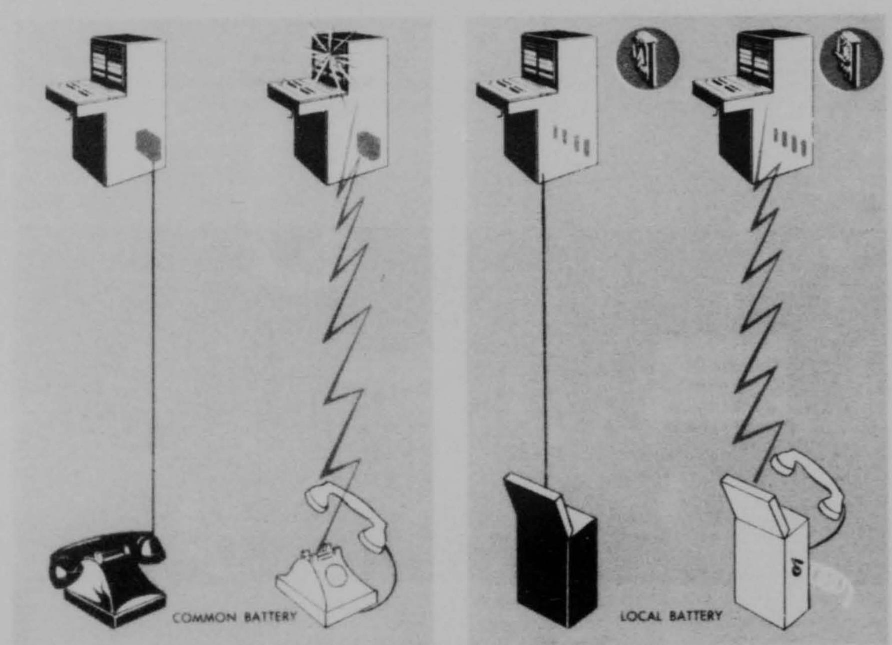
CONDUCTOR LOOP RESISTANCE — (OHMS)	TRANSMISSION LOSS (db)	
	24 VOLTS 50 OHMS IN CENTRAL OFFICE	48 VOLTS 400 OHMS IN CENTRAL OFFICE
0—200	*	*
200—400	0	0
400—600	2	1
600—800	4	2
800—1000	7	3

* FOR THESE SHORT LOOPS THE COMMON BATTERY TELEPHONE IS SLIGHTLY BETTER THAN THE LOCAL BATTERY TELEPHONE.

Figure 2-24 Comparison of Common Battery & Local Battery Transmission Losses

Common-Battery Switchboards

A common-battery switchboard is distinguished, principally, by its storage battery which is common to all of the battery supply and automatic signaling circuits in the switchboard. Battery supply for telephones on the loops is obtained from the cord circuits except in the cordless switchboard where it is obtained from the switchboard



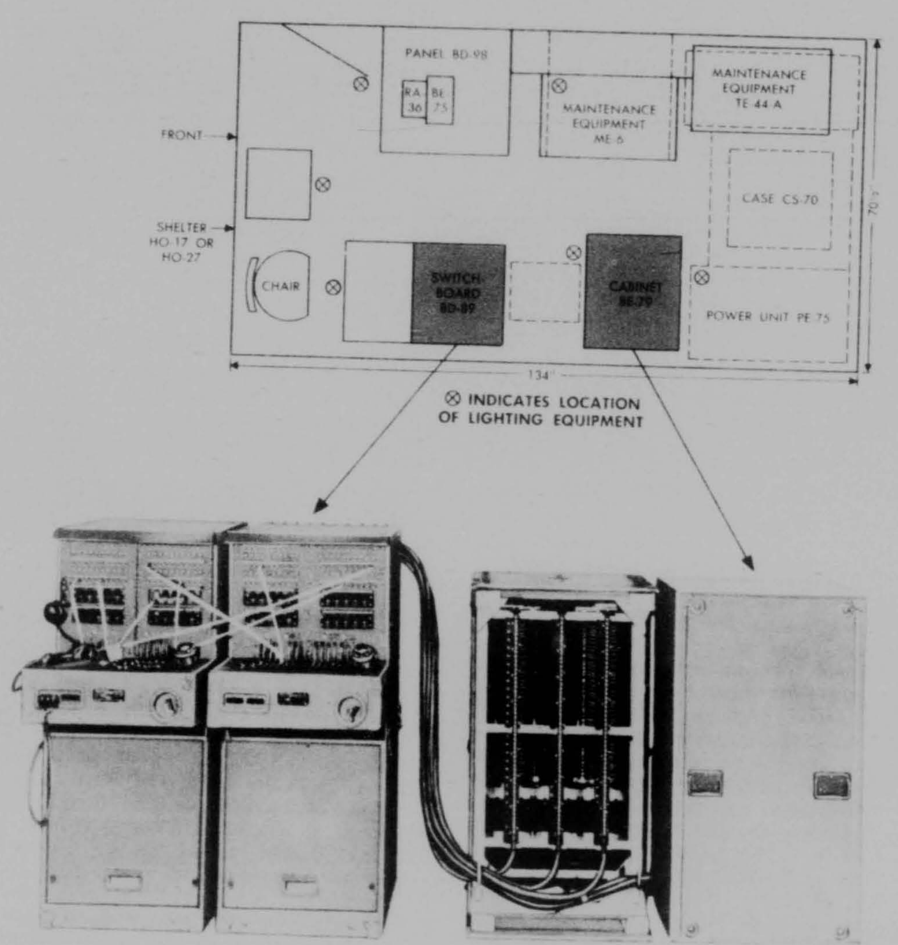


Figure 2-25 Telephone Central Office Set TC-2 Installed

THIS PAGE IS DECLASSIFIED IAW EO 13526

connecting paths. Other battery supply circuits are provided for the operators' telephones. Automatic signaling circuits are associated with the lines and cord lamp signals which are controlled from the switchhooks of the telephones on the loops. Similar signals are controlled from ringing on the trunks. These features contribute to high operating efficiency and are particularly desirable in large centrals.

Comparison of Common Battery Switchboards With Magneto Switchboards. The advantages of common battery switchboards in comparison with magneto switchboards are principally as follows:

a) Automatic signaling in response to the movements of the hookswitches at the telephones provides fast and reliable signals with almost no conscious effort by the telephone users. This reduces the work of the switchboard operators by eliminating, to a great extent, the need for monitoring to avoid excessive holding of trunks after conversations are finished.

b) A single storage battery for the switchboard and associated telephones is more desirable than dry batteries.

c) A common-battery telephone is lighter than a magneto telephone because it does not contain a hand generator or dry batteries.

The disadvantages of common-battery switchboards are in the working limits for signaling on the common-battery loops. These limits are based on the operating capabilities of the switchboard and require that the insulation resistances of these loops be maintained at more than 10,000 ohms. The insulation resistances on magneto loops can be as low as 1,000 ohms. The higher insulation resistances require greater care in the construction and more labor in the maintenance of the outside plant. The permissible conductor resistances of common battery loops are from 50 ohms to 1,000 ohms depending on the particular switchboard, whereas magneto loops generally can have 2,000 or 3,000 ohms, provided that voice transmission considerations permit.

On long loops, transmission is poorer with common battery telephones than with local battery telephones.

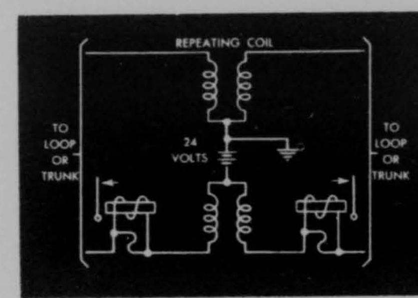

Figure 2-26 Repeating Coil 24 Volt Battery Supply Circuit

Battery Supply Circuits. The battery supply circuits in the cord circuits of some switchboards such as the Western Electric Company No. 11 Switchboard are of the **repeating coil type** with a 24-volt battery, as illustrated in Figure 2-26. In this circuit, the battery is connected in series with the windings of the repeating coil and the voice currents follow the same path as the battery supply currents through the battery. Although the voice currents from many different circuits pass through the same battery, these currents do not produce cross talk because the impedance of the battery is very low (less than 0.1 ohm), — provided that the leads to the battery are properly arranged.

Battery supply circuits of the **bridged impedance type** are arranged with the battery connected in series with retardation coils or relays which are bridged across the voice channels in the cord circuits. A battery supply circuit with a single bridged impedance is illustrated in Figure 2-27a. A similar circuit with two bridged impedances is illustrated in Figure 2-27b. The DC resistance of each of the inductors is small enough to permit the flow of an adequate amount of battery supply current for the telephone. However, their impedance to voice-frequency currents is high enough to avoid excessive transmission loss. In cord circuits such as those of Switchboard BD-110-( ), two bridged impedances are provided, one for the front cord and the other for the back cord; capacitors are connected in series with the voice channels between the bridged impedances (Fig. 2-27). In the double bridged impedance

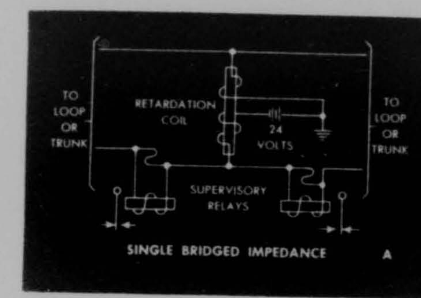

Figure 2-27a Single & Double Bridged Impedance

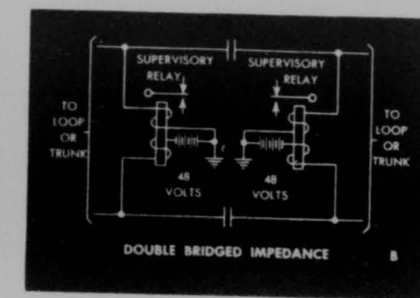

Figure 2-27b Battery Supply Circuits

type of battery supply circuit, each loop connects to a separate relay while in the single bridged impedance circuit both loops connect to a single retardation coil. The single bridged impedance type of circuit is suitable only where most of the loops are relatively short because the shunting effect of a short loop on the same cord circuit.

Signaling on Common-Battery Loops. When a call to a cord switchboard is originated at a common-battery telephone, direct current flows from the switchboard line circuit. This causes the lighting of all line lamps connected to that line. When the call is answered by an operator, the flow of current from the line circuit is cut off by the connection of a cord to a jack, but the battery supply current then flows over the loop from the cord circuit. Battery supply currents flow through the windings of relays, the contacts of which control the supervisory lamps or signals. Telephones are signaled from the switchboard with ringing current applied to the loop by the operation of a ringing key in the cord circuit.

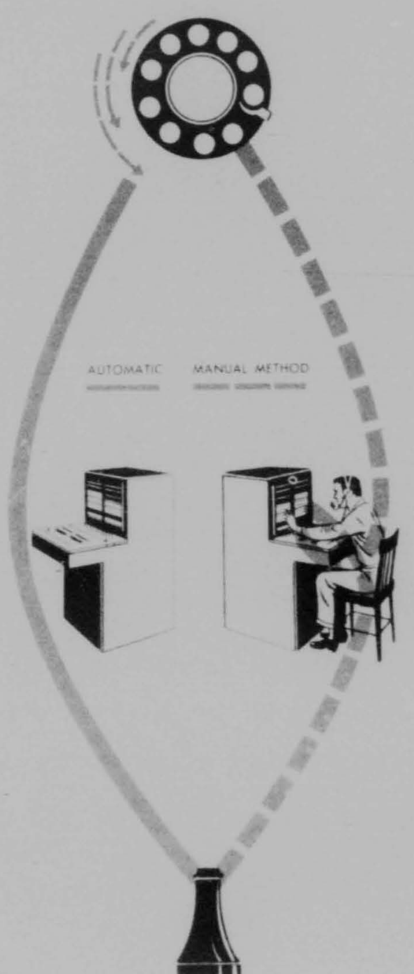
Common Battery Cord Circuits. The cord circuits in common battery switchboards contain the battery supply circuits described in the paragraph above; they also contain relays and lamps for producing supervisory signals; and they include keys for ringing on loops and trunks, and for connecting the circuits to the operator's telephones. The different types of common battery cord circuits are broadly classified as local cords, universal cords, and PBX cords. All cords in a single type of switchboard are of the same type.

5. AUTOMATIC TELEPHONY

General

An outstanding disadvantage of the manually operated switchboard system is the fact that the boards require operators, and time

THIS PAGE IS DECLASSIFIED IAW EO 13526



is consumed in making connections through switchboards. From the earliest days of telephony, the inventors have devised various schemes for eliminating this disadvantage.

While the bulk of our tactical equipment is composed of manual types, this is not true in the case of the telephone systems of large installations such as peacetime permanent stations or wartime high level headquarters. Today, the communicator must be aware of the problems and principles involved in automatic telephony.

Basically, automatic telephone systems are those in which the switching operation is automatic. Such systems make it possible for telephone stations to connect with other desired stations through a process which amounts to remote control.

Basic Automatic Systems

There are generally three types of automatic systems. These are as follows:

The step-by-step system incorporating driving magnets in each switch. This switch is put into operation by the calling party and through a series of short steps makes connections with the called party's line.

The power-driven system in which the switches are connected through clutching to driving motors. The calling party applies control to the switch which makes the necessary connection.

The all-relay system in which the calling party selects the called party through a system of relays without any form of power switch arrangement. Each of these systems has, as we have seen, different methods of selecting the called party. The device that initiates these is a keying device known commonly as the "dial". Automatic systems are normally referred to as "dial" systems.

The system most commonly used on Air Force bases is the step-by-step system. Since it was the invention of Almon B. Strowger in 1889, it is called the Strowger step-by-step system. Such a system requires a dial at the telephone, relays and switches at the switching central, and the normal ringing equipment at the called telephone.

The Dial System

The dial system sequence and process is as follows:

Dial: serves to transmit the coded impulses. This corresponds to the caller asking the switchboard operator for the called number.

Line Relays: serve to supply power to the appropriate switches. These correspond to

similar relays in manual boards which activate lights on the board.

Line Finder: is a switch mechanism connected to the telephone circuit. It has the function of seeking a calling line from a large group of lines. There are in most military boards about 20 such switches for each 100 numbers. These correspond to the signal lamps and caller's jackstrip on the manual board.

Selectors: switch mechanisms similar to line finders in principle, but with the purpose of hunting and selecting groups. Thus, if a caller wants number 600, the selector finds an available channel on which number 600 may be reached. This corresponds to the operator picking up the proper plug and looking for the proper channel.
